'*method2*' : cannot override '*method1*' because it is not supported by the language

This error occurs when you derive from a base class that was written in another language and when the compiler does not support the method that you are attempting to override.

Compiler Error CS0570

'*class*' references a type not unsupported by the language

This error occurs when using imported metadata that was generated by another compiler. Your code attempted to use a class member that the compiler cannot process.

The following samples generate CS0570:

The following C++ program uses an attribute that is not usable by C#:

```
// CPP0570.cpp
// compile with: /clr /LD
#using <mscorlib.dll>
using namespace System;
using namespace System::Runtime::CompilerServices;

namespace CS0570_Server {
   // This class is marked with RequiredAttributeAttribute.
   // It may not be consumed by other languages.
   [RequiredAttributeAttribute(__typeof(Int32))]
   public __gc class Scenario1 {
   public:
      int intVar;
   };

   public __gc class CS0570Class {
   public:
      Scenario1* sc1_field;
      __property virtual Scenario1* get_sc1_prop() {
         return sc1_field;
      }
      Scenario1* sc1_method() {return 0;}
   };
};
```

Next, compile the following C# program:

```
// CS0570.cs
// compile with: /r:CPP0570.dll
using System;
using CS0570_Server;

public class C {
   public static int Main() {
      CS0570Class r = new CS0570Class();
      r.sc1_field = null;      // CS0570
      object o = r.sc1_prop;   // CS0570
      r.sc1_method();         // CS0570
      int retval = 0x03;
      if (0 == retval)
         Console.WriteLine("PASSED");
      else
         Console.WriteLine("FAILED, retval=="+retval.ToString());
      return retval;
   }
}
```

Compiler Error CS0571

'*function*' : cannot explicitly call operator or accessor

Certain operators have internal names. For example, **op_Increment** is the internal name of the ++ operator. You should not use or explicitly call such method names.

The following sample generates CS0571:

```
// CS0571.cs
public class MyClass
{
   public static MyClass operator ++ (MyClass c)
   {
      return null;
   }

   public static int prop
   {
      get
      {
         return 1;
      }
      set
      {
      }
   }

   public static void Main()
   {
      op_Increment(null);   // CS0571
      // use the increment operator as follows
      // MyClass x = new MyClass();
      // x++;

      set_prop(1);      // CS0571
      // try the following line instead
      // prop = 1;
   }
}
```

Compiler Error CS0572

'*type*' : cannot reference a type through an expression; try '*path_to_type*' instead

An attempt was made to access a member of a class through an identifier, which is not permitted in this situation.

The following sample generates CS0572:

```
// CS0572.cs
using System;
class C
{
   public class Inner
   {
      public static int v = 9;
   }
}

class D : C
{
   public static void Main()
   {
      C cValue = new C();
      Console.WriteLine(cValue.Inner.v);   // CS0572
      // try the following line instead
      // Console.WriteLine(C.Inner.v);
   }
}
```

Compiler Error CS0573

'*field declaration*' : cannot have instance field initializers in structs

You cannot initialize an instance field of a struct. Fields of value types will be initialized to their default values, and reference-type fields will be initialized to **null**. For more information, see Default Values Table.

The following sample generates CS0573:

```
// CS0573.cs
namespace x
{
   public class clx
   {
      public static void Main()
      {
      }
   }

   public struct cly
   {
      clx a = new clx();   // CS0573
      // clx a;            // OK
      int i = 7;           // CS0573
      // int i;            // OK
   }
}
```

See Also

11.3.4 Default values

Compiler Error CS0574

Name of destructor must match name of class

The name of a destructor must be the class name preceded by a tilde (~).

The following sample generates CS0574:

```
// CS0574.cs
namespace x
{
   public class iii
   {
      ~iiii()   // CS0574
      {
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0575

Only class types can contain destructors

A struct cannot contain a destructor.

The following sample generates CS0575:

```
// CS0575.cs
namespace x
{
   public struct iii
   {
      ~iii()   // CS0575
      {
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0576

Namespace '' already contains a definition for 'System'

An attempt was made to use the **System** namespace twice.

The following sample generates CS0576:

```
// CS0576.cs
using System.Collections;
using System = System.Collections;   // CS0576, delete this line

public class z
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0577

Conditional not valid on '*function*' because it is a constructor, destructor, operator, or explicit interface implementation

Conditional cannot be applied to the specified methods.

The following sample generates CS0577:

```
// CS0577.cs
interface I
{
   void m();
}

public class MyClass : I
{
   [System.Diagnostics.Conditional("a")]   // CS0577
   // cannot use the above attribute on an explicit interface definition
   void I.m()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0578

Conditional not valid on '*function*' because its return type is not void

ConditionalAttribute cannot be applied to a method that has a return type other than **void**. The reason for this is that any other return type for a method may be needed by another part of your program.

The following sample generates CS0578:

```
// CS0578.cs
public class MyClass
{
   [System.Diagnostics.ConditionalAttribute("a")]
   public int TestMethod()   // CS0578
   {
      return 0;
   }

   public static void Main()
   {
   }
}
```

To resolve this error, you must either delete **ConditionalAttribute**, or you must change the return value of the method to **void**.

Compiler Error CS0579

Duplicate '*attribute*' attribute

It is not possible to specify the same attribute more than once unless the attribute specifies **AllowMultiple=true** in its AttributeUsage.

```
// CS0579.cs
using System;
public class MyAttribute : Attribute
{
}

[AttributeUsage(AttributeTargets.All,AllowMultiple=true)]
public class MyAttribute2 : Attribute
{
}

public class z
{
   [MyAttribute, MyAttribute]     // CS0579
   public void zz()
   {
   }

   [MyAttribute2, MyAttribute2]   // OK
   public void zzz()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0580

Too many unnamed arguments to attribute '*attribute*'

The number of unnamed arguments is not correct for the attribute. See the definition of the attribute and pass the correct arguments. For more information, see Attributes.

The following sample generates CS0580:

```
// CS0580.cs
using System;
using System.Runtime.CompilerServices;

public class bug
{
   [IndexerName("abc", "def")]   // CS0580
   // name attribute takes one unnamed string parameter
   // try the following line instead
   // [IndexerName("abc")]
   public int this [int index]
   {
      get
      {
         return 0;
      }
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0581

Named arguments not allowed on attribute '*attribute*'

Some attributes do not take named arguments.

The following sample generates CS0581:

```
// CS0581.cs
using System.Runtime.CompilerServices;

public class MyClass
{
   [IndexerName("xxx", namedarg=3)]   // CS0581
   // try the following line instead
   // [IndexerName("xxx")]
   public int this[int index]
   {
      get
      {
         return 0;
      }
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0582

Conditional not valid on interface members

ConditionalAttribute is not valid on an interface member.

The following sample generates CS0582:

```
// CS0582.cs
interface MyIFace
{
   [System.Diagnostics.ConditionalAttribute("DEBUG")]   // CS0582, remove conditional attribu
te
   void zz();
}

public class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0583

Internal Compiler Error: likely culprit is '*culprit*'.

Please create a bug report file with the '/bugreport' option, and submit the report to your assigned problem reporting contact.

Use the /bugreport compiler option to capture the problem.

Compiler Error CS0584

Internal Compiler Error: stage '*stage*' symbol '*symbol*'

Try to determine if the compiler is failing due to its inability to parse unexpected syntax. Then, contact Microsoft Product Support Services.

Compiler Error CS0585

Internal Compiler Error: stage '*stage*'

Try to determine if the compiler is failing due to its inability to parse unexpected syntax. Then, contact Microsoft Product Support Services.

Compiler Error CS0586

Internal Compiler Error: stage '*stage*'

Try to determine if the compiler is failing due to its inability to parse unexpected syntax. Then, contact Microsoft Product Support Services.

Compiler Error CS0587

Internal Compiler Error: stage '*stage*'

Try to determine if the compiler is failing due to its inability to parse unexpected syntax. Then, contact Microsoft Product Support Services.

Compiler Error CS0588

Internal Compiler Error: stage 'LEX'

Try to determine if the compiler is failing due to its inability to parse unexpected syntax. Then, contact Microsoft Product Support Services.

Compiler Error CS0589

Internal Compiler Error: stage 'PARSE'

Try to determine if the compiler is failing due to its inability to parse unexpected syntax. Then, contact Microsoft Product Support Services.

Compiler Error CS0590

User-defined operators cannot return void

The purpose of a user-defined operator is to return an object.

The following sample generates CS0590:

```
// CS0590.cs
namespace x
{
   public class a
   {
      public static void operator+(a A1, a A2)   // CS0590
      {
      }

      // try the following user-defined operator
      /*
      public static a operator+(a A1, a A2)
      {
         return A2;
      }
      */

      public static int Main()
      {
         return 1;
      }
   }
}
```

Compiler Error CS0591

Invalid value for argument to '*attribute*' attribute

An attribute was passed either an invalid argument or two mutually exclusive arguments.

The following sample generates CS0591:

```
// CS0591.cs
using System;

[AttributeUsage(0)]   // CS0591
class I: Attribute
{
}

public class a
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0592

Attribute '*attribute*' is not valid on this declaration type. It is valid on '*type*' declarations only.

An attribute was applied to a declaration for which it was not intended.

The following sample generates CS0592:

```
// CS0592.cs
using System;

[AttributeUsage(AttributeTargets.Interface)]
public class MyAttribute : Attribute
{
}

[MyAttribute]
public class A  // CS0592, MyAttribute is not valid for a class
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0594

Floating-point constant is outside the range of type '*type*'

A value was assigned to a floating-point variable that is too large for the variables of this data type. See Integral Types Table for information about the range of values allowed in data types.

The following sample generates CS0594:

```
// CS0594.cs
namespace MyNamespace
{
   public class MyClass
   {
      public static void Main()
      {
         float f = 6.77777777777E400;   // CS0594, value too large
      }
   }
}
```

Compiler Error CS0596

The Guid attribute must be specified with the ComImport attribute

The **Guid** attribute must be present when using the **ComImport** attribute.

The following sample generates CS0596:

```
// CS0596.cs
using System.Runtime.InteropServices;

namespace x
{
   [ComImport]   // CS0596
   // try the following line to resolve this CS0596
   // [ComImport, Guid("00000000-0000-0000-0000-000000000001")]
   public class a
   {
   }

   public class b
   {
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0597

Too few unnamed arguments for attribute '*attribute*'

An attribute did not have the required number of arguments.

Compiler Error CS0599

Invalid value for named attribute argument '*argument*'

An invalid argument was passed to an attribute.

Compiler Error CS0601

The DllImport attribute must be specified on a method marked 'static' and 'extern'.

The **DllImport** attribute was used on a method that did not have the correct access keywords.

The following sample generates CS0601:

```
// CS0601.cs
using System.Runtime.InteropServices;
using System.Text;

public class C
{
   [DllImport("KERNEL32.DLL")]
   extern int GetCurDirectory(int bufSize, StringBuilder buf);   // CS0601
   // try the following line instead
   // static extern int GetCurDirectory(int bufSize, StringBuilder buf);
}

public class MainClass
{
   public static void Main ()
   {
   }
}
```

Compiler Warning (level 1) CS0602

The feature '*old_feature*' is deprecated. Please use '*new_feature*' instead

A language feature used in your code (*old_feature*) is still supported, but that support may be removed in a future release. Instead, you should use the recommended syntax (*new_feature*).

Compiler Error CS0609

Cannot set the name attribute on an indexer marked override

The name attribute (**IndexerNameAttribute**) cannot be applied to an indexed property that is an override. For more information, see Indexers.

The following sample generates CS0609:

```
// CS0609.cs
using System;
using System.Runtime.CompilerServices;

public class idx
{
   public virtual int this[int iPropIndex]
   {
      get
      {
         return 0;
      }
      set
      {
      }
   }
}

public class MonthDays : idx
{
   [IndexerName("MonthInfoIndexer")]   // CS0609, delete to resolve this CS0609
   public override int this[int iPropIndex]
   {
      get
      {
         return 0;
      }
      set
      {
      }
   }
}

public class test
{
   public static void Main( string[] args )
   {
   }
}
```

Compiler Error CS0610

Field or property cannot be of type '*type*'

There are some types that cannot be used as fields or properties. These types include **System.ArgIterator** and **System.TypedReference**.

The following sample generates CS0610 as a result of using **System.TypedReference** as a field:

```
// CS0610.cs
public class MainClass
{
   System.TypedReference i;   // CS0610
   public static void Main ()
   {
   }

   public static void Test(System.TypedReference i)   // OK
   {
   }
}
```

Compiler Error CS0611

Array elements cannot be of type '*type*'

There are some types that cannot be used as the type of an array. These types include **System.TypedReference** and **System.ArgIterator**.

The following sample generates CS0611 as a result of using **System.TypedReference** as an array element:

```
// CS0611.cs
public class a
{
   public static void Main()
   {
      System.TypedReference[] ao = new System.TypedReference [10];   // CS0611
      // try the following line instead
      // int[] ao = new int[10];
   }
}
```

Compiler Warning (level 1) CS0612

'*member*' is obsolete

The class designer marked a member with the Obsolete attribute. This means that the member might not be supported in a future version of the class.

The following sample shows how accessing an obsolete member generates CS0612:

```
// CS0612.cs
// compile with: /W:1
using System;

class MyClass
{
   [Obsolete]
   public static void ObsoleteMethod()
   {
   }

   [Obsolete]
   public static int ObsoleteField;
}

class MainClass
{
   static public void Main()
   {
      MyClass.ObsoleteMethod();    // CS0612 here: method is deprecated
      MyClass.ObsoleteField = 0;   // CS0612 here: field is deprecated
   }
}
```

Compiler Error CS0616

'*class*': is not an attribute class

An attempt was made to use a non-attribute class in an attribute block. All the attribute types need to be inherited from **System.Attribute**.

The following sample generates CS0616:

```
// CS0616.cs
[CMyClass(i=5)]   // CS0616
public class CMyClass
{
   public static void Main()
   {
   }
};
```

The following sample shows how you might define an attribute:

```
// CreateAttrib.cs
using System;

[AttributeUsage(AttributeTargets.Class|AttributeTargets.Interface)]
public class MyAttr : Attribute
{
   public int Name = 0;
   public int Count = 0;

   public MyAttr (int iCount, int sName)
   {
      Count = iCount;
      Name = sName;
   }

   public static void Main()
   {
   }
}

[MyAttr(5, 50)]
class Class1
{
}

[MyAttr(6, 60)]
interface Interface1
{
}
```

Compiler Error CS0617

'*reference*' is not a valid named attribute argument. Named attribute arguments must be fields which are not readonly, static or const, or read-write properties which are not static.

An attempt was made to access a private member of an attribute class.

The following sample generates CS0617:

```
// CS0617.cs
using System;

[AttributeUsage(AttributeTargets.Struct|AttributeTargets.Class|AttributeTargets.Interface)]
public class MyClass : Attribute
{
   public int Name;

   public MyClass (int sName)
   {
      Name = sName;
      Bad = -1;
   }

   public readonly int Bad;
   // try the following line instead
   // public int Bad;
}

[MyClass(5, Bad=0)] class Class1   // CS0617
{
}

public class MyClass2
{
   public static void Main ()
   {
   }
}
```

Compiler Warning (level 2) CS0618

'*member*' is obsolete: '*text*'

A class member was marked with the Obsolete attribute, such that a warning will be issued when the class member is referenced.

The following sample generates CS0618:

```
// CS0618.cs
// compile with: /W:2
using System;

public class C
{
   [Obsolete("Use newMethod instead", false)]   // warn if referenced
   public static void m2()
   {
   }

   public static void newMethod()
   {
   }
}

class MyClass
{
   public static void Main()
   {
      C.m2();  // CS0618
   }
}
```

Compiler Error CS0619

'*member*' is obsolete: '*text*'

A class member was marked with the Obsolete attribute, such that an error will be issued when the class member is referenced.

The following sample generates CS0619:

```
// CS0619.cs
using System;

public class C
{
   [Obsolete("Use newMethod instead", true)]   // generates an error on use
   public static void m()
   {
   }

   // this is the method you should be using
   public static void newMethod()
   {
   }
}

class MyClass
{
   public static void Main()
   {
      C.m();   // CS0619
   }
}
```

Compiler Error CS0620

Indexers can't have void type

The return type of an indexer cannot be **void**. An indexer must return a value.

The following sample generates CS0620:

```
// CS0620.cs
class MyClass
{
   public static void Main()
   {
      MyClass test = new MyClass();
      System.Console.WriteLine(test[2]);
   }

   void this [int intI]   // CS0620, return type cannot be void
   {
      get
      {
         // will need to return some value
      }
   }
}
```

Compiler Error CS0621

'*member*' : virtual or abstract members cannot be private

Private **virtual** or **abstract** members are not allowed.

The following sample generates CS0621:

```
// CS0621.cs
abstract class MyClass
{
   private virtual void DoNothing1()   // CS0621
   {
   }

   private abstract void DoNothing2();   // CS0621

   public static void Main()
   {
   }
}
```

Compiler Error CS0622

Can only use array initializer expressions to assign to array types. Try using a new expression instead.

Syntax that is appropriate to initialize an array was used in the declaration of a non-array.

The following sample generates CS0622:

```
// CS0622.cs
using System;

public class Test
{
   public static void Main ()
   {
      Test t = { new Test() };   // CS0622
      // Try the following instead:
      // Test[] t = { new Test() };
   }
}
```

Compiler Error CS0623

Array initializers can only be used in a variable or field initializer. Try using a new expression instead.

An array was initialized incorrectly.

The following sample generates CS0623:

```
// CS0623.cs
class MyClass
{
   public int[] x = { 2, 3, {4}};   // CS0623

   // The following declarations show how to initialize an array:
   // public int[] x = { 2, 3, 4};   // single-dimensional array
   // int[]x = new int[] {1,2,3};   // dynamically created array
   // int[,]x = { {1,2}, {3,4}, {5,6} };   // multidimensional array
   // object[]z = { null, "test", new int[] {2,3} };   // array of objects
   // int[][]x = { new int[]{2,3}, new int[]{4,5} };   // array of ints
   // private static readonly char[] array = { ',', ' ' };

   public static void Main()
   {
   }
}
```

Compiler Error CS0625

'*field*' : Instance field types marked with StructLayout(LayoutKind.Explicit) must have a FieldOffset attribute.

When a struct is marked with an explicit **StructLayout** attribute, all fields in the struct must have the FieldOffset attribute. For more information, see StructLayoutAttribute Class.

The following sample generates CS0625:

```
// CS0625.cs
using System;
using System.Runtime.InteropServices;

[StructLayout(LayoutKind.Explicit)]
struct Worksheet
{
   // uncomment the next line to resolve
   // [FieldOffset(5)]
   public int i;   // CS0625, not static; an instance field
}

public class MainClass
{
   public static void Main ()
   {
   }
}
```

Compiler Warning (level 1) CS0626

Method, operator, or accessor '*method*' is marked external and has no attributes on it. Consider adding a DllImport attribute to specify the external implementation

A method marked **extern** should also be marked with an attribute, for example, the DllImport attribute.

The attribute specifies where the method is implemented. At run time, the program will need this information.

The following sample generates CS0626:

```
// CS0626.cs
// compile with: /warnaserror
using System.Runtime.InteropServices;

public class MyClass
{
   static extern public void mf(); // CS0626
   // try the following line
   // [DllImport("mydll.dll")] static extern public void mf();

   public static void Main()
   {
   }
}
```

Compiler Warning (level 4) CS0628

'*member*' : new protected member declared in sealed class

A sealed class cannot introduce a protected member because no other class will be able to inherit from the **sealed** class and use the **protected** member.

The following sample generates CS0628:

```
// CS0628.cs
// compile with: /W:4
sealed class C
{
   protected int i;   // CS0628
}

class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0629

Conditional member '*member*' cannot implement interface member '*base class member*'

The Conditional attribute cannot be used on the implementation of an interface.

The following sample generates CS0629:

```
// CS0629.cs
interface MyInterface
{
   void MyMethod();
}

public class MyClass : MyInterface
{
   [System.Diagnostics.Conditional("debug")]
   public void MyMethod()    // CS0629, remove the Conditional attribute
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0631

Indexers can't have ref or out parameters

The declaration for an indexer property cannot include the use of ref or out parameters.

The following sample generates CS0631:

```
// CS0631.cs
public class MyClass
{
   public int this[ref int i]   // CS0631
   // try the following line instead
   // public int this[int i]
   {
      get
      {
         return 0;
      }
   }
}

public class MyClass2
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0633

The argument to the IndexerName attribute must be a valid identifier

Any argument that you pass to the **IndexerName** attribute must be a valid identifier.

The following sample generates CS0633:

```
// CS0633.cs
using System;
using System.Runtime.CompilerServices;

public class MonthDays
{
   [IndexerName("bad indexer name")]   // CS0633
   // try the following line instead
   // [IndexerName("badindexername")]
   public int this[int iPropIndex]
   {
      get
      {
         return 0;
      }
      set
      {
      }
   }
}

public class test
{
   public static void Main( string[] args )
   {
   }
}
```

Compiler Error CS0634

'*arg*' : argument only valid for marshal of type System.Interop.UnmanagedType.CustomMarshaller

One of the arguments passed to the **Marshal** attribute can only be used when the marshal format is **System.Interop.UnmanagedType.CustomMarshaller**.

Compiler Error CS0635

'*attribute*' : System.Interop.UnmanagedType.CustomMarshaller requires named arguments ComType and Marshal

The **ComType** and **Marshal** arguments must be specified when the marshal format is **System.Interop.UnmanagedType.CustomMarshaller**.

Compiler Error CS0636

The FieldOffset attribute can only be placed on members of types marked with the StructLayout(LayoutKind.Explicit)

You must use the **StructLayout(LayoutKind.Explicit)** attribute on the struct declaration, if it contains any members marked with the **FieldOffset** attribute. For more information, see FieldOffset.

The following sample generates CS0636:

```
// CS0636.cs
using System;
using System.Runtime.InteropServices;

// To resolve the error, uncomment the following line:
// [StructLayout(LayoutKind.Explicit)]
struct Worksheet
{
   [FieldOffset(4)]public int i;   // CS0636
}

public class MainClass
{
   public static void Main ()
   {
   }
}
```

Compiler Error CS0637

The FieldOffset attribute not allowed on static or const fields

The FieldOffset attribute cannot be used on fields marked with static or const.

The following sample generates CS0637:

```
// CS0637.cs
using System;
using System.Runtime.InteropServices;

[StructLayout(LayoutKind.Explicit)]
public class MainClass
{
   [FieldOffset(3)]   // CS0637
   public static int i;
   public static void Main ()
   {
   }
}
```

Compiler Error CS0641

'*attribute*' : attribute is only valid on classes derived from System.Attribute

An attribute was used that can only be used on a class that derives from **System.Attribute**.

The following sample generates CS0641:

```
// CS0641.cs
using System;

[AttributeUsage(AttributeTargets.All)]
public class NonAttrClass   // CS0641
// try the following line instead
// public class NonAttrClass : Attribute
{
}

class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Warning (level 3) CS0642

Possible mistaken null statement

A semicolon after a conditional statement may cause your code to execute differently than intended.

The following sample generates CS0642:

```
// CS0642.cs
// compile with: /W:3
using System;

class MyClass
{
   public static void Main()
   {
      int i;

      for (i = 0; i < 10; i += 1);   // CS0642, semicolon intentional?
      {
         Console.WriteLine (i);
      }
   }
}
```

Compiler Error CS0643

'*arg*' duplicate named attribute argument

A parameter, ***arg***, on a user-defined attribute was specified twice. For more information, see Introduction to Attributes.

The following sample generates CS0643:

```
// CS0643.cs
using System;
using System.Runtime.InteropServices;

[AttributeUsage(AttributeTargets.Class)]
public class MyAttribute : Attribute
{
   public MyAttribute()
   {
   }

   public int x;
}

[MyAttribute(x = 5, x = 6)]   // CS0643, error setting x twice
// try the following line instead
// [MyAttribute(x = 5)]
class MyClass
{
}

public class MainClass
{
   public static void Main ()
   {
   }
}
```

Compiler Error CS0644

'*class1*' cannot inherit from special class '*class2*'

Classes cannot explicitly inherit from any of the following base classes:

- **System.Enum**
- **System.ValueType**
- **System.Delegate**
- **System.Array**

These are used as implicit base classes by the compiler. For example, **System.ValueType** is the implicit base class of structs.

The following sample generates CS0644:

```
// CS0644.cs
class MyClass : System.ValueType   // CS0644
{
}
```

Compiler Error CS0645

Identifier too long

A class name or other identifier can be no longer than 512 characters.

Compiler Error CS0646

Cannot specify the DefaultMember attribute on type containing an indexer

If a class or other type specifies **System.Reflection.DefaultMemberAttribute**, it cannot contain an indexer. For more information, see Properties.

The following sample generates CS0646:

```
// CS0646.cs
// to resolve, delete System.Reflection.DefaultMemberAttribute or
// remove the indexer
[System.Reflection.DefaultMemberAttribute("x")]   // CS0646
class MyClass
{
   public int this[int index]                     // an indexer
   // try the following line instead
   // public int prop
   {
      get
      {
         return 0;
      }
   }

   public int x;
   public static void Main()
   {
   }
}
```

Compiler Error CS0647

Error emitting '*attribute*' attribute -- '*reason*'

The following sample generates CS0647:

```
// CS0647.cs
using System.Runtime.InteropServices;

[Guid("z")]   // CS0647, incorrect uuid format.
// try the following line instead
// [Guid("00000000-0000-0000-0000-000000000001")]
public class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0648

'*type*' is a type not supported by the language

Metadata that was generated from another language, possibly using the Managed Extensions for C++, contained a type that was not marked as managed. Information about this type is included in the metadata, but the type is not available to programs written in C#.

Compiler Warning (level 4) CS0649

Field '*field*' is never assigned to, and will always have its default value '*value*'

The compiler detected an uninitialized private or internal field declaration that is never assigned a value.

The following sample generates CS0649:

```
// CS0649.cs
// compile with: /W:4
using System.Collections;

class MyClass
{
   Hashtable table;  // CS0649
   // You may have intended to initialize the variable to null
   // Hashtable table = null;

   // Or you may have meant to create an object here
   // Hashtable table = new Hashtable();

   public void Func(object o, string p)
   {
      // Or here
      // table = new Hashtable();
      table[p] = o;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0650

Syntax error, bad array declarator. To declare a managed array the rank specifier precedes the variable's identifier

An array was declared incorrectly.

The following sample generates CS0650:

```
// CS0650.cs
public class MyClass
{
   public static void Main()
   {
      int myarray[2];   // CS0650
      // try the following lines instead
      // int[] myarray = new int[2] {1,2};
      // myarray[0] = 0;
   }
}
```

Compiler Warning (level 2) CS0652

Comparison to integral constant is useless; the constant is outside the range of type '*type*'

The compiler detected a comparison between a constant and a variable where the constant is out of the range of the variable.

The following sample generates CS0652:

```
// CS0652.cs
// compile with: /W:2
public class Class1
{
   private static byte i = 0;
   public static void Main()
   {
      short j = 256;
      if (i == 256)   // CS0652, 256 is out of range for byte
         i = 0;
   }
}
```

Compiler Error CS0653

Cannot apply attribute class '*class*' because it is abstract

An abstract custom attribute class cannot be used as an attribute.

The following sample generates CS0653:

```
// CS0653.cs
using System;

public abstract class MyAttribute : Attribute
{
}

public class My2Attribute : MyAttribute
{
}

[My]   // CS0653
// try the following line instead
// [My2]
class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0654

Method '*method*' referenced without parentheses

A method was called incorrectly.

The following sample generates CS0654:

```
// CS0654.cs
using System;

class MyClass
{
   public static int ReturnZero(int i)
   {
      return 0;
   }

   public static void Main()
   {
      int i;
      i = ReturnZero;   // CS0654
      // try the following line instead
      i = ReturnZero(4);
   }
}
```

Compiler Error CS0655

'*parameter*' is not a valid named attribute argument because it is not a valid attribute parameter type.

See the Attributes Tutorial for a discussion of valid parameter types for an attribute.

The following sample generates CS0655:

```
// CS0655.cs
using System;

class MyAttribute : Attribute
{
   // decimal is not valid attribute parameter type
   public decimal d = 0;
   public int e = 0;
}

[My(d = 0)]   // CS0655
// try the following line instead
// [My(e = 0)]
class C
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0656

Missing compiler required member '*object.member*'

One of the following problems exists:

- Your installation of the common language runtime is corrupt.
- You have a reference to an assembly that defines a type that is also found in the common language runtime. However, your assembly's type is not defined the way the C# compiler expects.

Check your references to ensure that you are using the correct version of the common language runtime.

Compiler Error CS0657

'*attribute modifier*' is not a valid attribute location for this declaration. Valid attribute locations for this declaration are '*location*'

The compiler found an attribute modifier in an invalid location. See Attribute Targets for more information.

The following sample generates CS0657:

```
// CS0657.cs
using System;
public class TestAttribute : Attribute{}
[return: Test]   // CS0657, return not valid on a class
class Class1
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0658

'*attribute modifier*' is not a recognized attribute location. All attributes in this block will be ignored.

An invalid attribute modifier was specified. See Attribute Targets for more information.

The following sample generates CS0658:

```
// CS0658.cs
using System;
public class TestAttribute : Attribute{}
[badAttributeLocation: Test]   // CS0658, badAttributeLocation is invalid
class ClassTest
{
   public static void Main()
   {
   }
}
```

Compiler Warning (level 3) CS0659

'*class*' overrides Object.Equals(object o) but does not override Object.GetHashCode()

The compiler detected an override of the **Equals** function but no override for **GetHashCode**. An override of **Equals** implies that you also want to override **GetHashCode**.

The following sample generates CS0659:

```
// CS0659.cs
// compile with: /W:3
class Test   // CS0659
{
   public override bool Equals(object o)
   {
      return true;
   }

   public static void Main()
   {
   }
}
```

Compiler Warning (level 3) CS0660

'*class*' defines operator == or operator != but does not override Object.Equals(object o)

The compiler detected the user-defined equality or inequality operator, but no override for the **Equals** function. A user-defined equality or inequality operator implies that you also want to override the **Equals** function.

The following sample generates CS0660:

```
// CS0660.cs
// compile with: /W:3 /warnaserror
class Test   // CS0660
{
   public static bool operator == (object o, Test t)
   {
      return true;
   }

   // uncomment the Equals function to resolve
   // public override bool Equals(object o)
   // {
   //    return true;
   // }

   public override int GetHashCode()
   {
      return 0;
   }

   public static void Main()
   {
   }
}
```

Compiler Warning (level 3) CS0661

'class' defines operator == or operator != but does not override Object.GetHashCode()

The compiler detected the user-defined equality or inequality operator, but no override for the **GetHashCode** function. A user-defined equality or inequality operator implies that you also want to override the **GetHashCode** function.

The following sample generates CS0661:

```
// CS0661.cs
// compile with: /W:3
class Test   // CS0661
{
   public static bool operator == (object o, Test t)
   {
      return true;
   }

   public static bool operator != (object o, Test t)
   {
      return true;
   }

   public override bool Equals(object o)
   {
      return true;
   }

   // uncomment the GetHashCode function to resolve
   // public override int GetHashCode()
   // {
   //    return 0;
   // }

   public static void Main()
   {
   }
}
```

Compiler Error CS0662

'*method*' cannot specify only Out attribute on a ref parameter. Use both In and Out attributes, or neither.

An interface method has a parameter that uses ref with just the Out attribute. A **ref** parameter that uses the **Out** attribute must also use the In attribute.

The following sample generates CS0662:

```
// CS0662.cs
using System.Runtime.InteropServices;

interface I
{
   void method([Out] ref int i);   // CS0662
   // try one of the following lines instead
   // void method(ref int i);
   // void method([Out, In]ref int i);
}

class test
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0663

'*method*' cannot define overloaded methods which differ only on ref and out

Methods that differ only on their use of ref and out on a parameter are not allowed.

The following sample generates CS0663:

```
// CS0663.cs
class TestClass
{
   public static void Main()
   {
   }

   public void Test(ref int i)
   {
   }

   public void Test(out int i)   // CS0663
   {
   }
}
```

Compiler Error CS0664

Literal of type double cannot be implicitly converted to type '*type*'; use an '*suffix*' suffix to create a literal of this type

An assignment could not be completed; use a suffix to correct the instruction. The documentation for each type identifies the corresponding suffix for the type.

The following sample generates CS0664:

```
// CS0664.cs
class M
{
   static void Main()
   {
      decimal m = 1.0;   // CS0664
      // try the following line instead
      // decimal m = 1.0M;
      System.Console.WriteLine(m);
   }
}
```

Compiler Warning (level 3) CS0665

Assignment in conditional expression is always constant; did you mean to use == instead of = ?

A conditional expression used the = operator and not the == operator.

The following sample generates CS0665:

```
// CS0665.cs
// compile with: /W:3
class Test
{
   public static void Main()
   {
      bool i = false;

      if (i = true)   // CS0665
      // try the following line instead
      // if (i == true)
      {
      }

      System.Console.WriteLine(i);
   }
}
```

Compiler Error CS0666

'*member*' : new protected member declared in struct

A struct cannot be **abstract** and is always implicitly **sealed**. For more information, see 11.3.2 Inheritance.

The following sample generates CS0666:

```
// CS0666.cs
class M
{
   static void Main()
   {
   }
}

struct S
{
   protected int x;   // CS0666
}
```

Compiler Error CS0667

The feature 'MarshalAs attribute on method' is deprecated. Please use 'return : location override with MarshalAs attribute' instead'

The following sample generates CS0667:

```
// CS0667.cs
using System.Runtime.InteropServices;

public interface MyInterface
{
   [MarshalAs(UnmanagedType.LPWStr )] string Test(); // CS0667
   // try the following line instead
   // [return: MarshalAs(UnmanagedType.LPWStr)] string Test();

}

class MyTestClass
{
   static void Main()
   {
   }
}
```

COM Interop Tutorials | Platform Invoke Tutorial

Compiler Error CS0669

A class with the ComImport attribute cannot have a user-defined constructor

The COM interop layer in the common language runtime supplies the constructor for ComImport classes. Consequently, a COM object can be used as a managed object in the runtime.

The following sample generates CS0669:

```
// CS0669.cs
using System.Runtime.InteropServices;
[ComImport, Guid("00000000-0000-0000-0000-000000000001")]
class TestClass
{
   TestClass()   // CS0669, delete constructor to resolve
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0668

Two indexers have different names; the IndexerName attribute must be used with the same name on every indexer within a type

The values passed to the **IndexerName** attribute must be the same for all indexers in a type. For more information on the **IndexerName** attribute, see IndexerNameAttribute Class.

The following sample generates CS0668:

```
// CS0668.cs
using System;
using System.Runtime.CompilerServices;

class IndexerClass
{
   [IndexerName("IName1")]
   public int this [int index]   // indexer declaration
   {
      get
      {
         return index;
      }
      set
      {
      }
   }

   [IndexerName("IName2")]
   public int this [string s]    // CS0668, change IName2 to IName1
   {
      get
      {
         return int.Parse(s);
      }
      set
      {
      }
   }

   void Main()
   {
   }
}
```

Compiler Error CS0670

Field cannot have void type

A field was declared to be of type void.

The following sample generates CS0670:

```
// CS0670.cs
class C
{
   void f;   // CS0670
   // try the following line instead
   // public int f;

   public static void Main()
   {
      C myc = new C();
      myc.f = 0;
   }
}
```

Compiler Warning (level 1) CS0672

Member '*member1*' overrides obsolete member '*member2*. Add the Obsolete attribute to '*member1*'

The compiler found an **override** to a method marked as **obsolete**. However, the overriding method was not itself marked as obsolete. The overriding method will still generate CS0612, if called.

Review your method declarations and explicitly indicate whether a method (and all of its overrides) should be marked **obsolete**.

The following sample generates CS0672:

```
// CS0672.cs
// compile with: /W:1
class MyClass
{
   [System.Obsolete]
   public virtual void ObsoleteMethod()
   {
   }
}

class MyClass2 : MyClass
{
   public override void ObsoleteMethod()   // CS0672
   {
   }
}

class MainClass
{
   static public void Main()
   {
   }
}
```

Compiler Error CS0673

System.Void cannot be used from C# -- use typeof(void) to get the void type object.

System.Void cannot be used in C#.

The following sample generates CS0673:

```
// CS0673.cs
class MyClass
{
   public static void Main()
   {
      System.Type t = typeof(System.Void);   // CS0673
      // try the following line instead
      // System.Type t = typeof(void);
   }
}
```

Compiler Error CS0674

Do not use 'System.ParamArrayAttribute'. Use the 'params' keyword instead.

The C# compiler does not allow the use of System.ParamArrayAttribute; use params instead.

The following sample generates CS0674:

```
// CS0674.cs
using System;
public class MyClass
{

   public static void UseParams([ParamArray] int[] list)   // CS0674
   // try the following line instead
   // public static void UseParams(params int[] list)
   {
      for ( int i = 0 ; i < list.Length ; i++ )
         Console.WriteLine(list[i]);
      Console.WriteLine();
   }

   public static void Main()
   {
      UseParams(1, 2, 3);
   }
}
```

Compiler Warning (level 3) CS0675

Bitwise-or operator used on a sign-extended operand; consider casting to a smaller unsigned type first

The compiler implicitly widened and sign-extended a variable, and then used the resulting value in a bitwise OR operation. This can result in unexpected behavior.

The following sample generates CS0675:

```
// CS0675.cs
// compile with: /W:3
using System;

public class sign
{
   public static void Main()
   {
      int hi = 1;
      int lo = 1;
      long value = (((long)hi) << 32) | lo;              // CS0675
      // try the following line instead
      // long value = (((long)hi) << 32) | ((uint)lo);   // correct
   }
}
```

Compiler Error CS0676

Cannot pass volatile field '*variable*' as ref or out, or take its address

A variable that is marked with the **volatile** keyword cannot be passed to a ref or out parameter.

The following sample generates CS0676:

```
// CS0676.cs
using System;

class TestClass
{
   private volatile int i;

   public void TestVolatile(ref int ii)
   {
   }

   public static void Main()
   {
      TestClass x = new TestClass();
      x.TestVolatile(ref x.i);   // CS0676 don't pass volatile value as ref
   }
}
```

Compiler Error CS0677

'*variable*': a volatile field can not be of the type '*type*'

Fields declared with the **volatile** keyword must be one of the following types:

- Any reference type
- Any pointer type (in an **unsafe** context)
- The types **sbyte**, **byte**, **short**, **ushort**, **int**, **uint**, **char**, **float**, **bool**
- Enum types based on any of the above types

The following sample generates CS0677:

```
// CS0677.cs
class TestClass
{
   private volatile long i;   // CS0677

   public static void Main()
   {
   }
}
```

Compiler Error CS0678

'*variable*': a field can not be both volatile and readonly

Use of the volatile and readonly keywords is mutually exclusive.

The following sample generates CS0678:

```
// CS0678.cs
using System;

class TestClass
{
   private readonly volatile int i;   // CS0678
   // try the following line instead
   // private volatile int i;

   public static void Main()
   {
   }
}
```

Compiler Error CS0682

'type1' cannot implement 'type2' because it is not supported by the language

This error occurs when you try to implement an interface written in another language and the compiler does not support said interface.

Compiler Error CS0683

"'*explicitmethod*' explicit method implementation cannot implement '*method*' because it is an accessor

The following sample generates CS0683:

```
// CS0683.cs
interface IExample
{
   int Test { get; }
}

class CExample : IExample
{
   int IExample.get_Test() { return 0; } // CS0683
   int IExample.Test { get{ return 0; } } // correct
}
```

Compiler Warning (level 1) CS0684

'*interface*' interface marked with 'CoClassAttribute' not marked with 'ComImportAttribute'

If you specify **CoClassAttribute** on an interface, you must also specify **ComImportAttribute**.

The following sample generates CS0684:

```
// CS0684.cs
// compile with: /W:1
using System;
using System.Runtime.InteropServices;

[CoClass(typeof(C))] // CS0684
// try the following line instead
// [CoClass(typeof(C)), ComImport]
interface I
{
}

class C
{
   static void Main() {}
}
```

Compiler Warning (level 1) CS0688

'*member1*' (a method, property accessor, or event accessor) has a link demand, but overrides or implements '*member2*' (a method, property accessor, or event accessor) which does not have a link demand. A security hole may exist.

The following sample generates CS0688. To resolve the warning, remove the security attribute from the overriding method.

```
// CS0688.cs
// compile with: /W:1
using System;
using System.Security.Permissions;

class Base
{
   public virtual void DoScaryFileStuff()
   {
   }
}

class Derived: Base
{
   // To resolve the error, remove the following security attribute:
   [FileIOPermission(SecurityAction.LinkDemand)] // CS0688
   public override void DoScaryFileStuff()
   {
   }
   static void Main()
   {
   }
}
```

Alternatively, you could add the security attribute to the base overridden method as follows:

```
// CS0688b.cs
using System;
using System.Security.Permissions;

class Base
{
   [FileIOPermission(SecurityAction.LinkDemand, All=@"C:\\")]
   public virtual void DoScaryFileStuff()
   {
   }
}

class Derived: Base
{
   [FileIOPermission(SecurityAction.LinkDemand, All=@"C:\\")]

   public override void DoScaryFileStuff()
   {
   }
   static void Main()
   {
   }
}
```

Compiler Error CS0690

Input file '*file*' is not a valid PE because it contains invalid metadata

You are able to open the metadata file, but due to some localization problem, the metadata was corrupted. This is similar to error CS0009, except that you are able to open the metadata file.

Compiler Error CS1001

Identifier expected

You did not supply an identifier. For example, when declaring an enum, you must specify members.

The following sample generates CS1001:

```
// CS1001.cs
public class clx
{
   enum splitch : int
   {
      'a', 'b' // CS1001, 'a' is not a valid int identifier
   };

   public static void Main()
   {
   }
}
```

Compiler Error CS1002

; expected

The compiler detected a missing semicolon.

The following sample generates CS1002:

```
// CS1002.cs
namespace x
{
   abstract public class clx
   {
      int i   // CS1002, missing semicolon

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS1003

Syntax error, '*char*' expected

The compiler will generate this error for any one of several error conditions. Review your code to find the syntax error.

The following sample generates CS1003:

```
// CS1003.cs
public class b
{
   public static void Main()
   {
      int[] a;
      a[];   // CS1003
   }
}
```

Compiler Error CS1004

Duplicate '*modifier*' modifier

A duplicate modifier, such as an **access** modifier, was detected.

The following sample generates CS1004:

```
// CS1004.cs
public class clx
{
   public public static void Main()   // CS1004, two public keywords
   {
   }
}
```

Compiler Error CS1005

Indirection to managed type is not valid

It is not possible to use unsafe references (pointer syntax) on an object or string.

The following sample generates CS1005:

```
// CS1005.cs
namespace x
{
   public class C
   {
      public object* po;   // CS1005
      // try the following line instead
      // public object po;
   }

   public class a
   {
      public static int Main()
      {
         return 1;
      }
   }
}
```

Compiler Error CS1007

Property accessor already defined

When you declare a property, you must also declare its accessor methods. However, a property cannot have more than one **get** accessor method or more than one **set** accessor method.

The following sample generates CS1007:

```
// CS1007.cs
public class clx
{
   public int MyProperty
   {
      get
      {
         return 0;
      }
      get   // CS1007, this is the second get method
      {
         return 0;
      }
   }

   public static void Main() {}
}
```

Compiler Error CS1008

Type byte, sbyte, short, ushort, int, uint, long, or ulong expected

Certain data types, such as enums, can only be declared to hold data of specified types.

The following sample generates CS1008:

```
// CS1008.cs
abstract public class clx
{
   enum splitch : char   // CS1008, char not valid type for enums
   {
      x, y, z
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1009

Unrecognized escape sequence

An unexpected character followed a backslash (\) in a string. The compiler expects one of the valid escape characters; see Character Escapes for more information.

The following sample generates CS1009:

```
// CS1009-a.cs
class MyClass
{
   static void Main()
   {
      string a = "\m";   // CS1009
      // try the following line instead
      // string a = "\t";
   }
}
```

A common case for this error is using the backslash character in a file name, for example:

```
string filename = "c:\myFolder\myFile.txt";
```

To resolve this error, use "\\" or the @-quoted string literal, as shown in the following example:

```
// CS1009-b.cs
class MyClass
{
   static void Main()
   {
      string filename = "c:\myFolder\myFile.txt";   // CS1009
      // try the one of the following lines instead
      // string filename = "c:\\myFolder\\myFile.txt";
      // string filename = @"c:\myFolder\myFile.txt";
   }
}
```

Compiler Error CS1010

Newline in constant

A string was not properly delimited.

The following sample generates CS1010:

```
// CS1010.cs
class Sample
{
   static void Main()
   {
      string a = "Hello World;   // CS1010, add end quote
   }
}
```

Compiler Error CS1011

Empty character literal

A char was declared and initialized to a null. The initialization of a **char** must specify a character.

The following sample generates CS1011:

```
// CS1011.cs
class Sample
{
   public char CharField = '';   // CS1011
}
```

Compiler Error CS1012

Too many characters in character literal

An attempt was made to initialize a char constant with more than one character.

The following sample generates CS1012:

```
// CS1012.cs
class Sample
{
   static void Main()
   {
      char a = 'xx';   // CS1012
   }
}
```

Compiler Error CS1013

Invalid number

The compiler detected a malformed number.

The following sample generates CS1013:

```
// CS1013.cs
class Sample
{
   static void Main()
   {
       int i = 0x;   // CS1013
   }
}
```

Integral Types Table

Compiler Error CS1014

A get or set accessor expected

A method declaration was found in a property declaration. Only **get** and **set** methods are allowed to be declared in a property.

The following sample generates CS1014:

```
// CS1014.cs
class Sample
{
   public int TestProperty
   {
      get
      {
         return 0;
      }
      int z;   // CS1014, not get or set
   }

   static void Main() {}
}
```

See Also

Property Declaration | Accessors

Compiler Error CS1015

An object, string, or class type expected

An attempt was made to pass a predefined data type into a catch block. Only data types that derive from **System.Exception** can be passed into a **catch** block.

The following sample generates CS1015:

```
// CS1015.cs
class Sample
{
   static void Main()
   {
      try
      {
      }
      catch(int)   // CS1015, int is not derived from System.Exception
      {
      }
   }
}
```

See Also

Exception Handling Statements

Compiler Error CS1016

Named attribute argument expected

Unnamed attribute arguments must appear before the named arguments.

The following sample generates CS1016:

```
// CS1016.cs
using System;

[AttributeUsage(AttributeTargets.Class)]
public class HelpAttribute : Attribute
{
   public HelpAttribute(string url)   // url is a positional parameter
   {
      m_url = url;
   }

   public string Topic = null;      // Topic is a named parameter
   private string m_url = null;
}

[HelpAttribute(Topic="Samples", "http://intranet/inhouse")]   // CS1016
// try the following line instead
//[HelpAttribute("http://intranet/inhouse", Topic="Samples")]
public class MainClass
{
   public static void Main ()
   {
   }
}
```

Compiler Error CS1017

Try statement already has an empty catch block

A **catch** block that does not take any parameters must be the last in a series of **catch** blocks.

The following sample generates CS1017:

```
// CS1017.cs
using System;

namespace x
{
   public class b : Exception
   {
   }

   public class a
   {
      public static void Main()
      {
         try
         {
         }

         catch   // CS1017, must be last catch
         {
         }

         catch(b)
         {
            throw;
         }
      }
   }
}
```

See Also

Exception Handling Statements

Compiler Error CS1018

Keyword this or base expected

The compiler encountered an incomplete constructor declaration.

The following sample generates CS1018 and suggests several ways to resolve the error:

```
// CS1018.cs
namespace x
{
   public class C
   {
   }

   public class a : C
   {
      public a(int i)
      {
      }

      public a () :   // CS1018
      // possible resolutions:
      // public a () resolves by removing the colon
      // public a () : base() calls C's default constructor
      // public a () : this(1) calls the assignment constructor of class a
      {
      }

      public static int Main()
      {
         return 1;
      }
   }
}
```

Compiler Error CS1019

Overloadable unary operator expected

You have a unary operator that returns a value of another class. If you want this conversion, you need to do an **implicit** or **explicit** cast.

The following sample generates CS1019:

```
// CS1019.cs
public class ii
{
   int i
   {
      get
      {
         return 0;
      }
   }
}

public class a
{
   public static a operator ii(a aa)   // CS1019
   // try the following line instead
   //public static a operator ++(a aa)
   {
      return new a();
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1020

Overloadable binary operator expected

An attempt was made to define an operator overload, but the operator was not a binary operator, which takes two parameters.

The following sample generates CS1020:

```
// CS1020.cs
public class iii
{
   public static int operator ++(iii aa, int bb)   // CS1020, change ++ to +
   {
      return 0;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1021

Integral constant is too large

A value assigned to an integral type is larger than the largest possible unsigned integer value.

The following sample generates CS1021:

```
// CS1021.cs
enum F : int
{
   a=(int)2590000000000000000000   // CS1021
}

public class clx
{
   public static void Main()
   {
   }
}
```

Compiler Error CS1022

Type or namespace definition, or end-of-file expected

A source-code file does not have a matching set of braces.

The following sample generates CS1022:

```
// CS1022.cs
namespace x
{
}
}   // CS1022
```

Compiler Error CS1023

Embedded statement cannot be a declaration or labeled statement

An embedded statement, such as the statements following an **if** statement, can contain neither declarations nor labeled statements.

The following sample generates CS1023 twice:

```
// CS1023.cs
public class a
{
   public static void Main()
   {
      if (1)
         int i;      // CS1023, declaration is not valid here

      if (1)
         xx : i++;   // CS1023, labeled statement is not valid here
   }
}
```

Compiler Error CS1024

Preprocessor directive expected

A line began with the pound symbol (#), but the subsequent string was not a valid preprocessor directive.

The following sample generates CS1024:

```
// CS1024.cs
#import System   // CS1024
```

Compiler Error CS1025

Single-line comment or end-of-line expected

A line with a preprocessor directive cannot have a multiline comment.

The following sample generates CS1025:

```
#if true /* hello
*/   // CS1025
#endif   // this is a good comment
```

CS1025 could also occur if you attempt some invalid preprocessor directive, as follows:

```
// CS1025.cs
#define a

class Sample
{
   static void Main()
   {
      #if a 1   // CS1025, invalid syntax
         System.Console.WriteLine("Hello, World!");
      #endif
   }
}
```

Compiler Error CS1026

) expected

An incomplete statement was found.

A common cause of this error is placing a statement, rather than an expression, within an inline expression in an ASP.NET page. For example, the following is incorrect:

```
<%=new TimeSpan(DateTime.Now.Ticks - new DateTime(2001, 1, 1).Ticks).Days;%>
```

The following is correct:

```
<%=new TimeSpan(DateTime.Now.Ticks - new DateTime(2001, 1, 1).Ticks).Days %>
```

It is interpreted as follows:

```
<% Response.Write(new TimeSpan(DateTime.Now.Ticks - new DateTime(2001, 1, 1).Ticks).Days); %>
```

The following sample generates CS1026:

```
// CS1026.cs
#if (a == b   // CS1026, add closing )
#endif

class x
{
   public static void Main()
   {
   }
}
```

Compiler Error CS1027

#endif directive expected

A matching **#endif** preprocessor directive was not found for a specified **#if** directive. Or, the compiler may have found a **#endregion** directive when there was no matching **#region** directive inside a **#if** block.

The following sample generates CS1027:

```
// CS1027.cs
#if true   // CS1027, uncomment next line to resolve
// #endif

namespace x
{
   public class clx
   {
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS1028

Unexpected preprocessor directive

A preprocessor directive was found but not expected.

For example, a **#endif** was found with no preceding **#if**.

The following sample generates CS1028:

```
// CS1028.cs
#endif   // CS1028, no matching #if
namespace x
{
   public class clx
   {
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS1029

#error: '*text*'

Displays the text of an error defined with the #error directive.

The following sample shows how to create a user-defined error:

```
// CS1029.cs
class Sample
{
   static void Main()
   {
      #error Let's give an error here   // CS1029
   }
}
```

Compiler Warning (level 1) CS1030

#warning: '*text*'

Displays the text of a warning defined with the #warning directive.

The following sample shows how to create a user-defined warning:

```
// CS1030.cs
class Sample
{
   static void Main()
   {
      #warning Let's give a warning here   // CS1030
   }
}
```

Compiler Error CS1031

Type expected

A type specifier is expected.

The following sample generates CS1031:

```
// CS1031.cs
namespace x
{
   public class ii
   {
   }

   public class a
   {
      public static operator +(a aa)   // CS1031
      // try the following line instead
      // public static ii operator +(a aa)
      {
         return new ii();
      }

      public static void Main()
      {
         e = new base;   // CS1031, not a type
         e = new this;   // CS1031, not a type
         e = new ();      // CS1031, not a type
      }
   }
}
```

Compiler Error CS1032

Cannot define/undefine preprocessor symbols after first token in file

The **#define** and **#undef** preprocessor directives must be used at the beginning of a program, before any other keywords, such as those used in the namespace declaration.

The following sample generates CS1032:

```
// CS1032.cs
namespace x
{
   public class clx
   {
      #define a   // CS1032, put before namespace
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS1033

Compiler limit exceeded: File cannot exceed '*number*' lines

A source-code file exceeded the maximum allowable number of lines that the compiler can process. To resolve this error, create two or more source-code files from the original file. The maximum number of lines is 2,097,151 lines.

Compiler Error CS1034

Compiler limit exceeded: Line cannot exceed '*number*' characters

The limit for the number of characters allowed on a line is 2046.

Compiler Error CS1035

End-of-file found, '*/' expected

An opening comment delimiter was not matched with a closing delimiter.

The following sample generates CS1035:

```
// CS1035.cs
public class a
{
   public static void Main()
   {
   }
}
/*   // CS1035, needs closing comment
```

Compiler Error CS1036

(or . expected

The XML in a doc comment was badly formed.

The following sample generates CS1036:

```
// CS1036.cs
// compile with: /doc:x.xml
using System;

/// <seealso cref="System.String*"/>   // CS1036
public class Test
{
   public static void Main()
   {
   }
}
```

Compiler Error CS1037

Overloadable operator expected

When specifying a comment with /doc, the compiler encountered an invalid link.

The following sample generates CS1037:

```
// CS1037.cs
// compile with: /doc:x.xml

/// <summary>help text</summary>
public class A
{
   /// <summary>help text</summary>
   public static A operator / (A a1, A a2)
   {
      return null;
   }

   /// <seealso cref="A.operator@"/>   // CS1037
   // try the following line instead
   // /// <seealso cref="A.operator/"/>
   public static A Divide(A a1, A a2)
   {
      return a1 / a2;
   }

   /// <summary>help text</summary>
   public static void Main()
   {
   }
}
```

Compiler Error CS1038

#endregion directive expected

A #region directive did not have a matching #endregion directive.

The following sample generates CS1038:

```
// CS1038.cs
#region testing

public class clx
{
   public static void Main()
   {
   }
}
// CS1038
// uncomment the next line to resolve
// #endregion
```

Compiler Error CS1039

Unterminated string literal

The compiler detected an ill-formed string literal.

See 2.4.4.5 String literals for a discussion of the various ways to declare string literals.

The following sample generates CS1039:

```
// CS1039.cs
public class MyClass
{
   public static void Main()
   {
      string b = @"hello, world;   // CS1039
   }
}
```

To resolve the error, add the terminating quotation mark.

Compiler Error CS1040

Preprocessor directives must appear as the first non-whitespace character on a line

A preprocessor directive was found on a line and was not the first token on the line. A directive must be the first token on the line.

The following sample generates CS1040:

```
// CS1040.cs
/* Define a symbol, X */ #define X   // CS1040

// try the following two lines instead
// /* Define a symbol, X */
// #define X

public class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS1041

Identifier expected, '*keyword*' is a keyword

A reserved word for the C# language was found where an identifier was expected. Replace the keyword with a user-specified identifier.

The following sample generates CS1041:

```
// CS1041a.cs
class MyClass
{
   public void f(int long)   // CS1041
   // Try the following instead:
   // public void f(int i)
   {
   }

   public static void Main()
   {
   }
}
```

When you are importing from another programming language that does not have the same set of reserved words, you can modify the reserved identifier with the @ prefix, as demonstrated in the following sample. For more information on using the @ prefix, see 2.4.2 Identifiers.

An identifier with an `@` prefix is called a verbatim identifier.

```
// CS1041b.cs
class MyClass
{
   public void f(int long)   // CS1041
   // Try the following instead:
   // public void f(int @long)
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1043

{ or ; expected

A property accessor was declared incorrectly.

The following sample generates CS1043:

```
// CS1043.cs
public class MyClass
{
   public int DoSomething
   {
      get return 1;   // CS1043
      // try the following line instead
      // get { return 1;}
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1044

Cannot use more than one type in a for, using, fixed, or declaration statement

The compiler found an invalid statement.

The following sample generates CS1044:

```
// CS1044.cs
using System;

public class MyClass : IDisposable
{
   public void Dispose()
   {
      Console.WriteLine("Res1.Dispose()");
   }

   public static void Main()
   {
      using (MyClass mc1 = new MyClass(),
             MyClass mc2 = new MyClass())   // CS1044, remove an instantiation
      {
      }
   }
}
```

Compiler Error CS1055

An add or remove accessor expected

If your event is not declared as a field, it must define both **add** and **remove** accessor functions.

The following sample generates CS1055:

```
// CS1055.cs
delegate void del();
class Test
{
   public event del MyEvent
   {
      int i;   // CS1055
      // uncomment accessors and delete previous line to resolve
      // add
      // {
      //    MyEvent += value;
      // }
      // remove
      // {
      //    MyEvent -= value;
      // }
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1501

No overload for method '*method*' takes '*number*' arguments

A call was made to a class method, but there is no form of the method that takes the necessary number of arguments.

CS1501 could occur if you are calling a method on a class in a referenced assembly and if that method has default values on one or more of its parameters. C# does not let you create methods with a default value on a parameter, but another language that targets the runtime might. If a parameter (in a method in a referenced assembly) has a default value, you must still call the method and explicitly pass all parameters.

CS1501 could occur when you allocate memory for a delegate; you must also specify the name of the method that the delegate represents.

The following sample generates CS1501:

```
// CS1501.cs
public class a
{
   // declare the following constructor to resolve this CS1501
   /*
   public a(int i)
   {
   }
   */

   public static void Main()
   {
      a aa = new a(2);   // CS1501
   }
}
```

The following sample generates CS1501:

```
// CS1501a.cs
using System;

delegate string func(int i);   // declare the delegate

class a
{
   static func dt;   // class member-field of the declared delegate type

   public static void Main()
   {
      dt = new func();   // CS1501
      // try the following line instead
      // dt = new func(z);   // this works
      x(dt);
   }

   public static string z(int j)
   {
      Console.WriteLine(j);
      return j.ToString();
   }

   public static void x(func hello)
   {
      hello(8);
   }
}
```

Compiler Error CS1502

The best overloaded method match for '*declaration*' has some invalid arguments

This error occurs when the argument types being passed to the method do not match the parameter types of that method. If the called method is overloaded, then none of the overloaded versions has a signature that matches the argument types being passed.

To resolve this problem, do one of the following:

- Double-check the types of the arguments being passed. Make sure that they match the arguments of the method being called.
- If appropriate, convert any mismatched parameters using the System.Convert Class.
- If appropriate, cast any mismatched parameters to match the type that the method is expecting.
- If appropriate, define another overloaded version of the method to match the parameter types that are being sent.

The following sample generates CS1502:

```
// CS1502.cs
namespace x
{
   public class a
   {
      public a(char i)
      // try the following constructor instead
      // public a(int i)
      {
      }

      public static void Main()
      {
         a aa = new a(2222);   // CS1502
      }
   }
}
```

Compiler Error CS1503

Argument '*arg*': cannot convert from '*type1*' to '*type2*'

The type of one argument in a method does not match the type that was passed when the class was instantiated.

See CS1502 for a discussion on how to resolve this error.

Compiler Error CS1504

Source file '*file*' could not be opened ('*reason*')

A source file could not be opened or read by the compiler. The file may be locked by another application, or there could be some other operating system problem. The message includes the operating system's reason for why the compiler could not open or read the file.

Compiler Error CS1507

Cannot link resource file '*file*' when building a module

/resource or /linkresource was used in the same compilation with /target:module, which is not allowed.

Compiler Error CS1508

Resource identifier '*identifier*' has already been used in this assembly

In a compilation, the same identifier (***identifier***) was passed to two or more /resource or /linkresource compiler options.

For example, the following options would generate CS1508:

```
/resource:anyfile.bmp,DuplicatIdent /linkresource:a.bmp,DuplicatIdent
```

Compiler Error CS1509

Referenced file '*file*' is not an assembly; use '/addmodule' option instead

An output file (output file 1), produced in a compilation that used /target:module (does not have an assembly manifest), was specified to /reference. So, rather than appending an assembly to the assembly for the current program, the metadata information in output file 1 will be added to the assembly for the current program.

Compiler Error CS1510

A ref or out argument must be an lvalue

Only a variable can be passed as a ref parameter in a method call. A **ref** value is similar to passing a pointer.

The following sample generates CS1510:

```
// CS1510.cs
public class C
{
   public static int i = 0;

   public static void mf(ref int i)
   {
      i++;
   }

   public static void Main ()
   {
      mf (ref 1);   // CS1510, can't pass a number as a ref parameter
      // try the following to resolve the error
      // mf (ref i);
   }
}
```

Compiler Error CS1511

Keyword base is not available in a static method

The base keyword was used in a static method.

The following sample generates CS1511:

```
// CS1511.cs
public class A
{
   public int j = 0;
}

class C : A
{
   public void func()
   {
      base.j = 3;   // base allowed here
   }

   public static int Main ()
   {
      base.j = 3;   // CS1511
      return 1;
   }
}
```

Compiler Error CS1512

Keyword base is not available in the current context

The base keyword was used outside of a method, property, or constructor.

The following sample generates CS1512:

```
// CS1512.cs
using System;

class Base {}

class CMyClass : Base
{
   private String xx = base.ToString();   // CS1512
   // try putting this initialization in the constructor instead
   // public CMyClass()
   // {
   //    xx = base.ToString();
   // }

   public static void Main()
   {
      CMyClass z = new CMyClass();
   }
}
```

Compiler Error CS1513

} expected

The compiler expected a closing curly brace (`}`) that was not found.

The following sample generates CS1513:

```
// CS1513
namespace y   // CS1513, no close curly brace
{
   class x
   {
      public static void Main()
      {
      }
   }
```

Compiler Error CS1514

{ expected

The compiler expected an opening curly brace (`{`) that was not found.

The following sample generates CS1514:

```
// CS1514.cs
namespace x
// CS1514, no open curly brace
```

Compiler Error CS1515

'in' is expected

In a foreach, in statement, the "in" part is missing.

The following sample generates CS1515:

```
using System;

class Driver
{
   static void Main()
   {
      int[] arr = new int[] {1, 2, 3};

      // try the following line instead
      // foreach (int x in arr)
      foreach (int x arr)      // CS1515, "in" is missing
      {
         Console.WriteLine(x);
      }
   }
}
```

Compiler Error CS1517

Invalid preprocessor expression

The compiler encountered an invalid preprocessor expression.

For more information, see Preprocessor Directives.

The following sample shows some valid and invalid preprocessor expressions:

```
// CS1517.cs
#if symbol      // OK
#endif
#if !symbol     // OK
#endif
#if (symbol)    // OK
#endif
#if true        // OK
#endif
#if false       // OK
#endif
#if 1           // CS1517
#endif
#if ~symbol     // CS1517
#endif
#if *           // CS1517
#endif

class x
{
   public static void Main()
   {
   }
}
```

Compiler Error CS1518

Expected class, delegate, enum, interface, struct, or union

A declaration was found that is not supported in a namespace. Inside a namespace, the compiler accepts only classes, structs, enums, interfaces, namespaces, and delegates.

The following sample generates CS1518:

```
// CS1518.cs
namespace x
{
   sealed class c1 {};      // OK
   namespace f2 {};         // OK
   sealed f3 {};            // CS1518
}
```

Compiler Error CS1519

Invalid token '*token*' in class, struct, or interface member declaration

Any class, struct, or interface member declaration that contains invalid modifiers before the type will generate this error.

The following sample generates CS1519:

```
// CS1519.cs
public class IMyInterface
{
   checked void f4();   // CS1519
   lock void f5();      // CS1519
   namespace;           // CS1519
   int i;               // OK
}
```

Compiler Error CS1520

Class, struct, or interface method must have a return type

A method that is declared in a class, struct, or interface must have an explicit return type.

The following sample generates CS1520:

```
// CS1520a.cs
public class x
{
   f7()   // CS1520, needs return type
   // try the following definition
   // void f7()
   {
   }

   public static void Main()
   {
   }
}
```

Alternatively, this error might be encountered when the case of a constructor's name differs from that of the class or struct declaration, as in the following sample:

```
// CS1520b.cs
public class Class1
{
   public class1()   // CS1520, incorrect case
   {
   }
   static void Main()
   {
   }
}
```

Compiler Error CS1521

Invalid base type

A base class specification was ill formed.

The following sample generates CS1521:

```
// CS1521.cs
class CMyClass
{
   public static void Main()
   {
   }
}

class CMyClass1 : CMyClass     // OK
{
}

class CMyClass2 : CMyClass[]   // CS1521
{
}

class CMyClass3 : CMyClass*    // CS1521
{
}
```

Compiler Warning (level 1) CS1522

Empty switch block

The compiler detected a switch block with no **case** or **default** statement. A **switch** block must have one or more **case** or **default** statements.

The following sample generates CS1522:

```
// CS1522.cs
// compile with: /W:1
using System;
class x
{
   public static void Main()
   {
      int i = 6;

      switch(i)   // CS1522
      {
         // add something to the switch block, for example:
         /*
         case (5):
            Console.WriteLine("5");
            return;
         default:
            Console.WriteLine("not 5");
            return;
         */
      }
   }
}
```

Compiler Error CS1523

The keyword case or default must precede code in switch block

Code was found in a switch statement that was part of neither a **case** nor a **default** block.

The following sample generates CS1523:

```
// CS1523.cs
class x
{
   public static void Main()
   {
      int i = 0;

      switch (i)
      {
         i = 6;   // CS1523, code not under a label
         // try the following
         /*
         default:
            i = 6;
         */
      }
   }
}
```

Compiler Error CS1524

Expected catch or finally

A **try** block must be followed by a **catch** or **finally** block.

The following sample generates CS1524:

```
// CS1524.cs
class x
{
   public static void Main()
   {
      try
      {
         // Code here
      }
      catch
      {
      }
      try
      {
         // Code here
      }
      finally
      {
      }
      try
      {
         // Code here
      }
   }     // CS1524, missing catch or finally
}
```

See Also

Exception Handling Statements

Compiler Error CS1525

Invalid expression term '*character*'

The compiler detected an invalid character in an expression.

The following sample generates CS1525:

```
// CS1525.cs
class x
{
   public static void Main()
   {
      int i = 0;
      i = i +   // OK - identifier
      'c' +     // OK - character
      (5) +     // OK - parenthesis
      [ +       // CS1525, operator not a valid expression element
      throw +   // CS1525, keyword not allowed in expression
      void;     // CS1525, void not allowed in expression
   }
}
```

An empty label can also generate CS1525, as in the following sample:

```
// CS1525b.cs
using System;
public class MyClass
{
   public static void Main()
   {
      goto FoundIt;
      FoundIt:      // CS1525
      // Uncomment the following line to resolve:
      // System.Console.Write("Hello");
   }
}
```

Compiler Error CS1526

'new' expression requires () or [] after type

The new operator, used to dynamically allocate memory for an object, was not specified correctly.

The following sample shows how to use **new** to allocate space for an array and an object.

```
// CS1526.cs
public class y
{
   public static int i = 0;
   public int myi = 0;
}

public class z
{
   public static void Main()
   {
      y py = new y;   // CS1526
      y[] aoys = new y[10];   // Array of Ys

      for (int i = 0; i < aoys.Length; i++)
         aoys[i] = new y();   // an object of type y
   }
}
```

Compiler Error CS1527

Namespace elements cannot be explicitly declared as private, protected, or protected internal

Type declarations in a namespace can have either public or internal access. If no accessibility is specified, **internal** is the default.

The following sample generates CS1527:

```
// CS1527.cs
namespace Sample
{
   private class C1 {};             // CS1527
   protected class C2 {};           // CS1527
   protected internal class C3 {};  // CS1527
}
```

Compiler Error CS1528

Expected ; or = (cannot specify constructor arguments in declaration)

A reference to a class was formed as if an object to the class was being created. For example, there was an attempt to pass a variable to a constructor. Use the new operator to create an object of a class.

The following sample generates CS1528:

```
// CS1528.cs
using System;

public class B
{
   public B(int i)
   {
      _i = i;
   }

   public void PrintB()
   {
      Console.WriteLine(_i);
   }

   private int _i;
}

public class mine
{
   public static void Main()
   {
      B b(3);   // CS1528, reference is not an object
      // try one of the following
      // B b;
      // or
      // B bb = new B(3);
      // bb.PrintB();
   }
}
```

Compiler Error CS1529

A using clause must precede all other namespace elements

Statements with a using clause must appear first in a namespace.

The following sample generates CS1529:

```
// CS1529.cs
namespace x
{
   namespace subspace
   {
      using Microsoft;

      class SomeClass
      {
      };

      using Microsoft;        // CS1529, place before class definition
   }

   using System.Reflection;   // CS1529, place before namespace 'subspace'
}

using System;                 // CS1529, place at the beginning of the file
```

Compiler Error CS1530

Keyword new not allowed on namespace elements

It is not necessary to specify the new keyword on any construct that is in a namespace.

The following sample generates CS1530:

```
// CS1530.cs
namespace a
{
   new class i   // CS1530
   {
   }

   // try the following instead
   class ii
   {
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS1533

Invoke cannot be called directly on a delegate

The **Invoke** method cannot be called on a delegate. For example:

```
// CS1533.cs
using System;

public class A
{
   public static void Main()
   {
   }
}

public delegate void B(A a);

internal class C
{
   public void Baz(A a, B b)
   {
      b.Invoke(a);   // CS1533
      // try the following line instead
      // b(a);
   }
}
```

Compiler Error CS1534

Overloaded binary operator '*operator*' only takes two parameters

The definition of a binary overloadable operator must take two parameters.

The following sample generates CS1534:

```
// CS1534.cs
class MyClass
{
   public static MyClass operator - (MyClass MC1, MyClass MC2, MyClass MC3)   // CS1534
   // try the following line instead
   // public static MyClass operator - (MyClass MC1, MyClass MC2)
   {
      return new MyClass();
   }

   public static int Main()
   {
      return 1;
   }
}
```

Compiler Error CS1535

Overloaded unary operator '*operator*' only takes one parameter

The definition of a unary overloadable operator must take one parameter.

The following sample generates CS1535:

```
// CS1535.cs
class MyClass
{
   // uncomment the method parameter to resolve CS1535
   public static MyClass operator ++ (/*MyClass MC1*/)   // CS1535
   {
      return new MyClass();
   }

   public static int Main()
   {
      return 1;
   }
}
```

Compiler Error CS1536

Invalid parameter type void

It is not necessary or valid to specify a void parameter other than a void pointer.

The following sample generates CS1536:

```
// CS1536.cs
class a
{
   public static int x( void )   // CS1536
   // try the following line instead
   // public static int x()
   {
      return 0;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1537

The using alias '*alias*' appeared previously in this namespace

You defined a symbol twice as an alias for a namespace. A symbol can only be defined once.

The following sample generates CS1537:

```
// CS1537.cs
namespace x
{
   using System;
   using Object = System.Object;
   using Object = System.Object;   // CS1537, delete this line to resolve
   using System = System;
}
```

Compiler Error CS1540

Cannot access protected member '*member*' via a qualifier of type '*type1*'; the qualifier must be of type '*type2*' (or derived from it)

Although a derived class can access protected members of its base class, it cannot do so through an instance of the base class.

The following sample generates CS1540:

```
// CS1540.cs
public class Base
{
   protected void func()
   {
   }
}

public class Derived : Base
{
   public static void test(Base anotherInstance)
   // the method declaration could be changed as follows
   // public static void test(Derived anotherInstance)
   {
      anotherInstance.func();   // CS1540
   }
}

public class Tester : Derived
{
   public static void Main()
   {
      Base pBase = new Base();
      // the allocation could be changed as follows
      // Derived pBase = new Derived();
      test(pBase);
   }
}
```

Compiler Error CS1541

Invalid include option: '*symbol*' — cannot include directories

The compiler detected an attempt to specify a directory rather than a specific file. For example, when you use the /reference compiler option, you must specify a file; it is not possible to specify a directory.

For example, the following parameter passed to the **/reference** compiler option would generate CS1541:

```
/reference:c:\
```

Compiler Error CS1542

'*dll*' cannot be added to this assembly because it already is an assembly; use '/R' option instead

The file that was referenced with the /addmodule compiler option was not built with /target:module; use /reference to reference the file in this compilation.

Compiler Error CS1545

Property, indexer, or event '*property*' is not supported by the language; try directly calling accessor methods '*set accessor*' or '*get accessor*'

Your code is consuming an object that has a default indexer and tried to use the indexed syntax. To resolve this error, call the property's get or set accessor method.

The following sample generates CS1545:

```
// CPP1545.cpp
// compile with: /clr /LD
#using <mscorlib.dll>
using namespace System;

public __gc class Employee {
public:
   Employee(String * s, int d) {
      _name = s;
      _dept = d;
   };

   __property String * get_name() {
      return _name;
   }

   __property int get_dept() {
      return _dept;
   }

private:
   String * _name;
   int _dept;
};

public __gc class Manager {
public:
   __property Employee * get_Report(String * s) {
      for (pEmp = Reports ; pEmp && (pEmp -> emp -> name != s);
         pEmp = pEmp -> next);
      if (pEmp)
         return pEmp -> emp;
      else
         return 0;
   }

   __property void set_Report(String* s, Employee* e) {
     for(pEmp = Reports; pEmp && (pEmp -> emp -> name != s);
      pEmp = pEmp -> next);
      if (!pEmp) {
         EmpList * emp1 = new EmpList;
         emp1 -> emp = e;
         emp1 -> next = Reports;
         Reports = emp1;
      }
   }
private:
   static Manager() {
      Reports = 0;
   }
   __gc struct EmpList {
   Employee * emp;
   EmpList * next;
   };
   EmpList * pEmp;
   static EmpList * Reports;
};
```

And then the C# program:

```
// CS1545.cs
// compile with: /r:CPP1545.dll
class x {
   public static void Main() {
      Manager Ed = new Manager();
      Employee Bob = new Employee("Bob Smith", 12);

      // track Ed's reports
      Ed.Report( Bob.name ) = Bob;   // CS1545
      // try the following line instead
      // Ed.set_Report( Bob.name, Bob);
   }
}
```

Compiler Error CS1546

Property, indexer, or event '*property*' is not supported by the language; try directly calling accessor method '*accessor*'

Your code is consuming an object that has a default indexed property and tried to use the indexed syntax. To resolve this error, call the property's accessor method.

The following sample generates CS1546. It consists of a .cpp file, which compiles to a .dll, and a .cs file, which uses that .dll.

```
// CPP1546.cpp
// compile with: /clr /LD
#using <mscorlib.dll>

using namespace System;
public __gc class MCPP
{
public:
   __property int get_Prop(int i, int b){return i;}
};
```

This is the C# file:

```
// CS1546.cs
// compile with: /r:CPP1546.dll
using System;
public class Test
{
   public static void Main()
   {
      int i = 0;
      MCPP mcpp = new MCPP();
      i = mcpp.Prop(1,1);   // CS1546
      // try the following line instead
      // i = mcpp.get_Prop(1,1);
   }
}
```

Indexers | Defining and Using Properties

Compiler Error CS1547

Keyword 'void' cannot be used in this context

The compiler detected an invalid use of the void keyword.

The following sample generates CS1547:

```
// CS1547.cs
public class MyClass
{
   void BadMethod()
   {
      void i;   // CS1547, cannot have variables of type void
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1548

Cryptographic failure while signing assembly '*assembly*' — '*reason*'

This error occurs when the signing of the assembly fails for some reason. There are several possible reasons why this could occur. The most common are that the assembly key file directive (usually in the AssemblyInfo.cs file) has an incorrect path to the key file, or the path is not a relative path to the build directory, or there is something wrong with the key file. For example, if the key file is in the project folder, the following should appear in AssemblyInfo.cs:

```
[assembly: AssemblyKeyFile("..\\..\\SnkFileName.snk")]
```

For more information, see KB Article Q328379.

Compiler Error CS1549

Appropriate cryptographic service not found

An RSA compatible cryptographic service provider was not installed.

Compiler Error CS1551

Indexers must have at least one parameter

An indexer that takes no arguments was declared.

The following sample generates CS1551:

```
// CS1551.cs
public class MyClass
{
   int intI;

   int this[]   // CS1551
   // try the following line instead
   // int this[int i]
   {
      get
      {
         return intI;
      }
      set
      {
         intI = value;
      }
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1552

Array type specifier, [], must appear before parameter name

The position of the array type specifier is after the variable name in the array declaration.

The following sample generates CS1552:

```
// CS1552.cs
public class C
{
   public static void Main(string args[])   // CS1552
   // try the following line instead
   // public static void Main(string [] args)
   {
   }
}
```

Compiler Error CS1553

Declaration is not valid; use '*modifier* operator <dest-type> (...' instead

The return type for an operator must immediately precede the parameter list, and *modifier* is either **implicit** or **explicit**.

The following sample generates CS1553:

```
// CS1553.cs
class MyClass
{
   public static int implicit operator (MyClass f)   // CS1553
   // try the following line instead
   // public static implicit operator int (MyClass f)
   {
      return 6;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1554

Declaration is not valid; use '<type> operator *op* (...' instead

The return type for a user-defined operator must appear before the keyword operator.

The following sample generates CS1554:

```
// CS1554.cs
class MyClass
{
   public static operator ++ MyClass (MyClass f)    // CS1554
   // try the following line instead
   // public static MyClass operator ++ (MyClass f)
   {
      return new MyClass ();
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS1555

Could not find '*class*' for Main method in program '*program*'

A class was specified to the /main compiler option, but the class name was not found in the source code.

Compiler Error CS1556

'*construct*' specified for Main method must be a valid class or struct

The /main compiler option was passed an identifier that was not a class name.

Compiler Error CS1557

'*class*' specified for Main method not found in program '*output file1*', was found in '*output file2*'

The /main compiler option was specified for one output file in a multi-output file compilation. However, the class was not found in the source code for the /main compilation; it was found in a source code file for one of the other output files in the compilation.

Compiler Error CS1558

'*class*' does not have a suitable Main method

The /main compiler option specified a class in which to look for a Main method. However, the Main method was not defined correctly.

Compiler Error CS1559

'*object*' is imported and cannot be used as an entry point for program '*program*'

An invalid class was specified to the /main compiler option; the class cannot be used as a location for the Main method.

Compiler Error CS1560

Filename specified for #line is too long

The file name that was specified with #line exceeded **_MAX_PATH** (256 characters) or the line on which **#line** was found exceeded 2000 characters.

Compiler Error CS1562

Outputs without source must have the /out option specified

The compilation could create an output file, but there was no source code file as input from which the name of the output file could be implied. For example, you may be trying to compile a metadata- or resource-only file.

Use the /out compiler option to specify the name of the output file.

Compiler Error CS1563

Output '*output file*' does not have any source files

The /out compiler option was specified, but no source code files follow. You should either not use **/out**, or you should specify the source code files following **/out**.

Compiler Error CS1565

Conflicting options specified: Win32 resource file; Win32 icon

It is not valid to specify both the /win32res compiler option and the /win32ico compiler option in the same compilation.

Compiler Error CS1566

Error reading resource file '*file*' — '*reason*'

The compiler had trouble with the file name passed to the /resource compiler option.

Compiler Error CS1567

Error generating Win32 resource: '*file*'

Your compilation either used the /win32icon compiler option or did not use /win32res, which causes the compiler to generate a file that contains resource information, but the compiler was unable to create the file due to insufficient disk space or some other error.

If you are unable to resolve the file-generation problem, you could use /win32res, which does not generate a file that contains resource information.

Compiler Error CS1569

Error generating XML documentation file '*file*' ('*reason*')

When generating an XML file with /doc, the file could not be opened and written to for the indicated reason.

Compiler Warning (level 1) CS1570

XML comment on '*construct*' has badly formed XML — '*reason*'

When using /doc, any comments in the source code must be in XML. Any error with your XML markup will generate CS1570. For example:

- If you are passing a string to a **cref**, such as in an <exception> tag, the string must be enclosed in double quotation marks.
- If you are using a tag, such as <seealso>, which does not have a closing tag, you must specify a forward slash before the closing angle bracket.
- If you need to use a greater-than or less-than symbol in the text of description, you need to represent them with **>** or **<**.
- The file or path attribute on an <include> tag was missing or improperly formed.

The following sample generates CS1570:

```
// CS1570.cs
// compile with: /W:1
namespace ns
{
   // the following line generates CS1570
   /// <summary> returns true if < 5 </summary>
   // try this instead
   // /// <summary> returns true if &lt;5 </summary>

   public class MyClass
   {
      public static void Main ()
      {
      }
   }
}
```

Compiler Warning (level 2) CS1571

XML comment on '*construct*' has a duplicate param tag for '*parameter*'

When using the /doc compiler option, multiple comments were found for the same method parameter. Remove one of the duplicate lines.

The following sample generates CS1571:

```
// CS1571.cs
// compile with: /W:2 /doc:x.xml

/// <summary>help text</summary>
public class MyClass
{
   /// <param name='Int1'>Used to indicate status.</param>
   /// <param name='Char1'>An initial.</param>
   /// <param name='Int1'>Used to indicate status.</param> // CS1571
   public static void MyMethod(int Int1, char Char1)
   {
   }

   /// <summary>help text</summary>
   public static void Main ()
   {
   }
}
```

Compiler Warning (level 2) CS1572

XML comment on '*construct*' has a param tag for '*parameter*', but there is no parameter by that name

When using the /doc compiler option, a comment was specified for a parameter that does not exist for the method. Change the value passed to the name attribute or remove one of the comment lines.

The following sample generates CS1572:

```
// CS1572.cs
// compile with: /W:2 /doc:x.xml

/// <summary>help text</summary>
public class MyClass
{
   /// <param name='Int1'>Used to indicate status.</param>
   /// <param name='Char1'>Used to indicate status.</param>
   /// <param name='Char2'>???</param> // CS1572
   public static void MyMethod(int Int1, char Char1)
   {
   }

   /// <summary>help text</summary>
   public static void Main ()
   {
   }
}
```

Compiler Warning (level 4) CS1573

Parameter '*parameter*' has no matching param tag in XML comment (but other parameters do)

When using the /doc compiler option, a comment was specified for some but not all parameters in a method. You may have forgotten to enter a comment for these parameters.

The following sample generates CS1573:

```
// CS1573.cs
// compile with: /W:4
public class MyClass
{
   /// <param name='Int1'>Used to indicate status.</param>
   // enter a comment for Char1?
   public static void MyMethod(int Int1, char Char1)
   {
   }

   public static void Main ()
   {
   }
}
```

Compiler Warning (level 1) CS1574

XML comment on '*construct*' has cref attribute '*item*' that could not be found

A string passed to a cref tag, for example, within an <exception> tag, referred to a member that is not available within the current build environment. The string that you pass to a cref tag must be the syntactically correct name of a member or field.

For more information, see Recommended Tags for Documentation Comments.

The following sample generates CS1574:

```
// CS1574.cs
// compile with: /W:1 /doc:x.xml
using System;

/// <exception cref="System.Console.WriteLin">An exception class.</exception>   // CS1574
// instead, uncomment and try the following line
// /// <exception cref="System.Console.WriteLine">An exception class.</exception>
class EClass : Exception
{
}

class TestClass
{
   public static void Main()
   {
      try
      {
      }
      catch(EClass)
      {
      }
   }
}
```

Compiler Error CS1575

A stackalloc expression requires [] after type

The size of the requested allocation, with stackalloc, must be specified in square brackets.

The following sample generates CS1575:

```
// CS1575.cs
// compile with: /unsafe
public class MyClass
{
   unsafe public static void Main()
   {
      int *p = stackalloc int (30);   // CS1575
      // try the following line instead
      // int *p = stackalloc int [30];
   }
}
```

Compiler Error CS1576

The line number specified for #line directive is missing or invalid

The compiler detected an error with the value passed to the #line directive.

The following sample generates CS1576:

```
// CS1576.cs
public class MyClass
{
   static void Main()
   {
      #line "abc.sc"         // CS1576
      // try the following line instead
      //#line  101 "abc.sc"
      intt i;  // error will be reported on line 101
   }
}
```

Compiler Error CS1577

Assembly generation failed — *reason*

The assembly-generation part of the compilation failed. See the errors documentation for the alink utility (Al.exe) for more information.

Compiler Error CS1578

Filename, single-line comment or end-of-line expected

After a #line directive, only a file name (in double quotation marks) or a single-line comment is allowed.

The following sample generates CS1578:

```
// CS1578.cs
class MyClass
{
   static void Main()
   {
      #line 101 abc.cs   // CS1578
      // try the following line instead
      //#line 101 "abc.cs"
      intt i;          // error will be reported on line 101
   }
}
```

Compiler Error CS1579

foreach statement cannot operate on variables of type '*type1*' because '*type2*' does not contain a definition for '*member*', or it is inaccessible

A data type (*type1*) does not contain a member that allows foreach to iterate through *type2*.

The following sample generates CS1579:

```
// CS1579.cs
using System;

public class C1
{
   public int GetEnumerator ()
   {
      return 0;
   }
}

public class MainClass
{
   public static void Main ()
   {
      C1 c1 = new C1();

      foreach (int x in c1)   // CS1579
      {
      }
   }
}
```

Compiler Warning (level 1) CS1580

Invalid type for parameter '*parameter number*' in XML comment cref attribute

When attempting to reference an overload form of a method, the compiler detected a syntax error. Typically, this indicates that the parameter name, and not the type, was specified. A malformed line will appear in the generated XML file.

The following sample generates CS1580:

```
// CS1580.cs
// compile with: /W:1 /doc:x.xml
using System;

/// <seealso cref="Test(i)"/>   // CS1580
// try the following line instead
// /// <seealso cref="Test(int)"/>
public class MyClass
{
   /// <summary>help text</summary>
   public static void Main()
   {
   }

   /// <summary>help text</summary>
   public void Test(int i)
   {
   }

   /// <summary>help text</summary>
   public void Test(char i)
   {
   }
}
```

Compiler Warning (level 1) CS1581

Invalid return type in XML comment cref attribute

When attempting to reference a method, the compiler detected an error due to an invalid return type.

The following sample generates CS1581:

```
// CS1581.cs
// compile with: /W:1 /doc:x.xml

/// <summary>help text</summary>
public class MyClass
{
   /// <summary>help text</summary>
   public static void Main()
   {
   }

   /// <summary>help text</summary>
   public static explicit operator int(MyClass f)
   {
      return 0;
   }
}

/// <seealso cref="MyClass.explicit operator intt(MyClass)"/>   // CS1581
// try the following line instead
// /// <seealso cref="MyClass.explicit operator int(MyClass)"/>
public class MyClass2
{
}
```

Compiler Error CS1583

'*file*' is not a valid Win32 resource file

A file was passed to the /win32res compiler option that was not a valid resource file.

Compiler Warning (level 1) CS1584

XML comment on '*member*' has syntactically incorrect cref attribute '*invalid_syntax*'

One of the parameters passed to a tag for documentation comments had invalid syntax.

The following sample generates CS1584:

```
// CS1584.cs
// compile with: /W:1 /doc:x.xml
/// <remarks>Test class</remarks>
public class Test
{
   /// <remarks>
   /// Called in <see cref="Test::Main"/>.   // CS1584, try Test.Main
   /// </remarks>
   public static void Test2()
   {
   }

   /// <remarks>Main method</remarks>
   public static void Main()
   {
      Test2();
   }
}
```

Compiler Error CS1585

Member modifier '*keyword*' must precede the member type and name

The access specifier in a method signature did not occur in the correct location.

The following sample generates CS1585:

```
// CS1585.cs
public class Class1
{
   public void static Main(string[] args)   // CS1585
   // try the following line instead
   // public static void Main(string[] args)
   {
   }
}
```

Compiler Error CS1586

Array creation must have array size or array initializer

An array was declared incorrectly.

The following sample generates CS1586:

```
// CS1586.cs
using System;
class MyClass
{
   public static void Main()
   {
      int[] a = new int[];   // CS1586
      // try the following line instead
      int[] b = new int[5];
   }
}
```

Compiler Warning (level 2) CS1587

XML comment is not placed on a valid language element

Recommended tags for documentation comments are not allowed on all language elements. For example, a tag is not allowed on a namespace.

The following sample generates CS1587:

```
// CS1587.cs
// compile with: /W:2 /doc:x.xml

/// <summary>test</summary>   // CS1587, tag not allowed on namespace
namespace MySpace
{
   class MyClass
   {
      public static void Main()
      {
      }
   }
}
```

See Also

Recommended Tags for Documentation Comments

Compiler Error CS1588

Cannot determine common language runtime directory -- '*reason*'

The compiler cannot retrieve the directory that the .NET Framework common language runtime is installed in. This error indicates that the common language runtime is improperly installed.

Compiler Warning (level 1) CS1589

Unable to include XML fragment '*fragment*' of file '*file*' -- *reason*

The syntax (*fragment*) of a <include> tag, which referenced a file (*file*), was incorrect for the specified ***reason***.

A malformed line will be placed in the generated XML file.

The following sample generates CS1589:

```
// CS1589.cs
// compile with: /W:1 /doc:CS1589_out.xml

/// <include file='CS1589.doc' path='MyDocs/MyMembers[@name="test"]/' />   // CS1589
// try the following line instead
// /// <include file='CS1589.doc' path='MyDocs/MyMembers[@name="test"]/*' />
class Test
{
   public static void Main()
   {
   }
}
```

Compiler Warning (level 1) CS1590

Invalid XML include element -- Missing file attribute

A path or doc attribute, passed to the <include> tag, was missing or incomplete.

The following sample generates CS1590:

```
// CS1590.cs
// compile with: /W:1 /doc:x.xml

/// <include path='MyDocs/MyMembers[@name="test"]/*' />   // CS1590
// try the following line instead
// /// <include file='x.doc' path='MyDocs/MyMembers[@name="test"]/*' />
class Test
{
   public static void Main()
   {
   }
}
```

Compiler Warning (level 4) CS1591

Missing XML comment for publicly visible type or member '*Type_or_Member*'

The /doc compiler option was specified, but one or more constructs did not have comments.

The following sample generates CS1591:

```
// CS1591.cs
// compile with: /W:4 /doc:x.xml

/// text
public class Test
{
   // /// text
   public static void Main()   // CS1591, remove "//" from previous line
   {
   }
}
```

Compiler Warning (level 1) CS1592

Badly formed XML in included comments file -- '*reason*'

A problem, reported as ***reason***, was found in the file specified by the <include> tag.

Compiler Error CS1593

Delegate '*del*' does not take '*number*' arguments

The number of arguments passed to a delegate invocation does not agree with the number of parameters in the delegate declaration.

The following sample generates CS1593:

```
// CS1593.cs
using System;
delegate string func(int i);   // declare delegate

class a
{
   public static void Main()
   {
      func dt = new func(z);
      x(dt);
   }

   public static string z(int j)
   {
      Console.WriteLine(j);
      return j.ToString();
   }

   public static void x(func hello)
   {
      hello(8, 9);   // CS1593
      // try the following line instead
      // hello(8);
   }
}
```

Compiler Error CS1594

Delegate '*delegate*' has some invalid arguments

The type of an argument passed to a delegate invocation does not agree with the type of the parameter in the delegate declaration.

The following sample generates CS1594:

```
// CS1594.cs
using System;
delegate string func(int i);   // declare delegate

class a
{
   public static void Main()
   {
      func dt = new func(z);
      x(dt);
   }

   public static string z(int j)
   {
      Console.WriteLine(j);
      return j.ToString();
   }

   public static void x(func hello)
   {
      hello("8");   // CS1594
      // try the following line instead
      // hello(8);
   }
}
```

Compiler Warning (level 1) CS1595

'*type*' is defined in multiple places; using definition from '*assembly*'

A project referenced two assemblies, each of which contains the same type definition. The compiler chose one of the assemblies from which to take the definition of type based on the order of files passed to /reference.

See Add Reference Dialog Box for information on how to add a reference in the development environment.

The following sequence of compilations generates CS1595:

```
// CS1595_1.cs
// compile with: /W:1 /target:library
namespace N1
{
   public class C1
   {
      public C1()
      {
         System.Console.WriteLine("Hi1");
      }
   }
}
```

```
// CS1595_2.cs
// compile with: /t:library
namespace N1
{
   public class C1
   {
      public C1()
      {
         System.Console.WriteLine("Hi2");
      }
   }
}
```

```
// CS1595_3.cs
// compile with: /r:CS1595_1.dll,CS1595_2.dll
class Test
{
   public static void Main(string[] args)
   {
      N1.C1 obj = new N1.C1();   // CS1595
   }
}
```

Compiler Warning (level 1) CS1596

XML documentation not updated during this incremental rebuild; use /incremental- to update XML documentation

When using incremental builds (/incremental) with /doc, /doc is essentially ignored; the source code files will not be processed for comments and the XML file will not be updated.

Compiler Error CS1597

Semicolon after method or accessor block is not valid

Semicolons are not needed (or allowed) to end a method or accessor block.

The following sample generates CS1597:

```
// CS1597.cs
class TestClass
{
   public static void Main()
   {
   };   // CS1597, remove semicolon
}
```

Compiler Warning (level 1) CS1598

XML parser could be not be loaded for the following reason: '*reason*'. The XML documentation file '*file*' will not be generated.

The /doc option was specified, but the compiler could not find and load msxml3.dll. Make sure that the file msxml3.dll is installed and registered.

Compiler Error CS1599

Method or delegate cannot return type '*type*'

Some types in the base class library, for example, TypedReference and ArgIterator cannot be used as return types.

The following sample generates CS1599:

```
// CS1599.cs
using System;

class MyClass
{
   public static void Main()
   {
   }

   public TypedReference Test1()   // CS1599
   {
      return null;
   }

   public ArgIterator Test2()   // CS1599
   {
      return null;
   }
}
```

Compiler Error CS1600

Compilation cancelled by user

A compilation with the C# compiler was cancelled while using the Visual Studio IDE.

Compiler Error CS1601

Method or delegate parameter cannot be of type '*type*'

Some types in the base class library, for example, TypedReference and ArgIterator cannot be used as parameter types with the ref or out keywords.

The following sample generates CS1601:

```
// CS1601.cs
using System;

class MyClass
{
   public void Test1 (ref TypedReference t)   // CS1601
   {
   }

   public void Test2 (out ArgIterator t)   // CS1601
   {
   }
}
```

Compiler Error CS1602

'*symbol*' is already defined in this assembly

A module contains a symbol for a type, and that module is included in the compilation of an assembly that also defines the same symbol. Change the name of one of the symbols.

The following sequence generates C1602. First, create a module:

```
// CS1602.cs
// compile with: /target:module
namespace Test
{
   public class B
   {
   }
}
```

Then, create an assembly and add the module:

```
// CS1602a.cs
// compile with: /addmodule:CS1602.netmodule

namespace Test
{
   public class B   // CS1602
   // try the following line instead
   // public class C
   {
   }

   public class Client
   {
      static public void Main()
      {
      }
   }
}
```

Compiler Error CS1603

Incremental build requires a target name specified with /out

You must specify /out when using the /incremental option.

Compiler Error CS1613

The managed coclass wrapper class '*class*' for interface '*interface*' is invalid or cannot be found (are you missing an assembly reference?)

An attempt was made to instantiate a COM object from an interface. The interface has the **ComImport** and **CoClass** attributes, but the compiler cannot find the type given for the **CoClass** attribute.

To resolve this error, you can try one of the following:

- Add a reference to the assembly that has the coclass (most of the time the interface and coclass should be in the same assembly). See /reference or Add Reference Dialog Box for information.
- Fix the **CoClass** attribute on the interface.

The following sample demonstrates correct usage of **CoClassAttribute**:

```
// CS1613.cs
using System;
using System.Runtime.InteropServices;

[Guid("1FFD7840-E82D-4268-875C-80A160C23296")]
[ComImport()]
[CoClass(typeof(A))]
public interface IA{}
public class A : IA {}

public class AA
{
   public static void Main()
   {
      IA i;
      i = new IA(); // This is equivalent to new A().
                    // because of the CoClass attribute on IA
   }
}
```

Compiler Error CS1614

'*attribute*' is ambiguous; use either '@*attribute*' or '*attribute*Attribute'

The compiler has encountered an ambiguous attribute specification.

For convenience, the C# compiler allows you to specify **ExampleAttribute** as just `[Example]`. However, ambiguity arises if an attribute class named **Example** exists along with **ExampleAttribute**, because the compiler cannot tell if `[Example]` refers to the **Example** attribute or the **ExampleAttribute** attribute. To clarify, use `[@Example]` for the **Example** attribute and `[ExampleAttribute]` for **ExampleAttribute**.

The following sample generates CS1614:

```
// CS1614.cs
using System;

// Both of the following classes are valid attributes with valid
// names (MySpecial and MySpecialAttribute). However, because the lookup
// rules for attributes involves auto-appending the 'Attribute' suffix
// to the identifier, these two attributes become ambiguous; that is,
// if you specify MySpecial, the compiler can't tell if you want
// MySpecial or MySpecialAttribute.

public class MySpecial : Attribute {
   public MySpecial() {}
}

public class MySpecialAttribute : Attribute {
   public MySpecialAttribute() {}
}

class MakeAWarning {
   [MySpecial()] // CS1614
                 // Ambiguous: MySpecial or MySpecialAttribute?
   public static void Main() {
   }

   [@MySpecial()] // This isn't ambiguous, it binds to the first attribute above.
   public static void NoWarning() {
   }

   [MySpecialAttribute()] // This isn't ambiguous, it binds to the second attribute above.
   public static void NoWarning2() {
   }

   [@MySpecialAttribute()] // This is also legal.
   public static void NoWarning3() {
   }
}
```

Compiler Error CS1604

Cannot assign to '*variable*' because it is read-only

An assignment was made to a read-only variable.

The following sample generates CS1604:

```
// CS1604.cs
class NoWrite
{
   public static void Main()
   {
      int [] a = {1,2,3};

      foreach(int k in a)
      {
         k = k + 1;   // CS1604, k is read-only
         System.Console.WriteLine(k);
      }
   }
}
```

Compiler Error CS1605

Cannot pass '*var*' as a ref or out argument because it is read-only

A variable passed as a ref or out parameter is expected to be modified in the called method. Therefore, it is not possible to pass a read-only parameter as **ref** or **out**.

The following sample generates CS1605:

```
// CS1605.cs
class NoWrite
{
   public static void Main()
   {
      int [] a = {1,2,3};
      foreach(int k in a)
      {
         RefMethod(ref k);   // CS1605, can't pass k as ref parameter
      }
   }

   static void RefMethod(ref int i)
   {
   }
}
```

Compiler Error CS1606

Assembly signing failed; output may not be signed -- *reason*

The assembly was produced, but when the compiler attempted to finish signing it, there was a failure.

Compiler Warning (level 1) CS1607

Assembly generation -- *reason*

A warning was generated from the assembly-creation phase of the compilation. For more information, see Al.exe Tool Errors and Warnings.

Compiler Error CS1608

The RequiredAttribute attribute is not permitted on C# types

RequiredAttributeAttribute is not allowed on types defined in C# code.

Compiler Error CS1609

Modifiers cannot be placed on property or event accessor declarations

Modifiers can only be placed on property or event declarations and not on the property or event accessor declarations. For more information, see Accessors.

The following sample generates CS1609:

```
// CS1609.cs
class c
{
   public int Prop   //  modifier on property declaration OK
   {
      get
      {
         return 0;
      }
      private set   // CS1609
      // try the following line instead
      // set
      {
      }
   }

   public static void Main()
   {
   }
}
```

Compiler Warning (level 4) CS1610

Unable to delete temporary file '*file*' used for default Win32 resource -- *resource*

When using the /win32res compiler option and when your **%TEMP%** directory does not have DELETE permission, this warning indicates that the compiler could not delete a temporary file that it created.

Make sure that you have read/write/delete permissions for the **%TEMP%** directory.

If necessary, you can manually delete these files and there will be no harm to C# or any of your programs.

Compiler Error CS1611

The params parameter cannot be declared as ref or out

The keywords ref or out cannot be used with the params keyword.

The following sample generates CS1611:

```
// CS1611.cs
public class MyClass
{
   public static void Test(params ref int[] a)   // CS1611, remove ref
   {
   }

   public static void Main()
   {
      Test(1);
   }
}
```

Compiler Error CS1612

Cannot modify the return value of '*expression*' because it is not a variable

An attempt was made to modify a value type that was the result of an intermediate expression. Because the value is not persisted, the value will be unchanged.

To resolve this error, store the result of the expression in an intermediate value, or use a reference type for the intermediate expression.

The following sample generates CS1612:

```
// CS1612.cs
class Reference
{
   public int i;

   public int Prop
   {
      get
      {
         return i;
      }
      set
      {
         i = value;
      }
   }

   public override string ToString()
   {
      return "i = " + i.ToString();
   }
}

struct Value
{
   public int i;

   public int Prop
   {
      get
      {
         return i;
      }
      set
      {
         i = value;
      }
   }

   public override string ToString()
   {
      return "i = " + i.ToString();
   }
}

class Example
{
   private Reference _r;   // Reference type
   private Value _v;       // Value type

   public Example()
   {
      _r = new Reference();
      _v = new Value();
   }
```

```
    public Reference RefProp
    {
       get
       {
          return _r;
       }
       set
       {
          _r = value;
       }
    }

    public Value ValueProp
    {
       get
       {
          return _v;
       }
       set
       {
          _v = value;
       }
    }

    public static void Main()
    {
       Example e = new Example();

       System.Console.WriteLine(e.RefProp);     // Prints 0
       e.RefProp.i = 5;                         // Legal
       System.Console.WriteLine(e.RefProp);     // Prints 5

       e.RefProp.Prop = 6;                      // Legal
       System.Console.WriteLine(e.RefProp);     // Prints 6
       System.Console.WriteLine(e.ValueProp);   // Prints 0

       // Invalid because ValueProp returns a value on the stack,
       // and although you could set that value,
       // it doesn't reflect back into the original property.
       e.ValueProp.i = 7;   // CS1612

       // If the above statment was allowed, this would still print 0.
       System.Console.WriteLine(e.ValueProp);

       // Invalid because ValueProp returns a value on the stack,
       // and although you could set that value,
       // it doesn't reflect back into the original property.
       e.ValueProp.Prop = 8;   // CS1612

       // If the above statement was allowed, this would still print 0.
       System.Console.WriteLine(e.ValueProp);

       Value v = e.ValueProp;
       v.i = 9;
       System.Console.WriteLine(v);             // Prints 9
       System.Console.WriteLine(e.ValueProp);   // Still prints 0
       v.Prop = 10;
       System.Console.WriteLine(v);             // Prints 10
       System.Console.WriteLine(e.ValueProp);   // Still prints 0
       e.ValueProp = v;

       // The following line prints 10 (this is the proper way).
       System.Console.WriteLine(e.ValueProp);
    }
}
```

Compiler Error CS1618

Cannot create delegate with '*method*' because it has a Conditional attribute

You cannot create a delegate with a conditional method because the method might not exist in some builds.

The following sample generates CS1618:

```
// CS1618.cs
using System;
using System.Diagnostics;

delegate void del();

class MakeAnError {
   public static void Main() {
      del d = new del(ConditionalMethod);   // CS1618
      // Invalid because on builds where DEBUG is not set,
      // there will be no "ConditionalMethod".
   }

   [Conditional("DEBUG")]
   public static void ConditionalMethod()
   {
      Console.WriteLine("Do something only in debug");
   }
}
```

Compiler Error CS1619

Cannot create temporary file '*filename*' -- *reason*

The compiler was unable to create a temporary file for the given reason (for example, the disk is full).

Compiler Error CS1900

Warning level must be in the range 0-4

The /warn compiler option can only take one of five possible values (0, 1, 2, 3, or 4). Any other value passed to **/warn** will result in CS1900.

The following sample generates CS1900:

```
// CS1900.cs
// compile with: /W:5
// CS1900 expected
class x
{
   public static void Main()
   {
   }
}
```

Compiler Error CS1901

Conflicting options specified: Warning level 0; Treat warnings as errors

The /warn and /warnaserror compiler options are mutually exclusive; you cannot both turn warnings off and have warnings reported as errors.

The following sample generates CS1901:

```
// CS1901.cs
// compile with: /W:0 /warnaserror
// CS1901 expected
class x
{
   public static void Main()
   {
   }
}
```

Compiler Error CS1902

Invalid option '*option*' for /debug; must be full or pdbonly

An invalid option was passed to the /debug compiler option.

The following sample generates CS1902:

```
// CS1902.cs
// compile with: /debug:x
// CS1902 expected
class x
{
   public static void Main()
   {
   }
}
```

Compiler Error CS1904

'*number*' is not a valid warning number

A number that was passed to the /nowarn compiler option was not a valid warning.

The following sample generates CS1904:

```
// CS1904.cs
// compile with: /nowarn:invalid_warning_number
// CS1904 generated
class X
{
   public static void Main()
   {
   }
}
```

Compiler Error CS2000

Compiler initialization failed unexpectedly

This error indicates various initialization failures. Reinstall Visual Studio.

Compiler Error CS2001

Source file '*file*' could not be found

A source file name was passed to the compiler, but could not be located. Check the spelling of the file name.

Compiler Warning (level 1) CS2002

Source file '*file*' specified multiple times

A source file name was passed to the compiler more than once. You can only specify a file once to the compiler to build an output file.

The following sample generates CS2002:

```
// CS2002.cs
// compile with: CS2002.cs
public class A
{
public static void Main(){}
}
```

To generate the error, compile the example with the command line:

```
csc CS2002.cs CS2002.cs
```

Compiler Error CS2003

Response file '*file*' included multiple times

A response file was passed to the compiler more than once. A response file can only be passed to the compiler once per output file.

For more on response files, see @ (Specify Response File).

Compiler Error CS2005

Missing file specification for '*option*' command-line option

A compiler option was only partially specified.

For example, when using /recurse, you must specify the file to search: **/recurse:***filename***.cs**.

The following sample generates CS2005:

```
// CS2005.cs
// compile with: /recurse:
// CS2005 expected
class x
{
   public static void Main()
   {
   }
}
```

Compiler Error CS2006

Command-line syntax error: Missing '*text*' for '*option*' switch

The syntax for *option* requires additional text. For information, see Compiler Options.

Compiler Error CS2007

Unrecognized command-line option: '*option*'

The compiler was passed a string that was not a compiler option, even though it began with a forward slash (/).

The following sample generates CS2007:

```
// CS2007.cs
// compile with: /recur
// CS2007 expected
class x
{
   public static void Main()
   {
   }
}
```

Compiler Error CS2008

No inputs specified

The compiler was invoked and compiler options were specified, but no source-code files were passed.

Compiler Error CS2011

Unable to open response file '*file*'

A response file was specified in a compilation, but the compiler was unable to locate and open the file.

For more on response files, see @ (Specify Response File).

Compiler Error CS2012

Can't open '*file*' for writing

While using the /bugreport:*file* compiler option, the file could not be opened for writing. Make sure you specified a valid file name and that the file is not read-only.

Compiler Error CS2013

Invalid image base number '*value*'

An invalid value (not a number) was passed to the /baseaddress compiler option.

The following sample generates CS2013:

```
// CS2013.cs
// compile with: /target:library /baseaddress:x
// CS2013 expected
class MyClass
{
}
```

Compiler Warning (level 1) CS2014

Compiler option '*old option*' is obsolete, please use '*new option*' instead

The form of the compiler option is deprecated. See C# Compiler Options for more information.

Compiler Error CS2015

'*file*' is a binary file instead of a source code file

A file was passed to the compiler that was a binary file. The compiler expects a source code file.

Compiler Error CS2016

Code page '*codepage*' is invalid or not installed

The /codepage compiler option was passed an invalid value.

The following sample generates CS2016:

```
// CS2016.cs
// compile with: /codepage:x
// CS2016 expected
class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS2017

Cannot specify /main if building a module or library

You cannot specify a main entry point when you are building a /target:library.

The following sample generates CS2017:

```
// CS2017.cs
// compile with: /main:MyClass /target:library
// CS2017 expected
class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS2018

Unable to find messages file 'cscmsgs.dll'

The .dll file that contains the compiler's error and warning messages was not found. This file must be present in the same directory as the other compiler support files.

Compiler Error CS2019

Invalid target type for /target: must specify 'exe', 'winexe', 'library', or 'module'

The /target compiler option was used, but an invalid parameter was passed. To resolve this error, recompile the program using the form of the **/target** option that is appropriate to your output file.

The following sample generates CS2017:

```
// CS2019.cs
// compile with: /target:libra
// CS2019 expected
class MyClass
{
}
```

Compiler Error CS2020

Only the first set of input files can build a target other than 'module'

In a multi-output compilation, the first output file must be built with /target:exe, /target:winexe, or /target:library. Any subsequent output files must be built with /target:module.

Compiler Error CS2021

File name '*file*' is too long or invalid

All file names passed to the C# compiler must be no longer than **_MAX_PATH** (defined in a Windows header file). the compiler will give this error in the following situations:

- A file name (including the path) is longer than **_MAX_PATH**.
- The file name contains invalid characters.
- The file name contains wildcards where wildcards are not allowed (such as in resource file names).

Compiler Error CS2022

Options '/out' and '/target' must appear before source file names

The /out (Set Output Filename) and /target (Specify Output File Format) compiler options, when specified on the command line, must precede the source code files.

Compiler Warning (level 1) CS2023

Ignoring /noconfig option because it was specified in a response file

The /noconfig compiler option was specified in a response file, which is not allowed.

Compiler Error CS2024

Invalid file section alignment number '#'

An invalid value was passed to the /filealign compiler option.

The following sample generates CS2024:

```
// CS2024.cs
// compile with: /filealign:ex
// CS2024 expected
class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS3001

Argument type '*type*' is not CLS-compliant

A public, protected, or **protected internal** method must accept a parameter whose type is compliant with the Common Language Specification (CLS).

The following sample generates CS3001:

```
// CS3001.cs
[assembly:System.CLSCompliant(true)]

public class a
{
   public void bad(ushort i)   // CS3001
   {
   }

   private void OK(ushort i)   // OK, private method
   {
   }

   public static void Main()
   {
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3002

Return type of '*method*' is not CLS-compliant

A public, protected, or **protected internal** method must return a value whose type is compliant with the Common Language Specification (CLS).

The following sample generates CS3002:

```
// CS3002.cs
[assembly:System.CLSCompliant(true)]

public class a
{
   public ushort bad()   // CS3002, public method
   {
      ushort a;
      a = ushort.MaxValue;
      return a;
   }

   private ushort OK()   // OK, private method
   {
      ushort a;
      a = ushort.MaxValue;
      return a;
   }

   public static void Main()
   {
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3003

Type of '*variable*' is not CLS-compliant

A public, protected, or **protected internal** variable must be of a type that is compliant with the Common Language Specification (CLS).

The following sample generates CS3003:

```
// CS3003.cs
[assembly:System.CLSCompliant(true)]

public class a
{
   public ushort a1;   // CS3003, public variable
   public static void Main()
   {
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3004

Mixed and decomposed Unicode characters are not CLS-compliant

Only composed UNICODE characters are allowed in public, protected, or **protected internal** identifiers in order to be compliant with the Common Language Specification (CLS).

See Also

What Is the Common Language Specification

Compiler Error CS3005

Identifier '*identifier*' differing only in case is not CLS-compliant

A public, protected, or **protected internal** identifier, which differs from another **public**, **protected**, or **protected internal** identifier only in the case of one or more letters, is not compliant with the Common Language Specification (CLS).

The following sample generates CS3003:

```
// CS3005.cs
using System;
[assembly:CLSCompliant(true)]

public class a
{
   public static int a1 = 0;
   public static int A1 = 1;   // CS3005

   public static void Main()
   {
      Console.WriteLine(a1);
      Console.WriteLine(A1);
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3006

Overloaded method '*method*' differing only in ref or out is not CLS-compliant

A method does not cannot be overloaded based on the ref or out parameter and still comply with the Common Language Specification (CLS).

The following sample generates CS3006:

```
// CS3006.cs
using System;
[assembly: CLSCompliant(true)]

public class MyClass
{
   public void f(int i)
   {
   }

   public void f(ref int i)   // CS3006
   {
   }

   public static void Main()
   {
   }
}
```

To resolve this error, comment out the assembly-level attribute or remove one of the method definitions.

See Also

What Is the Common Language Specification

Compiler Error CS3008

Identifier '*identifier*' is not CLS-compliant

A public, protected, or **protected internal** identifier breaks compliance with the Common Language Specification (CLS) if it begins with an underscore character (_).

The following sample generates CS3008:

```
// CS3008.cs
using System;
[assembly:CLSCompliant(true)]

public class a
{
   public static int _a = 0;  // CS3008
   // OK, private
   // private static int _a1 = 0;

   public static void Main()
   {
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3009

'*type*': base type '*type*' is not CLS-compliant

A base type was marked as not having to be compliant with the Common Language Specification (CLS) in a module that was marked as being CLS compliant. Either remove the attribute that specifies the module is CLS compliant or remove the attribute that indicates the type is not CLS compliant.

The following sample generates CS3009:

```
// CS3009.cs
using System;
[assembly:CLSCompliant(true)]

[CLSCompliant(false)]
public class B
{
}

public class C : B   // CS3009
{
   public static void Main () {}
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3010

'*member*': CLS-compliant interfaces must have CLS-compliant members

In a module marked with `[assembly:CLCSompliant(true)]`, an interface contains a member marked with `[CLCSompliant(false)]`. Remove one of the Common Language Specification (CLS) compliance attributes.

The following sample generates CS3010:

```
// CS3010.cs
using System;
[assembly:CLSCompliant(true)]

public interface I
{
   [CLSCompliant(false)]
   int mf();   // CS3010
}

public class C : I
{
   public int mf()
   {
      return 1;
   }

   public static void Main()
   {
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3011

'*member*': only CLS-compliant members can be abstract

A class member cannot be both abstract and non-compliant with the Common Language Specification (CLS). The CLS specifies that all class members shall be implemented.

The following sample generates CS3011:

```
// CS3011.cs
using System;
[assembly:CLSCompliant(true)]

public abstract class I
{
   [CLSCompliant(false)]
   public abstract int mf();   // CS3011

   // OK
   [CLSCompliant(false)]
   public void mf2()
   {
   }
}

public class C : I
{
   public override int mf()
   {
      return 1;
   }

   public static void Main()
   {
   }
}
```

What Is the Common Language Specification

Compiler Warning (level 1) CS3012

You must specify the CLSCompliant attribute on the assembly

In order for a module to be compliant with the Common Language Specification (CLS) through `[module:System.CLCSompliant(true)]`, it must be built with the /target:module compiler option.

The following sample, when built without **/target:module**, generates CS3012:

```
// CS3012.cs
// compile with: /W:1
[module:System.CLSCompliant(true)]   // CS3012

public class C
{
   public static void Main()
   {
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3013

Added module is not CLS-compliant, or is missing CLSCompliant attribute

A module that was compiled with the /target:module compiler option was added to a compilation with /addmodule. However, the module's compliance with the Common Language Specification (CLS) does not agree with the CLS state of the current compilation.

CLS compliance is indicated with the module attribute. For example, `[module:CLSCompliant(true)]` indicates that the module is CLS compliant, and `[module:CLSCompliant(false)]` indicates that the module is not CLS compliant. The default is `[module:CLSCompliant(false)]`.

See Also

What Is the Common Language Specification

Compiler Error CS3014

'*member*' cannot be marked as CLS compliant because the assembly is not marked as compliant

In a source code file where compliance with the Common Language Specification (CLS) was declined, a construct in the file was marked as being CLS compliant. This is not allowed. Remove one of the **CLSCompliant** specifications.

The following sample generates CS3014:

```
// CS3014.cs
using System;
[assembly:CLSCompliant(false)]

public class I
{
   [CLSCompliant(true)]   // CS3014
   public void mf()
   {
   }

   public static void Main()
   {
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3015

'*method signature*' has no accessible constructors which use only CLS compliant types

To be compliant with the Common Language Specification (CLS), the argument list of an attribute class cannot contain an array.

The following sample generates C3015:

```
// CS3015.cs
using System;
[assembly:CLSCompliant(true)]

public class MyAttribute : Attribute
{
   public MyAttribute(int[] ai)   // CS3015
   // try the following line instead
   // public MyAttribute(int ai)
   {
   }
}

public class MyClass
{
   public static void Main()
   {
   }
}
```

See Also

What Is the Common Language Specification

Compiler Error CS3016

Arrays as attribute arguments is not CLS-compliant

It is not compliant with the Common Language Specification (CLS) to pass an array to an attribute.

The following sample generates CS3016:

```
// CS3016.cs
using System;
[assembly : CLSCompliant(true)]

[C(new int[] {1, 2})]   // CS3016
// try the following line instead
// [C()]
class C : Attribute
{
   public C()
   {
   }

   public C(int[] a)
   {
   }

   public static void Main ()
   {
   }
}
```

What Is the Common Language Specification

Compiler Warning (level 1) CS5000

Unknown compiler option '*/option*'

An invalid compiler option was specified.

Compiler Error CS5001

Program '*output file*' does not have an entry point defined

No Main method was found in the code that produces an executable file.

The following sample generates CS5001:

```
// CS5001.cs
// CS5001 expected
public class a
{
   // uncomment the following to resolve this error
   // public static void Main()
   // {
   // }
}
```

Visual C# Code Wizards

You can create a range of Visual C# projects in Visual Studio. For a list and description of the types of projects you can create, see Visual Basic and Visual C# Projects.

Templates make it easy to build robust projects. For details, see Using Visual C# Add New Item Templates.

Once you create a project, you can change it or add items to it from one of two views:

- From Solution Explorer, you can add items, forms, controls, components, or classes to your project. When you modify your project from Solution Explorer, generic code is automatically inserted into your project.
- From Class View, you can use one or more of the following wizards to add C# programming elements to your source code:
    - C# Class Wizard
    - C# Method Wizard
    - C# Property Wizard
    - C# Field Wizard
    - C# Indexer Wizard
    - C# Interface Method Wizard
    - C# Interface Property Wizard
    - C# Interface Indexer Wizard

Using Visual C# Add New Item Templates

You can easily add items that are common to Visual C# projects using the **Add New Item** command. When you use the **Add New Item** command, the Add New Item dialog box appears with a list of item templates, which add the appropriate files to your project.

> **Note** The list of item templates that appear in the Add New Item dialog box vary, depending on the type of project you are working with.

The following table shows an alphabetical list of Visual C# Add New Item templates.

Templates	Description
Add User Control	Adds a class for creating a Windows Form control using the visual designer.
Application Configuration File	Adds a .config file that you can use to configure your application settings.
Assembly Resource File	Adds a .NET resource file.
Bitmap File	Adds a Win32 bitmap file.
Class	Adds an empty class declaration.
Code File	Adds a blank .cs code file.
Component Class	Adds a class for creating components using the visual designer.
Crystal Report	Adds a Crystal Report file that publishes data to a Windows Form or Web Form . This template is not a Standard Edition feature.
Cursor File	Adds a Win32 cursor file.
Custom Control	Adds a class for creating a user-drawn Windows Form control.
Data Form Wizard	Adds a .cs file for creating an XML schema with DataSet classes.
Data Set	Adds an .xsd file for creating an XML schema with DataSet classes.
Frame Set	Adds an HTML file that hosts multiple HTML pages.
Global Applications Class	Adds a class for handling Web Application events.
HTML Page	Adds an HTML page that can include client-side code.
Icon File	Adds a Win32 icon file.
Inherited Form	Adds a new form based on an existing Windows Form.
Inherited User Control	Adds a new control based on an existing Windows Form control.
Installer Class	Adds a class to be invoked at set-up time.
JScript File	Adds a script file containing JScript code.
Mobile Web Form	Adds a Web form for use in applications that target mobile devices.
Mobile Web User Control	Adds a Web user control for use in applications that target mobile devices.
Static Discovery File	Adds a file used to publish information about a Web Service.
Style Sheet	Adds a cascading style sheet used for rich HTML style definitions.
Text File	Adds a blank text file.
User Control	Adds a class for creating a Windows Form control using the visual designer.
VBScript File	Adds a script file that contains VBScript code.
Web Configuration File	Adds a .config file you can use to configure your Web application settings.
Web Custom Control	Adds a class for creating an ASP.NET server control.
Web Form	Adds a form for Web applications.
Web Service	Adds a class for creating Web Services to use from other applications.
Web User Control	Adds an ASP.NET server control created using the visual designer.
Windows Form	Adds a form for Windows applications to your project.
Windows Service	Adds a class for creating Windows services.
Windows Script Host	Adds a .WSF file that contains script that is run as a Windows program.
XML File	Adds a blank .xml file.
XML Schema	Adds a file for creating a schema for XML documents.
XSLT File	Adds a file used to transform XML documents.

Adding a C# Class

You can add a class to your project either from Solution Explorer or from Class View.

Adding a C# Class Using Solution Explorer

You can build a generic class that is automatically declared under the current default namespace. For example, classes added to a project named WindowsApplication1 are added to the namespace WindowsApplication1.

To add a class in Solution Explorer

1. In Solution Explorer, right-click the project name and click **Add**, and then click **Add Class**.

   The **Add New Item** dialog box appears with the **C# Class** icon already selected.

2. In the dialog box, enter a class name in the **Name** field and click **Open**.

   The new class is added to your project.

For more control over user-defined elements when generating classes, you can either type the code or add the class using Class View.

Adding a Class Using Class View

When you add a class from Class View, you have maximum control defining elements while using C# Class Wizard.

To add a class in Class View

- In Class View, right-click the project name and click **Add**, and then click **Add Class**.

  The C# Class Wizard appears.

Visual C# Code Wizards | Visual C# Samples

C# Class Wizard

The C# Class Wizard appears when you add a C# class from Class View. For details, see Adding a C# Class The wizard has three pages that help you define class elements. You can access each page by clicking the page titles listed in the column on the left side of the wizard.

Page tab	Description
Class Options	Opens the default start page where you define general class elements.
Base Class	Opens the **Base Class** page where you can specify the class from which your class de rives.
Inheritance	Opens the **Inheritance** page where you can specify which inherited interface imple mentations your class uses.

Visual C# Code Wizards | Visual C# Samples

Class Options Tab, C# Class Wizard

The **Class Options** tab serves as the first page of the Class Wizard.

Class name

You must provide a class name. If you provide only a class name, the wizard creates a simple public class using the provided name, with no base class, no inheritance information, and no interfaces.

File name

The wizard automatically generates a new .cs file for each new class.

A separate .cs file per C# class is a natural unit in programming. The unit makes it easy to locate and access your class for editing. However, if you want to add your new class to an existing .cs file, then you can use the ellipsis button (...) to specify the .cs file in which the wizard will insert your new class.

Namespace

Select a namespace from the **Namespace** list, or type a name of your choice.

A top-level namespace is declared. For more information, see 9.2 Namespace declarations.

If you do not declare a namespace, the wizard creates your class under the project namespace. In Class View, you can see that your class will remain as part of that namespace until you provide, in the Source Editor, a namespace for that class.

Access

Define the accessibility level of your class by selecting from the **Access** list. For more information, see Accessibility Levels.

Option	Description
public	Specifies class declaration with no access restrictions.
internal	Specifies class declaration accessibility from files within the same assembly.

Class modifiers

Declare your class with type modifiers, particular to class inheritance, by selecting one of the **Class Modifier** options. The option **None** is set by default.

Option	Description
None	No additional modifiers are included in your class declaration.
Abstract	The class can only be used as the base class of other classes.
Sealed	Declares your class cannot be inherited.

Comment

The wizard converts comments you provide into XML documentation and encapsulates them in <summary> tags, which are used to provide short descriptions. You can find the comments in the .cs file (specified in **File Name**), placed right before the class declaration.

See Also

C# Class Wizard | Visual C# Code Wizards | Visual C# Samples

Base Class Tab, C# Class Wizard

The **Base Class** tab displays the Base Class page, where you can specify the class from which your class derives. For details, see 10.2.1 Inheritance.

Namespace

Select a namespace from the list.

Base class

Once you have specified a namespace, select a base class from the list.

C# does not allow derived classes with inheritance from multiple base classes. For details, see 10.1.2 Class base specification.

See Also

C# Class Wizard | Visual C# Code Wizards | Visual C# Samples

Inheritance Tab, C# Class Wizard

The **Inheritance** tab opens the Inheritance page, where you can specify which inherited interface implementations your class uses. For details, see 13.4.3 Interface implementation inheritance.

Current namespace

Select a namespace from the list.

Interfaces

Once you specify a namespace, a list of interfaces appears in the **Available interfaces** list. Choose the interface that will implement inheritance by highlighting the name of the interface and clicking the appropriate buttons.

Option	Description
Add	Adds the interface, selected in the **Available interfaces** list, to the **Selected interfaces** list .
Add all	Adds all interfaces in the **Available interfaces** list to the **Selected interfaces** list.
Remove	Removes the selected interface from the **Selected interfaces** list.
Remove all	Removes all interfaces from the **Selected interfaces** list.

Selected interfaces

Provides all implementations specified to be added to your new derived class.

Adding a Method to a C# Class

You can add a method to a C# class using a code wizard in Class View only.

To add a method to a C# class

1. In Class View, expand the project node to display the classes in the project.
2. Right-click the class to which you want to add a method.
3. On the shortcut menu, click **Add** and then click **Add Method** to display the C# Method Wizard.
4. Provide the method information in the appropriate wizard boxes. See C# Method Wizard for details.

To add a parameter to a method in a C# class

1. If the method has parameters, provide the modifier and the type, and then supply the **Parameter name**.
2. Click **Add** to add the parameter name to **Parameter list**. The parameter is added to the **Method signature** box at the bottom of the wizard.
3. Review the code in the **Method signature** line. If you need to remove a parameter, highlight it in the **Parameter list** and click **Remove**.
4. Click **Finish** to generate the method code in your project.

See Also

Visual C# Code Wizards | C# Class Wizard

C# Method Wizard

Add a method and define its elements using the one-page C# Method Wizard.

Method access

Sets the access to the method. Access modifiers are keywords for setting access to the method. Specify the access other classes have to the method. The method access level is set to **public** by default. The following access levels are available:

- public
- protected
- private
- internal
- **protected internal**

See Accessibility Levels for an overview of these five levels and for more information about specifying access for methods.

Return type

Sets the value type that the method returns in the return statement. The return type is set to **void** by default. For more information about C# return types, see Value Types and Built-in Types Table.

The following value types are available:

- bool
- byte
- char
- decimal
- double
- float
- int
- long
- object
- sbyte
- short
- string
- uint
- ulong
- ushort
- **void**

Method name

Sets the name of the method to add to the class. You must add at least the method name.

Modifier

Sets the parameter's modifier. **Modifier** is set to **None** by default. See Method Parameters for more information.

- **none**
- ref
- out

Parameter type

Sets the type for the **Parameter name**. The parameter type is set to **int** by default. The type is reflected in the **Method signature** box at the bottom of the wizard. The same values available for the return type are available for the parameter type, with the exception of **void**.

Parameter name

Sets the name of a parameter to pass through your method. After typing the name, you must click **Add** to add it to the list of parameters that will pass through your method.

If you do not provide a parameter name, the wizard ignores any **Modifier** or **Parameter type** selections.

Once you click **Add**, the parameter name appears in **Parameter list** and in **Method signature** at the bottom of the wizard.

If you supply a parameter name and then click **Finish** before you click **Add**, the parameter is not added to the method. You

must find the method and insert the parameter manually.

Add

Adds the parameter you specify in **Parameter name**, and its modifier and type, to the **Parameter list** and displays the complete parameter in the **Method signature** box at the bottom of the wizard. You must click **Add** to add a parameter to the list.

Remove

Removes the parameter you select in **Parameter list** from the list and from the **Method signature** box at the bottom of the wizard.

Parameter list

Displays all parameters and their modifiers and types currently added for the method. As you add parameters, the wizard updates the **Parameter list** to display each parameter, with its modifier and type.

Method modifiers

Modifies the declarations of types and type members. By default, no modifiers are included. Using this wizard, you can add the following modifiers.

Modifier option	Description
Static	The method belongs to the type itself rather than to a specific object.
Abstract	The method is a member of an abstract class. If the class to which you are adding the method is n ot abstract, this option is not available. See C# Class Wizard for more information.
Virtual	The method's implementation can be changed by an overriding member in a derived class.
Extern	Advanced. The method is implemented externally.
Override	Advanced. Provide a new implementation of a virtual member inherited from a base class.
New	Advanced. Explicitly hides a member inherited from a base class. To hide an inherited member, de clare it in the derived class using the same name, and modify it with the new modifier.

You can combine certain modifiers; however, some modifiers are mutually exclusive. For example, you can set your modifiers to **new virtual**, **extern static** or **override abstract**.

The following combinations of options are not allowed:

Modifier	Cannot combine with ...
static	**virtual**, **abstract**, and **override**
virtual	**static**, **abstract**, and **override**
override	**new**, **static**, and **virtual**
abstract	**virtual** and **static**
new	**override**
extern	**abstract**

Depending on your modifier selection, check boxes appear dimmed for excluded combinations.

Comment

Provides a short description to the method. Comments are converted into XML documentation and encapsulated by <summary> tags, which are used to provide the descriptions.

Method signature

Displays the method as it is added to your code when you click **Finish**. You cannot edit the text in this box. To change the method, change the appropriate fields in the wizard.

Types Reference Tables | Visual C# Code Wizards | Adding a Method to C# Class

Adding a Property to a C# Class

You can add a property to a C# class using a code wizard in Class View only. Adding a property using the C# Property Wizard adds a property stub body to the class's .cs file, which you can then edit.

To add a property to a C# class

1. In Class View, right-click the class name.

   If necessary, expand the nodes that expose the class where you want to add the property.

2. On the shortcut menu, click **Add**.
3. On the submenu, click **Add Property**, and the C# Property Wizard appears. For details, see C# Property Wizard.

See Also

Visual C# Code Wizards | Properties | Visual C# Samples

C# Property Wizard

Properties are named members of classes, structs, and interfaces. They provide a flexible mechanism to read, write, or compute the values of private fields through accessors.

Add a property and define its elements using the one-page C# Property Wizard.

Property access

Specifies the access other classes have to the property. Access modifiers are keywords for setting access to the property. The property access level is set to **public** by default. The following access levels are available:

- public
- protected
- private
- internal
- **protected internal**

See Accessibility Levels for an overview of these five levels and for more information about specifying access.

Property type

Sets the value type for the property. The property type is set to **int** by default. For more information about C# property types, see Value Types and Built-in Types Table.

The following value types are available:

- bool
- byte
- char
- decimal
- double
- float
- int
- long
- object
- sbyte
- short
- string
- uint
- ulong
- ushort

Property name

Sets the name of the property to add to the class.

Accessors

Sets the property accessor to **get**, **set**, or to both. The option for **Accessors** is set to **get/set** by default. See Accessors for more information about the accessors and their executable statements.

Accessor options	Description
get	Reads or computes the property and returns a value of the property and its type. If you choose this option, your property is read-only.
set	When you assign a value to the property, you invoke the set accessor with an argument that provides the new value. If you choose this option, your property is write-only. You cannot reference a write-only property except as a target of an assignment.
get/set	When you choose this option, your property contains both a get and a set accessor. It is a read-write property.

Property modifiers

Modifies the declarations of types and type members. Using this wizard, you can add one of the modifiers listed below. The static, virtual, and abstract modifiers are mutually exclusive.

Modifier options	Description
None	No additional modifiers are included in the property declaration.

Static	The property belongs to the type itself rather than to a specific object.
Virtual	The property's implementation can be changed by an overriding property in a derived class.
Abstract	The property is a member of an abstract class. If the class to which you are adding the property is not abstract, this option is not available. See C# Class Wizard for more information.

Comment

Comments are converted into XML documentation and encapsulated by <summary> tags, which are used to provide short descriptions.

Adding a Field to a C# Class

You can add a field to a C# class using a code wizard in Class View only.

To add a field to a C# class

1. In Class View, right-click the class name.

   If necessary, expand the nodes that expose the class where you want to add the field.

2. From the shortcut menu, click **Add**.
3. From the submenu, click **Add Field**. The C# Field Wizard appears. For details, see C# Field Wizard.

See Also

Visual C# Code Wizards | Visual C# Samples

C# Field Wizard

Add a field and define its elements using the one-page C# Field Wizard.

Field access

Access modifiers are keywords for setting access to the field. Specify the access other classes have to the field. The field access level is set to **public** by default. The following access levels are available:

- public
- protected
- private
- internal
- **protected internal**

See Accessibility Levels for an overview of these five levels and for more information about specifying access.

Field type

Either provide a value type or select a value type from the list. The field type is set to **int** by default. For more information about C# field types, see Value Types and Built-in Types Table.

The following value types are available:

- bool
- byte
- char
- decimal
- double
- float
- int
- long
- object
- sbyte
- short
- string
- uint
- ulong
- ushort

Field name

Provide the name of the field to add to the class.

Field modifiers

Modify the declarations of types and type members. Using this wizard, you can add one of the following modifiers. These modifiers are mutually exclusive.

Modifier option	Description
None	No additional modifiers are included in the field declaration.
Static	The field belongs to the type itself rather than to a specific object.
Constant	The field has a constant value and is declared as a const. It requires an initial value.

Field value

If you select **Constant** as a field modifier, you must assign a value to the field. If you do not select **Constant** as a field modifier, this box appears dimmed, and the field has no initial value.

Comment

Comments are converted into XML documentation and encapsulated by <summary> tags, which are used to provide short descriptions.

Adding an Indexer to a C# Class

You can add an indexer to a C# class using a code wizard in Class View only.

To add an indexer to a C# class

1. In Class View, right-click the class name.

   If necessary, expand the nodes to expose the class where you want to add the indexer.

2. On the shortcut menu, click **Add**.
3. On the submenu, click **Add Indexer**. The C# Indexer Wizard appears. For details, see C# Indexer Wizard.

See Also

Visual C# Code Wizards | Indexers | Visual C# Samples

C# Indexer Wizard

Add an indexer and define its elements using the one-page C# Indexer Wizard.

Indexer access

Access modifiers are keywords for setting access to the indexer. Specify the access other classes have to the indexer. The indexer access level is set to **public** by default.

The following access levels are available:

- public
- protected
- private
- internal
- **protected internal**

See Accessibility Levels for an overview of these five levels and for more information about specifying access.

Indexer type

From the list, select the value type for the indexer. The indexer type is set to **int** by default. For more information about C# indexer types, see Value Types and Built-in Types Table. The following value types are available:

- bool
- byte
- char
- decimal
- double
- float
- int
- long
- object
- sbyte
- short
- string
- uint
- ulong
- ushort

Parameter type

From the list, select the type for the **Parameter name**. The parameter type is set to **int** by default. The same values available for the indexer type are available for the parameter type.

Parameter name

Sets the name of a parameter for the interface indexer. After typing the name, you must click **Add** to add it to the list of parameters.

You must provide at least one parameter name for the interface indexer.

The parameters **out** and **ref** are not allowed.

Once you click **Add**, the parameter name is displayed in **Parameter list**.

If you supply a parameter name and then click **Finish** before you click **Add**, the parameter is not added to the indexer. You must find the interface indexer in your code and insert the parameter manually.

Add

Adds the parameter you specify in **Parameter name**, and its type, to the **Parameter list**. You must click **Add** to add a parameter to the list.

Remove

Removes the parameter you select in **Parameter list** from the list.

Parameter list

Displays all parameters and their types currently added for the indexer. As you add parameters, the wizard updates the **Parameter list** to display each parameter, with its type.

Indexer modifiers

Modify the declarations of types and type members. Using this wizard, you can add one of the following modifiers. These modifiers are mutually exclusive.

Modifier option	Description
None	No additional modifiers are included in the indexer declaration.
Virtual	The indexer's implementation can be changed by an overriding indexer in a derived class.
Abstract	The indexer is a member of an abstract class. If the class to which you are adding the indexer is n ot abstract, this option is not available. See C# Class Wizard for more information.

Comment

Comments are converted into XML documentation and encapsulated by <summary> tags, which are used to provide short descriptions.

Adding a Method to a C# Interface

In order to add a method to an interface from Class View, you must have already declared the interface in the Text Editor, so that it appears in the Class View window. For more information, see 13.1 Interface declarations.

You can use the C# Interface Method Wizard, which is only accessible in Class View, to add a new method to your interface.

To add a method to a C# interface

1. In Class View, select the interface.

   If necessary, expand the nodes that expose the interface where you want to add the method.

2. In Class View, right-click the interface name, and then select the **Add** menu item.

   -or-

   Open the **Project** menu.

3. Select the **Add Method** command to display the C# Interface Method Wizard.

See Also

Visual C# Code Wizards | Visual C# Samples

C# Interface Method Wizard

Add a method to an interface and define its elements using the one-page C# Interface Method Wizard.

Return type

Sets the value type that the interface method returns in the return statement. The return type is set to **void** by default. For more information about C# return types, see Value Types and Built-in Types Table.

The following value types are available:

- bool
- byte
- char
- decimal
- double
- float
- int
- long
- object
- sbyte
- short
- string
- uint
- ulong
- ushort
- **void**

Method name

Sets the name of the interface method to add to the class. You must add at least the method name.

Modifier

Sets the parameter's modifier. **Modifier** is set to **None** by default. See Method Parameters for more information.

- **None**
- ref
- out

Parameter type

Sets the type for the **Parameter name**. The parameter type is set to **int** by default. The type is reflected in the **Method signature** box at the bottom of the wizard. The same values available for the return type are available for the parameter type, with the exception of **void**.

Parameter name

Sets the name of a parameter to pass through your interface method. After typing the name, you must click **Add** to add it to the list of parameters that will pass through your interface method.

If you do not provide a parameter name, the wizard ignores any **Parameter type** selections.

Once you click **Add**, the parameter name appears in **Parameter list** and in **Method signature** at the bottom of the wizard.

If you supply a parameter name and then click **Finish** before you click **Add**, the parameter is not added to the interface method. You must find the interface method and insert the parameter manually.

Add

Adds the parameter you specify in **Parameter name**, its modifier, and its type to the **Parameter list** and displays the complete parameter in the **Method signature** box at the bottom of the wizard. You must click **Add** to add a parameter to the list.

Remove

Removes the parameter you select in **Parameter list** from the list and from the **Method signature** box at the bottom of the wizard.

Parameter list

Displays all parameters, their modifiers, and their types currently added for the method. As you add parameters, the wizard updates the **Parameter list** to display each parameter, with its modifier and type.

Comment

Provides a short description to the interface method. Comments are converted into XML documentation and encapsulated by <summary> tags, which are used to provide the descriptions.

Method signature

Displays the interface method as it is added to your code when you click **Finish**. You cannot edit the text in this box. To change the interface method, change the appropriate fields in the wizard.

C# Interface Property Wizard

Properties are named members of classes, structs, and interfaces. They provide a flexible mechanism to read, write, or compute the values of private fields through the **get** and **set** modifiers.

Add an interface property and define its elements using the one-page C# Interface Property Wizard.

Property type

Sets the value type for the property. The property type is set to **int** by default. For more information about C# property types, see Value Types and Built-in Types Table.

The following value types are available:

- bool
- byte
- char
- decimal
- double
- float
- int
- long
- object
- sbyte
- short
- string
- uint
- ulong
- ushort

Property name

Sets the name of the property to add to the interface.

Accessors

Sets the property to **get**, **set**, or **get/set**. The option for **Accessors** is set to **get/set** by default.

Modifier options	Description
get	Reads or computes the property and returns a value of the property and its type. If you choose this option, your property is read-only.
set	When you assign a value to the property, you invoke the **set** modifier with an argument that provides the new value. If you choose this option, your property is write-only. You cannot reference a write-only property except as a target of an assignment.
get/set	The property contains both a **get** and a **set** modifier. It is a read-write property.

Comment

Inserts a comment into the project immediately above the interface property.

Adding an Indexer to a C# Interface

In order to add an indexer to an interface from Class View, you must have already declared the interface in the Text Editor, so that it appears in the Class View window. For more information, see 13.1 Interface declarations.

You can use the C# Interface Indexer Wizard, which is only accessible in Class View, to add a new indexer to your interface.

To add an indexer to a C# interface

1. In Class View, select the interface.

   If necessary, expand the nodes that expose the interface where you want to add the indexer.

2. In Class View, right-click the interface name, and then select the **Add** menu item.

   -or-

   Open the **Project** menu.

3. Select the **Add Indexer** command to display the C# Interface Indexer Wizard.

See Also

Visual C# Code Wizards | Indexers | Visual C# Samples

C# Interface Indexer Wizard

Add an indexer to an interface and define its elements using the one-page C# Interface Indexer Wizard.

Indexer type

Sets the value type for the indexer. The indexer type is set to **int** by default. For more information about C# indexer types, see Value Types and Built-in Types Table.

The following value types are available:

- bool
- byte
- char
- decimal
- double
- float
- int
- long
- object
- sbyte
- short
- string
- uint
- ulong
- ushort

Parameter type

From the list, select the type for the **Parameter name**. The parameter type is set to **int** by default. The same values available for the indexer type are available for the parameter type.

Parameter name

Sets the name of a parameter for the interface indexer. After typing the name, you must click **Add** to add it to the list of parameters.

You must provide at least one parameter name for the interface indexer.

The parameters **out** and **ref** are not allowed.

Once you click **Add**, the parameter name is displayed in **Parameter list**.

If you supply a parameter name and then click **Finish** before you click **Add**, the parameter is not added to the indexer. You must find the interface indexer in your code and insert the parameter manually.

Add

Adds the parameter that you specify in **Parameter name** and its type to the **Parameter list**. You must click **Add** to add a parameter to the list.

Remove

Removes the parameter you select in **Parameter list** from the list.

Parameter list

Displays all parameters and their types currently added for the interface indexer. As you add parameters, the wizard updates the **Parameter list** to display each parameter with its type.

Comment

Comments are converted into XML documentation and encapsulated by <summary> tags, which are used to provide short descriptions.

C# Language Specification

Abstract

This document describes the syntax, semantics, and design of the C# programming language.

Authors

Scott Wiltamuth and Anders Hejlsberg

1. Introduction

C# (pronounced "C sharp") is a simple, modern, object-oriented, and type-safe programming language. It will immediately be familiar to C and C++ programmers. C# combines the high productivity of Rapid Application Development (RAD) languages and the raw power of C++.

Visual C# .NET is Microsoft's C# development tool. It includes an interactive development environment, visual designers for building Windows and Web applications, a compiler, and a debugger. Visual C# .NET is part of a suite of products, called Visual Studio .NET, that also includes Visual Basic .NET, Visual C++ .NET, and the JScript scripting language. All of these languages provide access to the Microsoft .NET Framework, which includes a common execution engine and a rich class library. The .NET Framework defines a "Common Language Specification" (CLS), a sort of lingua franca that ensures seamless interoperability between CLS-compliant languages and class libraries. For C# developers, this means that even though C# is a new language, it has complete access to the same rich class libraries that are used by seasoned tools such as Visual Basic .NET and Visual C++ .NET. C# itself does not include a class library.

The rest of this chapter describes the essential features of the language. While later chapters describe rules and exceptions in a detail-oriented and sometimes mathematical manner, this chapter strives for clarity and brevity at the expense of completeness. The intent is to provide the reader with an introduction to the language that will facilitate the writing of early programs and the reading of later chapters.

1.1 Getting started

The canonical "hello, world" program can be written as follows:

```
using System;
class Hello
{
   static void Main() {
      Console.WriteLine("hello, world");
   }
}
```

The source code for a C# program is typically stored in one or more text files with a file extension of `.cs`, as in `hello.cs`. Using the command-line compiler provided with Visual Studio .NET, such a program can be compiled with the command-line directive

```
csc hello.cs
```

which produces an application named `hello.exe`. The output produced by this application when it is run is:

```
hello, world
```

Close examination of this program is illuminating:

- The `using System;` directive references a namespace called `System` that is provided by the Microsoft .NET Framework class library. This namespace contains the `Console` class referred to in the `Main` method. Namespaces provide a hierarchical means of organizing the elements of one or more programs. A "using" directive enables unqualified use of the types that are members of the namespace. The "hello, world" program uses `Console.WriteLine` as shorthand for `System.Console.WriteLine`.
- The `Main` method is a member of the class `Hello`. It has the `static` modifier, and so it is a method on the class `Hello` rather than on instances of this class.
- The entry point for an application — the method that is called to begin execution — is always a static method named `Main`.
- The "hello, world" output is produced using a class library. The language does not itself provide a class library. Instead, it uses a class library that is also used by Visual Basic .NET and Visual C++ .NET.

For C and C++ developers, it is interesting to note a few things that do *not* appear in the "hello, world" program.

- The program does not use a global method for `Main`. Methods and variables are not supported at the global level; such elements are always contained within type declarations (e.g., class and struct declarations).
- The program does not use either "`::`" or "`->`" operators. The "`::`" is not an operator at all, and the "`->`" operator is used in only a small fraction of programs — those that employ unsafe code (Section A). The separator "`.`" is used in compound names such as `Console.WriteLine`.
- The program does not contain forward declarations. Forward declarations are never needed, as declaration order is not significant.
- The program does not use `#include` to import program text. Dependencies among programs are handled symbolically rather than textually. This approach eliminates barriers between applications written using multiple languages. For example, the `Console` class need not be written in C#.

1.2 Types

C# supports two kinds of types: value types and reference types. Value types include simple types (e.g., `char`, `int`, and `float`), enum types, and struct types. Reference types include class types, interface types, delegate types, and array types.

Value types differ from reference types in that variables of the value types directly contain their data, whereas variables of the reference types store references to objects. With reference types, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With value types, the variables each have their own copy of the data, and it is not possible for operations on one to affect the other.

The example

```
using System;
class Class1
{
   public int Value = 0;
}
class Test
{
   static void Main() {
      int val1 = 0;
      int val2 = val1;
      val2 = 123;
      Class1 ref1 = new Class1();
      Class1 ref2 = ref1;
      ref2.Value = 123;
      Console.WriteLine("Values: {0}, {1}", val1, val2);
      Console.WriteLine("Refs: {0}, {1}", ref1.Value, ref2.Value);
   }
}
```

shows this difference. The output produced is

```
Values: 0, 123
Refs: 123, 123
```

The assignment to the local variable `val1` does not impact the local variable `val2` because both local variables are of a value type (the type `int`) and each local variable of a value type has its own storage. In contrast, the assignment `ref2.Value = 123;` affects the object that both `ref1` and `ref2` reference.

The lines

```
Console.WriteLine("Values: {0}, {1}", val1, val2);
Console.WriteLine("Refs: {0}, {1}", ref1.Value, ref2.Value);
```

deserve further comment, as they demonstrate some of the string formatting behavior of `Console.WriteLine`, which, in fact, takes a variable number of arguments. The first argument is a string, which may contain numbered placeholders like `{0}` and `{1}`. Each placeholder refers to a trailing argument with `{0}` referring to the second argument, `{1}` referring to the third argument, and so on. Before the output is sent to the console, each placeholder is replaced with the formatted value of its corresponding argument.

Developers can define new value types through enum and struct declarations, and can define new reference types via class, interface, and delegate declarations. The example

```
using System;
public enum Color
{
   Red, Blue, Green
}
public struct Point
{
   public int x, y;
}
public interface IBase
```

```
{
   void F();
}
public interface IDerived: IBase
{
   void G();
}
public class A
{
   protected virtual void H() {
      Console.WriteLine("A.H");
   }
}
public class B: A, IDerived
{
   public void F() {
      Console.WriteLine("B.F, implementation of IDerived.F");
   }
   public void G() {
      Console.WriteLine("B.G, implementation of IDerived.G");
   }
   override protected void H() {
      Console.WriteLine("B.H, override of A.H");
   }
}
public delegate void EmptyDelegate();
```

shows an example of each kind of type declaration. Later sections describe type declarations in detail.

1.2.1 Predefined types

C# provides a set of predefined types, most of which will be familiar to C and C++ developers.

The predefined reference types are `object` and `string`. The type `object` is the ultimate base type of all other types. The type `string` is used to represent Unicode string values. Values of type `string` are immutable.

The predefined value types include signed and unsigned integral types, floating point types, and the types `bool`, `char`, and `decimal`. The signed integral types are `sbyte`, `short`, `int`, and `long`; the unsigned integral types are `byte`, `ushort`, `uint`, and `ulong`; and the floating point types are `float` and `double`.

The `bool` type is used to represent Boolean values: values that are either true or false. The inclusion of `bool` makes it easier to write self-documenting code, and also helps eliminate the all-too-common C++ coding error in which a developer mistakenly uses "`=`" when "`==`" should have been used. In C#, the example

```
int i = ...;
F(i);
if (i = 0)   // Bug: the test should be (i == 0)
   G();
```

results in a compile-time error because the expression `i = 0` is of type `int`, and `if` statements require an expression of type `bool`.

The `char` type is used to represent Unicode characters. A variable of type `char` represents a single 16-bit Unicode character.

The `decimal` type is appropriate for calculations in which rounding errors caused by floating point representations are unacceptable. Common examples include financial calculations such as tax computations and currency conversions. The `decimal` type provides 28 significant digits.

The table below lists the predefined types, and shows how to write literal values for each of them.

Type	Description	Example
`object`	The ultimate base type of all other types	`object o = null;`
`string`	String type; a string is a sequence of Unicode characters	`string s = "hello";`
`sbyte`	8-bit signed integral type	`sbyte val = 12;`
`short`	16-bit signed integral type	`short val = 12;`
`int`	32-bit signed integral type	`int val = 12;`
`long`	64-bit signed integral type	`long val1 = 12;` `long val2 = 34L;`
`byte`	8-bit unsigned integral type	`byte val1 = 12;`
`ushort`	16-bit unsigned integral type	`ushort val1 = 12;`
`uint`	32-bit unsigned integral type	`uint val1 = 12;` `uint val2 = 34U;`

`ulong`	64-bit unsigned integral type	`ulong val1 = 12;`
		`ulong val2 = 34U;`
		`ulong val3 = 56L;`
		`ulong val4 = 78UL;`

`float`	Single-precision floating point type	`float val = 1.23F;`
`double`	Double-precision floating point type	`double val1 = 1.23;` `double val2 = 4.56D;`
`bool`	Boolean type; a `bool` value is either true or false	`bool val1 = true;` `bool val2 = false;`
`char`	Character type; a `char` value is a Unicode character	`char val = 'h';`
`decimal`	Precise decimal type with 28 significant digits	`decimal val = 1.23M;`

Each of the predefined types is shorthand for a system-provided type. For example, the keyword `int` refers to the struct `System.Int32`. As a matter of style, use of the keyword is favored over use of the complete system type name.

Predefined value types such as `int` are treated specially in a few ways but are for the most part treated exactly like other structs. Operator overloading enables developers to define new struct types that behave much like the predefined value types. For instance, a `Digit` struct can support the same mathematical operations as the predefined integral types, and can define conversions between `Digit` and predefined types.

The predefined types employ operator overloading themselves. For example, the comparison operators `==` and `!=` have different semantics for different predefined types:

- Two expressions of type `int` are considered equal if they represent the same integer value.
- Two expressions of type `object` are considered equal if both refer to the same object, or if both are `null`.
- Two expressions of type `string` are considered equal if the string instances have identical lengths and identical characters in each character position, or if both are `null`.

The example

```
using System;
class Test
{
   static void Main() {
      string s = "Test";
      string t = string.Copy(s);
      Console.WriteLine(s == t);
      Console.WriteLine((object)s == (object)t);
   }
}
```

produces the output

```
True
False
```

because the first comparison compares two expressions of type `string`, and the second comparison compares two expressions of type `object`.

1.2.2 Conversions

The predefined types also have predefined conversions. For instance, conversions exist between the predefined types `int` and `long`. C# differentiates between two kinds of conversions: implicit conversions and explicit conversions. Implicit conversions are supplied for conversions that can safely be performed without careful scrutiny. For instance, the conversion from `int` to `long` is an implicit conversion. This conversion always succeeds, and never results in a loss of information. The following example

```
using System;
class Test
{
   static void Main() {
      int intValue = 123;
      long longValue = intValue;
      Console.WriteLine("{0}, {1}", intValue, longValue);
   }
}
```

implicitly converts an `int` to a `long`.

In contrast, explicit conversions are performed with a cast expression. The example

```
using System;
class Test
{
   static void Main() {
      long longValue = Int64.MaxValue;
      int intValue = (int) longValue;
      Console.WriteLine("(int){0} = {1}", longValue, intValue);
   }
}
```

uses an explicit conversion to convert a `long` to an `int`. The output is:

```
(int) 9223372036854775807 = -1
```

because an overflow occurs. Cast expressions permit the use of both implicit and explicit conversions.

1.2.3 Array types

Arrays may be single-dimensional or multi-dimensional. Both "rectangular" and "jagged" arrays are supported.

Single-dimensional arrays are the most common type. The example

```
using System;
class Test
{
   static void Main() {
      int[] arr = new int[5];
      for (int i = 0; i < arr.Length; i++)
         arr[i] = i * i;
      for (int i = 0; i < arr.Length; i++)
         Console.WriteLine("arr[{0}] = {1}", i, arr[i]);
   }
}
```

creates a single-dimensional array of `int` values, initializes the array elements, and then prints each of them out. The output produced is:

```
arr[0] = 0
arr[1] = 1
arr[2] = 4
arr[3] = 9
arr[4] = 16
```

The type `int[]` used in the previous example is an array type. Array types are written using a non-*array-type* followed by one or more rank specifiers. The example

```
class Test
{
   static void Main() {
      int[] a1;         // single-dimensional array of int
      int[,] a2;         // 2-dimensional array of int
      int[,,] a3;         // 3-dimensional array of int
      int[][] j2;         // "jagged" array: array of (array of int)
      int[][][] j3;      // array of (array of (array of int))
   }
}
```

shows a variety of local variable declarations that use array types with `int` as the element type.

Array types are reference types, and so the declaration of an array variable merely sets aside space for the reference to the array. Array instances are actually created via array initializers and array creation expressions. The example

```
class Test
{
   static void Main() {
      int[] a1 = new int[] {1, 2, 3};
      int[,] a2 = new int[,] {{1, 2, 3}, {4, 5, 6}};
      int[,,] a3 = new int[10, 20, 30];
      int[][] j2 = new int[3][];
      j2[0] = new int[] {1, 2, 3};
      j2[1] = new int[] {1, 2, 3, 4, 5, 6};
      j2[2] = new int[] {1, 2, 3, 4, 5, 6, 7, 8, 9};
   }
}
```

shows a variety of array creation expressions. The variables `a1`, `a2` and `a3` denote rectangular arrays, and the variable `j2` denotes a jagged array. It should be no surprise that these terms are based on the shapes of the arrays. Rectangular arrays always have a rectangular shape. Given the length of each dimension of the array, its rectangular shape is clear. For example, the lengths of `a3`'s

three dimensions are 10, 20, and 30 respectively, and it is easy to see that this array contains `10*20*30` elements.

In contrast, the variable `j2` denotes a "jagged" array, or an "array of arrays". Specifically, `j2` denotes an array of an array of `int`, or a single-dimensional array of type `int[]`. Each of these `int[]` variables can be initialized individually, and this allows the array to take on a jagged shape. The example gives each of the `int[]` arrays a different length. Specifically, the length of `j2[0]` is `3`, the length of `j2[1]` is `6`, and the length of `j2[2]` is `9`.

In C++, an array declared as `int x[3][5][7]` would be considered a three-dimensional rectangular array, while in C#, the declaration `int[][][]` declares a jagged array type.

The element type and shape of an array — including whether it is jagged or rectangular, and the number of dimensions it has — are part of its type. On the other hand, the size of the array — as represented by the length of each of its dimensions — is not part of an array's type. This split is made clear in the language syntax, as the length of each dimension is specified in the array creation expression rather than in the array type. For instance the declaration

```
int[,,] a3 = new int[10, 20, 30];
```

has an array type of `int[,,]` and an array creation expression of `new int[10, 20, 30]`.

For local variable and field declarations, a shorthand form is permitted so that it is not necessary to re-state the array type. For instance, the example

```
int[] a1 = new int[] {1, 2, 3};
```

can be shortened to

```
int[] a1 = {1, 2, 3};
```

without any change in program semantics.

The context in which an array initializer such as `{1, 2, 3}` is used determines the type of the array being initialized. The example

```
class Test
{
   static void Main() {
      short[] a = {1, 2, 3};
      int[]   b = {1, 2, 3};
      long[] c = {1, 2, 3};
   }
}
```

shows that the same array initializer syntax can be used for several different array types. Because context is required to determine the type of an array initializer, it is not possible to use an array initializer in an expression context without explicitly stating the type of the array.

1.2.4 Type system unification

C# provides a "unified type system". All types — including value types — derive from the type `object`. It is possible to call object methods on any value, even values of "primitive" types such as `int`. The example

```
using System;
class Test
{
   static void Main() {
      Console.WriteLine(3.ToString());
   }
}
```

calls the `object`-defined `ToString` method on an integer literal, resulting in the output "`3`".

The example

```
class Test
{
   static void Main() {
      int i = 123;
      object o = i;      // boxing
      int j = (int) o;   // unboxing
   }
}
```

is more interesting. An `int` value can be converted to `object` and back again to `int`. This example shows both boxing and unboxing. When a variable of a value type needs to be converted to a reference type, an object box is allocated to hold the value, and the value is copied into the box. Unboxing is just the opposite. When an object box is cast back to its original value type, the value is copied out of the box and into the appropriate storage location.

This type system unification provides value types with the benefits of object-ness without introducing unnecessary overhead. For programs that don't need `int` values to act like objects, `int` values are simply 32-bit values. For programs that need `int` values to behave like objects, this capability is available on demand. This ability to treat value types as objects bridges the gap between value types and reference types that exists in most languages. For example, a `Stack` class can provide `Push` and `Pop` methods that take and return `object` values.

```
public class Stack
{
   public object Pop() {...}
   public void Push(object o) {...}
}
```

Because C# has a unified type system, the `Stack` class can be used with elements of any type, including value types like `int`.

1.3 Variables and parameters

Variables represent storage locations. Every variable has a type that determines what values can be stored in the variable. Local variables are variables that are declared in methods, properties, or indexers. A local variable is defined by specifying a type name and a declarator that specifies the variable name and an optional initial value, as in:

```
int a;
int b = 1;
```

but it is also possible for a local variable declaration to include multiple declarators. The declarations of `a` and `b` can be rewritten as:

```
int a, b = 1;
```

A variable must be assigned before its value can be obtained. The example

```
class Test
{
   static void Main() {
      int a;
      int b = 1;
      int c = a + b;   // error, a not yet assigned
      ...
   }
}
```

results in a compile-time error because it attempts to use the variable `a` before it is assigned a value. The rules governing definite assignment are defined in Section 5.3.

A field (Section 10.4) is a variable that is associated with a class or struct, or with an instance of a class or struct. A field declared with the `static` modifier defines a static variable, and a field declared without this modifier defines an instance variable. A static field is associated with a type, whereas an instance variable is associated with an instance. The example

```
using Personnel.Data;
class Employee
{
   private static DataSet ds;
   public string Name;
   public decimal Salary;
   ...
}
```

shows an `Employee` class that has a private static variable and two public instance variables.

Formal parameter declarations also define variables. There are four kinds of parameters: value parameters, reference parameters, output parameters, and parameter arrays.

A value parameter is used for "in" parameter passing, in which the value of an argument is passed into a method, and modifications of the parameter do not impact the original argument. A value parameter refers to its own variable, one that is distinct from the corresponding argument. This variable is initialized by copying the value of the corresponding argument. The example

```
using System;
class Test {
   static void F(int p) {
      Console.WriteLine("p = {0}", p);
      p++;
   }
   static void Main() {
      int a = 1;
      Console.WriteLine("pre:  a = {0}", a);
      F(a);
```

```
      Console.WriteLine("post: a = {0}", a);
   }
}
```

shows a method `F` that has a value parameter named `p`. The example produces the output

```
pre:  a = 1
p = 1
post: a = 1
```

even though the value parameter `p` is modified.

A reference parameter is used for "by reference" parameter passing, in which the parameter acts as an alias for a caller-provided argument. A reference parameter does not itself define a variable, but rather refers to the variable of the corresponding argument. Modifications of a reference parameter impact the corresponding argument. A reference parameter is declared with a `ref` modifier. The example

```
using System;
class Test {
   static void Swap(ref int a, ref int b) {
      int t = a;
      a = b;
      b = t;
   }
   static void Main() {
      int x = 1;
      int y = 2;

      Console.WriteLine("pre:  x = {0}, y = {1}", x, y);
      Swap(ref x, ref y);
      Console.WriteLine("post: x = {0}, y = {1}", x, y);
   }
}
```

shows a `Swap` method that has two reference parameters. The output produced is:

```
pre:  x = 1, y = 2
post: x = 2, y = 1
```

The `ref` keyword must be used in both the declaration of the formal parameter and in uses of it. The use of `ref` at the call site calls special attention to the parameter so that a developer reading the code will understand that the value of the argument could change as a result of the call.

An output parameter is similar to a reference parameter, except that the initial value of the caller-provided argument is unimportant. An output parameter is declared with an `out` modifier. The example

```
using System;
class Test {
   static void Divide(int a, int b, out int result, out int remainder) {
      result = a / b;
      remainder = a % b;
   }
   static void Main() {
      for (int i = 1; i < 10; i++)
         for (int j = 1; j < 10; j++) {
            int ans, r;
            Divide(i, j, out ans, out r);
            Console.WriteLine("{0} / {1} = {2}r{3}", i, j, ans, r);
         }
   }
}
```

shows a `Divide` method that includes two output parameters — one for the result of the division and another for the remainder.

For value, reference, and output parameters, there is a one-to-one correspondence between caller-provided arguments and the parameters used to represent them. A parameter array enables a many-to-one relationship: many arguments can be represented by a single parameter array. In other words, parameter arrays enable variable length argument lists.

A parameter array is declared with a `params` modifier. There can be only one parameter array for a given method, and it must always be the last parameter specified. The type of a parameter array is always a single dimensional array type. A caller can either pass a single argument of this array type, or any number of arguments of the element type of this array type. For instance, the example

```
using System;
class Test
{
   static void F(params int[] args) {
      Console.WriteLine("# of arguments: {0}", args.Length);
      for (int i = 0; i < args.Length; i++)
         Console.WriteLine("\targs[{0}] = {1}", i, args[i]);
   }
   static void Main() {
      F();
      F(1);
      F(1, 2);
      F(1, 2, 3);
      F(new int[] {1, 2, 3, 4});
   }
}
```

shows a method `F` that takes a variable number of `int` arguments, and several invocations of this method. The output is:

```
# of arguments: 0
# of arguments: 1
   args[0] = 1
# of arguments: 2
   args[0] = 1
   args[1] = 2
# of arguments: 3
   args[0] = 1
   args[1] = 2
   args[2] = 3
# of arguments: 4
   args[0] = 1
   args[1] = 2
   args[2] = 3
   args[3] = 4
```

Most of the examples presented in this introduction use the `WriteLine` method of the `Console` class. The argument substitution behavior of this method, as exhibited in the example

```
int a = 1, b = 2;
Console.WriteLine("a = {0}, b = {1}", a, b);
```

is accomplished using a parameter array. The `WriteLine` method provides several overloaded methods for the common cases in which a small number of arguments are passed, and one method that uses a parameter array.

```
namespace System
{
   public class Console
   {
      public static void WriteLine(string s) {...}
      public static void WriteLine(string s, object a) {...}
      public static void WriteLine(string s, object a, object b) {...}
      ...
      public static void WriteLine(string s, params object[] args) {...}
   }
}
```

1.4 Automatic memory management

Manual memory management requires developers to manage the allocation and de-allocation of blocks of memory. Manual memory management can be both time-consuming and difficult. In C#, automatic memory management is provided so that developers are freed from this burdensome task. In the vast majority of cases, automatic memory management increases code quality and enhances developer productivity without negatively impacting either expressiveness or performance.

The example

```
using System;
public class Stack
{
   private Node first = null;
   public bool Empty {
      get {
         return (first == null);
      }
   }
   public object Pop() {
      if (first == null)
         throw new Exception("Can't Pop from an empty Stack.");
      else {
         object temp = first.Value;
         first = first.Next;
         return temp;
      }
   }
   public void Push(object o) {
      first = new Node(o, first);
   }
   private class Node
   {
      public Node Next;
      public object Value;
      public Node(object value): this(value, null) {}
      public Node(object value, Node next) {
         Next = next;
         Value = value;
      }
   }
}
```

shows a `Stack` class implemented as a linked list of `Node` instances. Node instances are created in the `Push` method and are garbage collected when no longer needed. A `Node` instance becomes eligible for garbage collection when it is no longer possible for any code to access it. For instance, when an item is removed from the `Stack`, the associated `Node` instance becomes eligible for garbage collection.

The example

```
class Test
{
   static void Main() {
      Stack s = new Stack();
      for (int i = 0; i < 10; i++)
         s.Push(i);
      s = null;
   }
}
```

shows code that uses the `Stack` class. A `Stack` is created and initialized with 10 elements, and then assigned the value `null`. Once the variable `s` is assigned null, the `Stack` and the associated 10 `Node` instances become eligible for garbage collection. The garbage collector is permitted to clean up immediately, but is not required to do so.

The garbage collector underlying C# may work by moving objects around in memory, but this motion is invisible to most C# developers. For developers who are generally content with automatic memory management but sometimes need fine-grained

control or that extra bit of performance, C# provides the ability to write "unsafe" code. Such code can deal directly with pointer types and object addresses. However, C# requires the programmer to fix objects to temporarily prevent the garbage collector from moving them.

This "unsafe" code feature is in fact a "safe" feature from the perspective of both developers and users. Unsafe code must be clearly marked in the code with the modifier `unsafe`, so developers can't possibly use unsafe language features accidentally, and the compiler and the execution engine work together to ensure that unsafe code cannot masquerade as safe code. These restrictions limit the use of unsafe code to situations in which the code is trusted.

The example

```
using System;
class Test
{
   static void WriteLocations(byte[] arr) {
      unsafe {
         fixed (byte* pArray = arr) {
            byte* pElem = pArray;
            for (int i = 0; i < arr.Length; i++) {
               byte value = *pElem;
               Console.WriteLine("arr[{0}] at 0x{1:X} is {2}",
                  i, (uint)pElem, value);
               pElem++;
            }
         }
      }
   }
   static void Main() {
      byte[] arr = new byte[] {1, 2, 3, 4, 5};
      WriteLocations(arr);
   }
}
```

shows an unsafe block in a method named `WriteLocations` that fixes an array instance and uses pointer manipulation to iterate over the elements. The index, value, and location of each array element are written to the console. One possible example of output is:

```
arr[0] at 0x8E0360 is 1
arr[1] at 0x8E0361 is 2
arr[2] at 0x8E0362 is 3
arr[3] at 0x8E0363 is 4
arr[4] at 0x8E0364 is 5
```

but of course the exact memory locations may be different in different executions of the application.

1.5 Expressions

C# includes unary operators, binary operators, and one ternary operator. The following table summarizes the operators, listing them in order of precedence from highest to lowest:

Section	Category	Operators
Section 7.5	Primary	`x.y  f(x)  a[x]  x++  x--  new` `typeof  checked  unchecked`
Section 7.6	Unary	`+  -  !  ~  ++x  --x  (T)x`
Section 7.7	Multiplicative	`*  /  %`
Section 7.7	Additive	`+  -`
Section 7.8	Shift	`<<  >>`
Section 7.9	Relational and type testing	`<  >  <=  >=  is  as`
Section 7.9	Equality	`==  !=`
Section 7.10	Logical AND	`&`
Section 7.10	Logical XOR	`^`
Section 7.10	Logical OR	`|`
Section 7.11	Conditional AND	`&&`
Section 7.11	Conditional OR	`||`
Section 7.12	Conditional	`?:`
Section 7.13	Assignment	`=  *=  /=  %=  +=  -=  <<=  >>=  &=  ^=  |=`

When an expression contains multiple operators, the precedence of the operators controls the order in which the individual operators are evaluated. For example, the expression `x + y * z` is evaluated as `x + (y * z)` because the `*` operator has higher precedence than the `+` operator.

When an operand occurs between two operators with the same precedence, the associativity of the operators controls the order in which the operations are performed:

- Except for the assignment operators, all binary operators are left-associative, meaning that operations are performed from left to right. For example, `x + y + z` is evaluated as `(x + y) + z`.

- The assignment operators and the conditional operator (`?:`) are right-associative, meaning that operations are performed from right to left. For example, `x = y = z` is evaluated as `x = (y = z)`.

Precedence and associativity can be controlled using parentheses. For example, `x + y * z` first multiplies `y` by `z` and then adds the result to `x`, but `(x + y) * z` first adds `x` and `y` and then multiplies the result by `z`.

1.6 Statements

C# borrows most of its statements directly from C and C++, though there are some noteworthy additions and modifications. The table below lists the kinds of statements that can be used, and provides an example for each.

Statement	Example

Statement lists and block statements	`static void Main() {`
	`  F();`
	`  G();`
	`  {`
	`  H();`
	`  I();`
	`  }`
	`}`

Labeled statements and `goto` statements	`static void Main(string[] args) {`
	`  if (args.Length == 0)`
	`  goto done;`
	`  Console.WriteLine(args.Length);`
	
	`done:`
	`  Console.WriteLine("Done");`
	`}`

Local constant declarations	`static void Main() {`
	`  const float pi = 3.14f;`
	`  const int r = 123;`
	`  Console.WriteLine(pi * r * r);`
	`}`

Local variable declarations	`static void Main() {`
	`  int a;`
	`  int b = 2, c = 3;`
	`  a = 1;`
	`  Console.WriteLine(a + b + c);`
	`}`

Expression statements	`static int F(int a, int b) {`
	`  return a + b;`
	`}`
	`static void Main() {`
	`  F(1, 2);  // Expression statement`
	`}`

`if` statements	`static void Main(string[] args) {`
	`  if (args.Length == 0)`
	`  Console.WriteLine("No args");`
	`  else`
	`  Console.WriteLine("Args");`
	`}`

`switch` statements	`static void Main(string[] args) {`
	`  switch (args.Length) {`
	`  case 0:`
	`  Console.WriteLine("No args");`
	`  break;`
	`  case 1:`
	`  Console.WriteLine("One arg ");`
	`  break;`
	`  default:`
	`  int n = args.Length;`
	`  Console.WriteLine("{0} args", n);`
	`  break;`
	`  }`
	`}`

`while` statements	`static void Main(string[] args) {`
	`  int i = 0;`
	`  while (i < args.Length) {`
	`  Console.WriteLine(args[i]);`
	`  i++;`
	`  }`
	`}`

`do` statements	`static void Main() {`
	`  string s;`
	`  do { s = Console.ReadLine(); }`
	`  while (s != "Exit");`
	`}`

`for` statements	`static void Main(string[] args) {`
	`  for (int i = 0; i < args.Length; i++)`
	`  Console.WriteLine(args[i]);`
	`}`

`foreach` statements	`static void Main(string[] args) {`
	`  foreach (string s in args)`
	`  Console.WriteLine(s);`
	`}`

`break` statements	`static void Main(string[] args) {`
	`  int i = 0;`
	`  while (true) {`
	`  if (i == args.Length)`
	`  break;`
	`  Console.WriteLine(args[i++]);`
	`  }`
	`}`

`continue` statements	`static void Main(string[] args) {`
	`  int i = 0;`
	`  while (true) {`
	`  Console.WriteLine(args[i++]);`
	`  if (i < args.Length)`
	`  continue;`
	`  break;`
	`  }`
	`}`

`return` statements	`static int F(int a, int b) {`
	`  return a + b;`
	`}`
	`static void Main() {`
	`  Console.WriteLine(F(1, 2));`
	`  return;`
	`}`

`throw` statements and `try` statements	`static int F(int a, int b) {`
	`  if (b == 0)`
	`  throw new Exception("Divide by zero");`
	`  return a / b;`
	`}`
	`static void Main() {`
	`  try {`
	`  Console.WriteLine(F(5, 0));`
	`  }`
	`  catch(Exception e) {`
	`  Console.WriteLine("Error");`
	`  }`
	`}`

`checked` and `unchecked` statements	`static void Main() {`
	`  int x = Int32.MaxValue;`
	
	`  Console.WriteLine(x + 1);  // Overflow`
	
	`  checked {`
	`  Console.WriteLine(x + 1);  // Exception`
	`  }`
	
	`  unchecked {`
	`  Console.WriteLine(x + 1);  // Overflow`
	`  }`
	`}`

`lock` statements	`static void Main() {`
	`  A a = ...;`
	`  lock(a) {`
	`  a.P = a.P + 1;`
	`  }`
	`}`

using statements	`static void Main() {`
	`  using (Resource r = new Resource()) {`
	`  r.F();`
	`  }`
	`}`

1.7 Classes

Class declarations define new reference types. A class can inherit from another class, and can implement interfaces.

Class members can include constants, fields, methods, properties, events, indexers, operators, instance constructors, destructors, static constructors, and nested type declarations. Each member has an associated accessibility (Section 3.5), which controls the regions of program text that are able to access the member. There are five possible forms of accessibility. These are summarized in the table below.

Form	Intuitive meaning
`public`	Access not limited.
`protected`	Access limited to the containing class or types derived from the containing class.
`internal`	Access limited to this program.
`protected internal`	Access limited to this program or types derived from the containing class.
`private`	Access limited to the containing type.

The example

```
using System;
class MyClass
{
   public MyClass() {
      Console.WriteLine("Instance constructor");
   }
   public MyClass(int value) {
      MyField = value;
      Console.WriteLine("Instance constructor");
   }
   ~MyClass() {
      Console.WriteLine("Destructor");
   }
   public const int MyConst = 12;
   public int MyField = 34;
   public void MyMethod(){
      Console.WriteLine("MyClass.MyMethod");
   }
   public int MyProperty {
      get {
         return MyField;
      }
      set {
         MyField = value;
      }
   }
   public int this[int index] {
      get {
         return 0;
      }
      set {
         Console.WriteLine("this[{0}] = {1}", index, value);
      }
   }
   public event EventHandler MyEvent;
```

```
   public static MyClass operator+(MyClass a, MyClass b) {
      return new MyClass(a.MyField + b.MyField);
   }
   internal class MyNestedClass
   {}
}
```

shows a class that contains each kind of member. The example

```
class Test
{
   static void Main() {
      // Instance constructor usage
      MyClass a = new MyClass();
      MyClass b = new MyClass(123);
      // Constant usage
      Console.WriteLine("MyConst = {0}", MyClass.MyConst);
      // Field usage
      a.MyField++;
      Console.WriteLine("a.MyField = {0}", a.MyField);
      // Method usage
      a.MyMethod();
      // Property usage
      a.MyProperty++;
      Console.WriteLine("a.MyProperty = {0}", a.MyProperty);
      // Indexer usage
      a[3] = a[1] = a[2];
      Console.WriteLine("a[3] = {0}", a[3]);
      // Event usage
      a.MyEvent += new EventHandler(MyHandler);
      // Overloaded operator usage
      MyClass c = a + b;
   }
   static void MyHandler(object sender, EventArgs e) {
      Console.WriteLine("Test.MyHandler");
   }
   internal class MyNestedClass
   {}
}
```

shows uses of these members.

1.7.1 Constants

A constant is a class member that represents a constant value: a value that can be computed at compile-time. Constants are permitted to depend on other constants within the same program as long as there are no circular dependencies. The rules governing constant expressions are defined in Section 7.15. The example

```
class Constants
{
   public const int A = 1;
   public const int B = A + 1;
}
```

shows a class named `Constants` that has two public constants.

Even though constants are considered static members, a constant declaration neither requires nor allows the `static` modifier. Constants can be accessed through the class, as in

```
using System;
class Test
{
   static void Main() {
      Console.WriteLine("{0}, {1}", Constants.A, Constants.B);
   }
}
```

which prints out the values of `Constants.A` and `Constants.B`, respectively.

1.7.2 Fields

A field is a member that represents a variable associated with an object or class. The example

```
class Color
{
   public static Color Red = new Color(0xFF, 0, 0);
   public static Color Blue = new Color(0, 0xFF, 0);
   public static Color Green = new Color(0, 0, 0xFF);
   public static Color White = new Color(0xFF, 0xFF, 0xFF);
   internal ushort redPart;
   internal ushort bluePart;
   internal ushort greenPart;
   public Color(ushort red, ushort blue, ushort green) {
      redPart = red;
      bluePart = blue;
      greenPart = green;
   }
}
```

which shows a `Color` class that has internal instance fields named `redPart`, `bluePart`, and `greenPart`, and static fields named `Red`, `Blue`, `Green`, and `White`.

The use of static fields in this manner is not ideal. The fields are initialized at some point before they are used, but after this initialization there is nothing to stop a client from changing them. Such a modification could cause unpredictable errors in other programs that use `Color` and assume that the values do not change. `Readonly` fields can be used to prevent such problems. Assignments to a `readonly` field can only occur as part of the declaration, or in an instance constructor or static constructor in the same class. A static `readonly` field can be assigned in a static constructor, and a non-static `readonly` field can be assigned in an instance constructor. Thus, the `Color` class can be enhanced by adding the `readonly` modifier to the static fields:

```
class Color
{
   public static readonly Color Red = new Color(0xFF, 0, 0);
   public static readonly Color Blue = new Color(0, 0xFF, 0);
   public static readonly Color Green = new Color(0, 0, 0xFF);
   public static readonly Color White = new Color(0xFF, 0xFF, 0xFF);
   internal ushort redPart;
   internal ushort bluePart;
   internal ushort greenPart;
   public Color(ushort red, ushort blue, ushort green) {
      redPart = red;
      bluePart = blue;
      greenPart = green;
   }
}
```

1.7.3 Methods

A method is a member that implements a computation or action that can be performed by an object or class. Methods have a possibly empty list of formal parameters, a return value (unless the method's *return-type* is `void`), and are either static or non-static. Static methods are accessed through the class. Non-static methods, which are also called instance methods, are accessed through instances of the class. The example

```
using System;
public class Stack
{
   public static Stack Clone(Stack s) {...}
   public static Stack Flip(Stack s) {...}
   public object Pop() {...}
   public void Push(object o) {...}
   public override string ToString() {...}
   ...
}
class Test
{
   static void Main() {
      Stack s = new Stack();
      for (int i = 1; i < 10; i++)
         s.Push(i);
      Stack flipped = Stack.Flip(s);
      Stack cloned = Stack.Clone(s);
      Console.WriteLine("Original stack: " + s.ToString());
      Console.WriteLine("Flipped stack: " + flipped.ToString());
      Console.WriteLine("Cloned stack: " + cloned.ToString());
   }
}
```

shows a `Stack` that has several static methods (`Clone` and `Flip`) and several instance methods (`Push`, `Pop`, and `ToString`).

Methods can be overloaded, which means that multiple methods may have the same name so long as they have unique signatures. The signature of a method consists of the name of the method and the number, modifiers, and types of its formal parameters. The signature of a method does not include the return type. The example

```
using System;
class Test
{
   static void F() {
      Console.WriteLine("F()");
   }
   static void F(object o) {
      Console.WriteLine("F(object)");
   }
   static void F(int value) {
      Console.WriteLine("F(int)");
   }
   static void F(ref int value) {
      Console.WriteLine("F(ref int)");
   }
   static void F(int a, int b) {
      Console.WriteLine("F(int, int)");
   }
   static void F(int[] values) {
      Console.WriteLine("F(int[])");
   }
   static void Main() {
      F();
      F(1);
      int i = 10;
      F(ref i);
      F((object)1);
      F(1, 2);
```

```
        F(new int[] {1, 2, 3});
    }
}
```

shows a class with a number of methods called `F`. The output produced is

```
F()
F(int)
F(ref int)
F(object)
F(int, int)
F(int[])
```

1.7.4 Properties

A property is a member that provides access to a characteristic of an object or a class. Examples of properties include the length of a string, the size of a font, the caption of a window, the name of a customer, and so on. Properties are a natural extension of fields. Both are named members with associated types, and the syntax for accessing fields and properties is the same. However, unlike fields, properties do not denote storage locations. Instead, properties have accessors that specify the statements to be executed when their values are read or written.

Properties are defined with property declarations. The first part of a property declaration looks quite similar to a field declaration. The second part includes a get accessor and/or a set accessor. In the example below, the `Button` class defines a `Caption` property.

```
public class Button
{
   private string caption;
   public string Caption {
      get {
         return caption;
      }
      set {
         caption = value;
         Repaint();
      }
   }
}
```

Properties that can be both read and written, such as `Caption`, include both get and set accessors. The get accessor is called when the property's value is read; the set accessor is called when the property's value is written. In a set accessor, the new value for the property is made available via an implicit parameter named `value`.

The declaration of properties is relatively straightforward, but the real value of properties is seen when they are used. For example, the `Caption` property can be read and written in the same way that fields can be read and written:

```
Button b = new Button();
b.Caption = "ABC";      // set; causes repaint
string s = b.Caption;   // get
b.Caption += "DEF";      // get & set; causes repaint
```

1.7.5 Events

An event is a member that enables an object or class to provide notifications. A class defines an event by providing an event declaration (which resembles a field declaration) though with an added `event` keyword, and an optional set of event accessors. The type of this declaration must be a delegate type.

An instance of a delegate type encapsulates one or more callable entities. For instance methods, a callable entity consists of an instance and a method on that instance. For static methods, a callable entity consists of just a method. Invoking a delegate instance with an appropriate set of arguments causes each of the delegate instance's callable entities to be invoked with the given set of arguments. '

In the example

```
public delegate void EventHandler(object sender, System.EventArgs e);
public class Button
{
   public event EventHandler Click;
   public void Reset() {
      Click = null;
   }
}
```

the `Button` class defines a `Click` event of type `EventHandler`. Inside the `Button` class, the `Click` member is exactly like a private field of type `EventHandler`. However, outside the `Button` class, the `Click` member can only be used on the left-hand side of the `+=` and `-=` operators. The `+=` operator adds a handler for the event, and the `-=` operator removes a handler for the event. The example

```
using System;
public class Form1
{
   public Form1() {
      // Add Button1_Click as an event handler for Button1's Click event
      Button1.Click += new EventHandler(Button1_Click);
   }
   Button Button1 = new Button();
   void Button1_Click(object sender, EventArgs e) {
      Console.WriteLine("Button1 was clicked!");
   }
   public void Disconnect() {
      Button1.Click -= new EventHandler(Button1_Click);
   }
}
```

shows a `Form1` class that adds `Button1_Click` as an event handler for `Button1`'s `Click` event. In the `Disconnect` method, that event handler is removed.

For a simple event declaration such as

```
public event EventHandler Click;
```

the compiler automatically provides the implementation underlying the `+=` and `-=` operators.

An implementer who wants more control can get it by explicitly providing add and remove accessors. For example, the `Button` class could be rewritten as follows:

```
public class Button
{
      private EventHandler handler;
      public event EventHandler Click {
         add { handler += value; }
         remove { handler -= value; }
      }
}
```

This change has no effect on client code, but allows the `Button` class more implementation flexibility. For example, the event handler for `Click` need not be represented by a field.

1.7.6 Operators

An operator is a member that defines the meaning of an expression operator that can be applied to instances of the class. There are three kinds of operators that can be defined: unary operators, binary operators, and conversion operators. All operators must be declared as public and static.

The following example defines a `Digit` type that represents decimal digits — integral values between `0` and `9`.

```
using System;
public struct Digit
{
   byte value;
   public Digit(byte value) {
      if (value < 0 || value > 9) throw new ArgumentException();
      this.value = value;
   }
   public Digit(int value): this((byte) value) {}
   public static implicit operator byte(Digit d) {
      return d.value;
   }
   public static explicit operator Digit(byte b) {
      return new Digit(b);
   }
   public static Digit operator+(Digit a, Digit b) {
      return new Digit(a.value + b.value);
   }
   public static Digit operator-(Digit a, Digit b) {
      return new Digit(a.value - b.value);
   }
   public static bool operator==(Digit a, Digit b) {
      return a.value == b.value;
   }
   public static bool operator!=(Digit a, Digit b) {
      return a.value != b.value;
   }
   public override bool Equals(object value) {
      if (value == null) return false;
      if (GetType() == value.GetType()) return this == (Digit)value;
      return false;
   }
   public override int GetHashCode() {
      return value.GetHashCode();
   }
   public override string ToString() {
      return value.ToString();
   }
}
class Test
{
   static void Main() {
      Digit a = (Digit) 5;
      Digit b = (Digit) 3;
      Digit plus = a + b;
      Digit minus = a – b;
      bool equals = (a == b);
      Console.WriteLine("{0} + {1} = {2}", a, b, plus);
      Console.WriteLine("{0} - {1} = {2}", a, b, minus);
      Console.WriteLine("{0} == {1} = {2}", a, b, equals);
   }
}
```

The `Digit` type defines the following operators:

- An implicit conversion operator from `Digit` to `byte`.
- An explicit conversion operator from `byte` to `Digit`.

- An addition operator that adds two `Digit` values and returns a `Digit` value.
- A subtraction operator that subtracts one `Digit` value from another, and returns a `Digit` value.
- The equality (`==`) and inequality (`!=`) operators, which compare two `Digit` values.

1.7.7 Indexers

An indexer is a member that enables an object to be indexed in the same way as an array. Whereas properties enable field-like access, indexers enable array-like access.

As an example, consider the `Stack` class presented earlier. The designer of this class might want to expose array-like access so that it is possible to inspect or alter the items on the stack without performing unnecessary `Push` and `Pop` operations. That is, class `Stack` is implemented as a linked list, but it also provides the convenience of array access.

Indexer declarations are similar to property declarations, with the main differences being that indexers are nameless (the "name" used in the declaration is `this`, since `this` is being indexed) and that indexers include indexing parameters. The indexing parameters are provided between square brackets. The example

```
using System;
public class Stack
{
   private Node GetNode(int index) {
      Node temp = first;
      while (index > 0 && temp != null) {
         temp = temp.Next;
         index--;
      }
      if (index < 0 || temp == null)
         throw new Exception("Index out of range.");      return temp;
   }
   public object this[int index] {
      get {
         return GetNode(index).Value;
      }
      set {
         GetNode(index).Value = value;
      }
   }
   ...
}
class Test
{
   static void Main() {
      Stack s = new Stack();
      s.Push(1);
      s.Push(2);
      s.Push(3);
      s[0] = 33;   // Changes the top item from 3 to 33
      s[1] = 22;   // Changes the middle item from 2 to 22
      s[2] = 11;   // Changes the bottom item from 1 to 11
   }
}
```

shows an indexer for the `Stack` class.

1.7.8 Instance constructors

An instance constructor is a member that implements the actions required to initialize an instance of a class.

The example

```
using System;
class Point
{
   public double x, y;
   public Point() {
      this.x = 0;
      this.y = 0;
   }
   public Point(double x, double y) {
      this.x = x;
      this.y = y;
   }
   public static double Distance(Point a, Point b) {
      double xdiff = a.x – b.x;
      double ydiff = a.y – b.y;
      return Math.Sqrt(xdiff * xdiff + ydiff * ydiff);
   }
   public override string ToString() {
      return string.Format("({0}, {1})", x, y);
   }
}
class Test
{
   static void Main() {
      Point a = new Point();
      Point b = new Point(3, 4);
      double d = Point.Distance(a, b);
      Console.WriteLine("Distance from {0} to {1} is {2}", a, b, d);
   }
}
```

shows a `Point` class that provides two public instance constructors, one of which takes no arguments, while the other takes two `double` arguments.

If no instance constructor is supplied for a class, then an empty one with no parameters is automatically provided.

1.7.9 Destructors

A destructor is a member that implements the actions required to destruct an instance of a class. Destructors cannot have parameters, they cannot have accessibility modifiers, and they cannot be called explicitly. The destructor for an instance is called automatically during garbage collection.

The example

```
using System;
class Point
{
   public double x, y;
   public Point(double x, double y) {
      this.x = x;
      this.y = y;
   }
   ~Point() {
      Console.WriteLine("Destructed {0}", this);
   }
   public override string ToString() {
      return string.Format("({0}, {1})", x, y);
   }
}
```

shows a `Point` class with a destructor.

1.7.10 Static constructors

A static constructor is a member that implements the actions required to initialize a class. Static constructors cannot have parameters, they cannot have accessibility modifiers, and they cannot be called explicitly. The static constructor for a class is called automatically.

The example

```
using Personnel.Data;
class Employee
{
   private static DataSet ds;
   static Employee() {
      ds = new DataSet(...);
   }
   public string Name;
   public decimal Salary;
   ...
}
```

shows an `Employee` class with a static constructor that initializes a static field.

1.7.11 Inheritance

Classes support single inheritance, and the type `object` is the ultimate base class for all classes.

The classes shown in earlier examples all implicitly derive from `object`. The example

```
using System;
class A
{
   public void F() { Console.WriteLine("A.F"); }
}
```

shows a class `A` that implicitly derives from `object`. The example

```
using System;
class B: A
{
   public void G() { Console.WriteLine("B.G"); }
}
class Test
{
   static void Main() {
      B b = new B();
      b.F();         // Inherited from A
      b.G();         // Introduced in B
      A a = b;         // Treat a B as an A
      a.F();
   }
}
```

shows a class `B` that derives from `A`. The class `B` inherits `A`'s `F` method, and introduces a `G` method of its own.

Methods, properties, and indexers can be virtual, which means that their implementation can be overridden in derived classes. The example

```
using System;
class A
{
   public virtual void F() { Console.WriteLine("A.F"); }
}
class B: A
{
   public override void F() {
      base.F();
      Console.WriteLine("B.F");
   }
}
class Test
{
   static void Main() {
      B b = new B();
      b.F();
      A a = b;
      a.F();
   }
}
```

shows a class `A` with a virtual method `F`, and a class `B` that overrides `F`. The overriding method in `B` contains a call, `base.F()`, which calls the overridden method in `A`.

A class can indicate that it is incomplete, and is intended only as a base class for other classes, by including the `abstract` modifier. Such a class is called an abstract class. An abstract class can specify abstract members — members that a non-abstract derived class must implement. The example

```
using System;
abstract class A
{
   public abstract void F();
}
class B: A
{
   public override void F() { Console.WriteLine("B.F"); }
}
class Test
{
   static void Main() {
      B b = new B();
      b.F();
      A a = b;
      a.F();
   }
}
```

introduces an abstract method `F` in the abstract class `A`. The non-abstract class `B` provides an implementation for this method.

1.8 Structs

The list of similarities between classes and structs is long — structs can implement interfaces, and can have the same kinds of members as classes. Structs differ from classes in several important ways, however: structs are value types rather than reference types, and inheritance is not supported for structs. Struct values are stored "on the stack" or "in-line". Careful programmers can sometimes enhance performance through judicious use of structs.

For example, the use of a struct rather than a class for a `Point` can make a large difference in the number of memory allocations performed at run time. The program below creates and initializes an array of 100 points. With `Point` implemented as a class, 101 separate objects are instantiated — one for the array and one each for the 100 elements.

```
class Point
{
   public int x, y;
   public Point(int x, int y) {
      this.x = x;
      this.y = y;
   }
}
class Test
{
   static void Main() {
      Point[] points = new Point[100];
      for (int i = 0; i < 100; i++)
         points[i] = new Point(i, i*i);
   }
}
```

If `Point` is instead implemented as a struct, as in

```
struct Point
{
   public int x, y;
   public Point(int x, int y) {
      this.x = x;
      this.y = y;
   }
}
```

only one object is instantiated — the one for the array. The `Point` instances are allocated in-line within the array. This optimization can be misused. Using structs instead of classes can also make an application run slower, or take up more memory, as passing a struct instance by value causes a copy of that struct to be created.

1.9 Interfaces

An interface defines a contract. A class or struct that implements an interface must adhere to its contract. Interfaces can contain methods, properties, events, and indexers as members.

The example

```
interface IExample
{
   string this[int index] { get; set; }
   event EventHandler E;
   void F(int value);
   string P { get; set; }
}
public delegate void EventHandler(object sender, EventArgs e);
```

shows an interface that contains an indexer, an event `E`, a method `F`, and a property `P`.

Interfaces may employ multiple inheritance. In the example

```
interface IControl
{
   void Paint();
}
interface ITextBox: IControl
{
   void SetText(string text);
}
interface IListBox: IControl
{
   void SetItems(string[] items);
}
interface IComboBox: ITextBox, IListBox {}
```

the interface `IComboBox` inherits from both `ITextBox` and `IListBox`.

Classes and structs can implement multiple interfaces. In the example

```
interface IDataBound
{
   void Bind(Binder b);
}
public class EditBox: Control, IControl, IDataBound
{
   public void Paint() {...}
   public void Bind(Binder b) {...}
}
```

the class `EditBox` derives from the class `Control` and implements both `IControl` and `IDataBound`.

In the previous example, the `Paint` method from the `IControl` interface and the `Bind` method from `IDataBound` interface are implemented using public members on the `EditBox` class. C# provides an alternative way of implementing these methods that allows the implementing class to avoid having these members be public. Interface members can be implemented using a qualified name. For example, the `EditBox` class could instead be implemented by providing `IControl.Paint` and `IDataBound.Bind` methods.

```
public class EditBox: IControl, IDataBound
{
   void IControl.Paint() {...}
   void IDataBound.Bind(Binder b) {...}
}
```

Interface members implemented in this way are called explicit interface members because each member explicitly designates the

interface member being implemented. Explicit interface members can only be called via the interface. For example, the `EditBox`'s implementation of the `Paint` method can be called only by casting to the `IControl` interface.

```
class Test
{
   static void Main() {
      EditBox editbox = new EditBox();
      editbox.Paint();   // error: no such method
      IControl control = editbox;
      control.Paint();   // calls EditBox's Paint implementation
   }
}
```

1.10 Delegates

Delegates enable scenarios that some other languages have addressed with function pointers. However, unlike function pointers, delegates are object-oriented and type-safe.

A delegate declaration defines a class that is derived from the class `System.Delegate`. A delegate instance encapsulates an invocation list, which is a list of one or more methods, each of which is referred to as a callable entity. For instance methods, a callable entity consists of an instance and a method on that instance. For static methods, a callable entity consists of just a method. Invoking a delegate instance with an appropriate set of arguments causes each of the delegate instance's callable entities to be invoked with the given set of arguments.

An interesting and useful property of a delegate instance is that it does not know or care about the classes of the methods it encapsulates; all that matters is that those methods be compatible (Section 15.1) with the delegate's type. This makes delegates perfectly suited for "anonymous" invocation. This is a powerful capability.

There are three steps in defining and using delegates: declaration, instantiation, and invocation. Delegates are declared using delegate declaration syntax. The example

```
delegate void SimpleDelegate();
```

declares a delegate named `SimpleDelegate` that takes no arguments and returns no result.

The example

```
class Test
{
   static void F() {
      System.Console.WriteLine("Test.F");
   }
   static void Main() {
      SimpleDelegate d = new SimpleDelegate(F);
      d();
   }
}
```

creates a `SimpleDelegate` instance and then immediately calls it.

There is not much point in instantiating a delegate for a method and then immediately calling that method via the delegate, as it would be simpler to call the method directly. Delegates really show their usefulness when their anonymity is used. The example

```
void MultiCall(SimpleDelegate d, int count) {
   for (int i = 0; i < count; i++) {
      d();
   }
}
```

shows a `MultiCall` method that repeatedly calls a `SimpleDelegate`. The `MultiCall` method does not know or care about the type of the target method for the `SimpleDelegate`, what accessibility that method has, or whether or not that method is static. All that matters is that the target method is compatible (Section 15.1) with `SimpleDelegate`.

1.11 Enums

An enum type declaration defines a type name for a related group of symbolic constants. Enums are used for "multiple choice" scenarios, in which a runtime decision is made from a fixed number of choices that are known at compile-time.

The example

```
enum Color
{
   Red,
   Blue,
   Green
}
class Shape
{
   public void Fill(Color color) {
      switch(color) {
         case Color.Red:
            ...
            break;
         case Color.Blue:
            ...
            break;
         case Color.Green:
            ...
            break;
         default:
            break;
      }
   }
}
```

shows a `Color` enum and a method that uses this enum. The signature of the `Fill` method makes it clear that the shape can be filled with one of the given colors.

The use of enums is superior to the use of integer constants — as is common in languages without enums — because the use of enums makes the code more readable and self-documenting. The self-documenting nature of the code also makes it possible for the development tool to assist with code writing and other "designer" activities. For example, the use of `Color` rather than `int` for a parameter type enables smart code editors to suggest `Color` values.

1.12 Namespaces and assemblies

The programs presented so far have stood on their own except for dependence on a few system-provided classes such as `System.Console`. It is far more common, however, for real-world applications to consist of several different pieces, each compiled separately. For example, a corporate application might depend on several different components, including some developed internally and some purchased from independent software vendors.

Namespaces and assemblies enable this component-based system. Namespaces provide a logical organizational system. Namespaces are used both as an "internal" organization system for a program, and as an "external" organization system — a way of presenting program elements that are exposed to other programs.

Assemblies are used for physical packaging and deployment. An assembly may contain types, the executable code used to implement these types, and references to other assemblies.

There are two main kinds of assemblies: applications and libraries. Applications have a main entry point and usually have a file extension of `.exe`; libraries do not have a main entry point, and usually have a file extension of `.dll`.

To demonstrate the use of namespaces and assemblies, this section revisits the "hello, world" program presented earlier, and splits it into two pieces: a class library that provides messages and a console application that displays them.

The class library will contain a single class named `HelloMessage`. The example

```
// HelloLibrary.cs
namespace Microsoft.CSharp.Introduction
{
   public class HelloMessage
   {
      public string Message {
         get {
            return "hello, world";
         }
      }
   }
}
```

shows the `HelloMessage` class in a namespace named `Microsoft.CSharp.Introduction`. The `HelloMessage` class provides a read-only property named `Message`. Namespaces can nest, and the declaration

```
namespace Microsoft.CSharp.Introduction
{...}
```

is shorthand for several levels of namespace nesting:

```
namespace Microsoft
{
   namespace CSharp
   {
      namespace Introduction
      {...}
   }
}
```

The next step in the componentization of "hello, world" is to write a console application that uses the `HelloMessage` class. The fully qualified name for the class — `Microsoft.CSharp.Introduction.HelloMessage` — could be used, but this name is quite long and unwieldy. An easier way is to use a "using namespace directive," which makes it possible to use all of the types in a namespace without qualification. The example

```
// HelloApp.cs
using Microsoft.CSharp.Introduction;
class HelloApp
{
   static void Main() {
      HelloMessage m = new HelloMessage();
```

```
        System.Console.WriteLine(m.Message);
    }
}
```

shows a using namespace directive that refers to the `Microsoft.CSharp.Introduction` namespace. The occurrences of `HelloMessage` are shorthand for `Microsoft.CSharp.Introduction.HelloMessage`.

C# also enables the definition and use of aliases. A using alias directive defines an alias for a type. Such aliases can be useful in situation in which name collisions occur between two class libraries, or when a small number of types from a much larger namespace are being used. The example

```
using MessageSource = Microsoft.CSharp.Introduction.HelloMessage;
```

shows a using alias directive that defines `MessageSource` as an alias for the `HelloMessage` class.

The code we have written can be compiled into a class library containing the class `HelloMessage` and an application containing the class `HelloApp`. The details of this compilation step might differ based on the compiler or tool being used. Using the command-line compiler provided in Visual Studio .NET, the command-line invocations are

```
csc /target:library HelloLibrary.cs
csc /reference:HelloLibrary.dll HelloApp.cs
```

which produce a class library named `HelloLibrary.dll` and an application named `HelloApp.exe`.

1.13 Versioning

Versioning is the process of evolving a component over time in a compatible manner. A new version of a component is source compatible with a previous version if code that depends on the previous version can, when recompiled, work with the new version. In contrast, a new version of a component is binary compatible if an application that depended on the old version can, without recompilation, work with the new version.

Most languages do not support binary compatibility at all, and many do little to facilitate source compatibility. In fact, some languages contain flaws that make it impossible, in general, to evolve a class over time without breaking at least some client code.

As an example, consider the situation of a base class author who ships a class named `Base`. In the first version, `Base` contains no `F` method. A component named `Derived` derives from `Base`, and introduces an `F`. This `Derived` class, along with the class `Base` on which it depends, is released to customers, who deploy to numerous clients and servers.

```
// Author A
namespace A
{
   public class Base      // version 1
   {
   }
}
// Author B
namespace B
{
   class Derived: A.Base
   {
      public virtual void F() {
         System.Console.WriteLine("Derived.F");
      }
   }
}
```

From this point, the versioning trouble begins. The author of `Base` produces a new version, giving it its own `F` method.

```
// Author A
namespace A
{
   public class Base      // version 2
   {
      public virtual void F() {      // added in version 2
         System.Console.WriteLine("Base.F");
      }
   }
}
```

This new version of `Base` should be both source and binary compatible with the initial version. (If it weren't possible to simply add a method then a base class could never evolve.) Unfortunately, the new `F` in `Base` makes the meaning of `Derived`'s `F` unclear. Did `Derived` mean to override `Base`'s `F`? This seems unlikely, since when `Derived` was compiled, `Base` did not even have an `F`! Further, if `Derived`'s `F` does override `Base`'s `F`, then it must adhere to the contract specified by `Base` — a contract that was unspecified when `Derived` was written! In some cases, this is impossible. For example, `Base`'s `F` might require that overrides of it always call the base. `Derived`'s `F` could not possibly adhere to such a contract.

C# addresses this versioning problem by requiring developers to state their intent clearly . In the original code example, the code was clear, since `Base` did not even have an `F`. Clearly, `Derived`'s `F` is intended as a new method rather than an override of a base method, since no base method named `F` exists.

If `Base` adds an `F` and ships a new version, then the intent of a binary version of `Derived` is still clear — `Derived`'s `F` is semantically unrelated, and should not be treated as an override.

However, when `Derived` is recompiled, the meaning is unclear — the author of `Derived` may intend its `F` to override `Base`'s `F`, or to hide it. Since the intent is unclear, the compiler produces a warning, and by default makes `Derived`'s `F` hide `Base`'s `F`. This course of action duplicates the semantics for the case in which `Derived` is not recompiled. The warning that is generated alerts `Derived`'s author to the presence of the `F` method in `Base`.

If `Derived`'s `F` is semantically unrelated to `Base`'s `F`, then `Derived`'s author can express this intent — and, in effect, turn off the warning–by using the `new` keyword in the declaration of `F`.

```
// Author A
namespace A
{
   public class Base         // version 2
   {
      public virtual void F() { // added in version 2
         System.Console.WriteLine("Base.F");
      }
   }
}
// Author B
namespace B
{
   class Derived: A.Base   // version 2a: new
   {
      new public virtual void F() {
         System.Console.WriteLine("Derived.F");
      }
   }
}
```

On the other hand, `Derived`'s author might investigate further, and decide that `Derived`'s `F` should override `Base`'s `F`. This intent can be specified by using the `override` keyword, as shown below.

```
// Author A
namespace A
{
   public class Base               // version 2
   {
      public virtual void F() { // added in version 2
         System.Console.WriteLine("Base.F");
      }
   }
}
// Author B
namespace B
{
   class Derived: A.Base   // version 2b: override
   {
      public override void F() {
         base.F();
         System.Console.WriteLine("Derived.F");
      }
   }
}
```

The author of `Derived` has one other option, and that is to change the name of `F`, thus completely avoiding the name collision. Although this change would break source and binary compatibility for `Derived`, the importance of this compatibility varies depending on the scenario. If `Derived` is not exposed to other programs, then changing the name of `F` is likely a good idea, as it would improve the readability of the program — there would no longer be any confusion about the meaning of `F`.

1.14 Attributes

C# is an imperative language, but like all imperative languages it does have some declarative elements. For example, the accessibility of a method in a class is specified by declaring it `public`, `protected`, `internal`, `protected internal`, or `private`. C# generalizes this capability, so that programmers can invent new kinds of declarative information, attach this declarative information to various program entities, and retrieve this declarative information at run-time. Programs specify this additional declarative information by defining and using attributes (Section 17).

For instance, a framework might define a `HelpAttribute` attribute that can be placed on program elements such as classes and methods, enabling developers to provide a mapping from program elements to documentation for them. The example

```
using System;
[AttributeUsage(AttributeTargets.All)]
public class HelpAttribute: Attribute
{
   public HelpAttribute(string url) {
      this.url = url;
   }
   public string Topic = null;
   private string url;
   public string Url {
      get { return url; }
   }
}
```

defines an attribute class named `HelpAttribute` that has one positional parameter (`string url`) and one named parameter (`string Topic`). As explained in Section 17.1, this attribute may be referenced by its full name, `HelpAttribute`, or by its implicit short name, `Help`. Positional parameters are defined by the formal parameters for public instance constructors of the attribute class, and named parameters are defined by public non-static read-write fields and properties of the attribute class.

The example

```
[Help("http://www.microsoft.com/.../Class1.htm")]
public class Class1
{
   [Help("http://www.microsoft.com/.../Class1.htm", Topic = "F")]
   public void F() {}
}
```

shows several uses of the `Help` attribute.

Attribute information for a given program element can be retrieved at run time by using reflection support. The example

```
using System;
class Test
{
   static void Main() {
      Type type = typeof(Class1);
      object[] arr = type.GetCustomAttributes(typeof(HelpAttribute), true);
      if (arr.Length == 0)
         Console.WriteLine("Class1 has no Help attribute.");
      else {
         HelpAttribute ha = (HelpAttribute) arr[0];
         Console.WriteLine("Url = {0}, Topic = {1}", ha.Url, ha.Topic);
      }
   }
}
```

checks to see if `Class1` has a `Help` attribute, and writes out the associated `Topic` and `Url` values if the attribute is present.

2. Lexical structure

This chapter defines the lexical structure of C# programs.

2.1 Programs

A C# program consists of one or more source files, known formally as compilation units (Section 9.1). A source file is an ordered sequence of Unicode characters. Source files typically have a one-to-one correspondence with files in a file system, but this correspondence is not required. For maximal portability, it is recommended that files in a file system be encoded with the UTF-8 encoding.

Conceptually speaking, a program is compiled using three steps:

- Transformation, which converts a file from a particular character repertoire and encoding scheme into a sequence of Unicode characters.
- Lexical analysis, which translates a stream of Unicode input characters into a stream of tokens.
- Syntactic analysis, which translates the stream of tokens into executable code.

2.2 Grammars

This specification presents the syntax of the C# programming language using two grammars. The lexical grammar (Section 2.2.2) defines how Unicode characters are combined to form line terminators, white space, comments, tokens, and pre-processing directives. The syntactic grammar (Section 2.2.3) defines how the tokens resulting from the lexical grammar are combined to form C# programs.

2.2.1 Grammar notation

The lexical and syntactic grammars are presented using grammar productions. Each grammar production defines a non-terminal symbol and the possible expansions of that non-terminal symbol into sequences of non-terminal or terminal symbols. In grammar productions, non-terminal symbols are shown in italic type, and terminal symbols are shown in a fixed-width font.

The first line of a grammar production is the name of the non-terminal symbol being defined, followed by a colon. Each successive indented line contains a possible expansion of the non-terminal given as a sequence of non-terminal or terminal symbols. For example, the production:

while-statement:
  while (*boolean*-expression) *embedded-statement*

defines a *while-statement* to consist of the token `while`, followed by the token "`(`", followed by a *boolean-expression*, followed by the token "`)`", followed by an *embedded-statement*.

When there is more than one possible expansion of a non-terminal symbol, the alternatives are listed on separate lines. For example, the production:

statement-list:
  statement
  statement-list *statement*

defines a *statement-list* to either consist of a *statement* or consist of a *statement-list* followed by a *statement*. In other words, the definition is recursive and specifies that a statement list consists of one or more statements.

A subscripted suffix "*opt*" is used to indicate an optional symbol. The production:

block:
  { $statement\text{-}list_{opt}$ }

is shorthand for:

block:
  { }
  { *statement-list* }

and defines a *block* to consist of an optional *statement-list* enclosed in "`{`" and "`}`" tokens.

Alternatives are normally listed on separate lines, though in cases where there are many alternatives, the phrase "one of" may precede a list of expansions given on a single line. This is simply shorthand for listing each of the alternatives on a separate line. For example, the production:

real-type-suffix: one of
  F f D d M m

is shorthand for:

real-type-suffix:
  F
  f
  D
  d
  M
  m

2.2.2 Lexical grammar

The lexical grammar of C# is presented in Section 2.3, Section 2.4, and Section 2.5. The terminal symbols of the lexical grammar are the characters of the Unicode character set, and the lexical grammar specifies how characters are combined to form tokens (Section 2.4), white space (Section 2.3.2), comments (Section 2.3.3), and pre-processing directives (Section 2.5).

Every source file in a C# program must conform to the input production of the lexical grammar (Section 2.3).

2.2.3 Syntactic grammar

The syntactic grammar of C# is presented in the chapters and appendices that follow this chapter. The terminal symbols of the syntactic grammar are the tokens defined by the lexical grammar, and the syntactic grammar specifies how tokens are combined to form C# programs.

Every source file in a C# program must conform to the compilation-unit production of the syntactic grammar (Section 9.1).

2.3 Lexical analysis

The input production defines the lexical structure of a C# source file. Each source file in a C# program must conform to this lexical grammar production.

input:
  input-section$_{opt}$
input-section:
  input-section-part
  input-section *input-section-part*
input-section-part:
  input-elements$_{opt}$ *new-line*
  pp-directive
input-elements:
  input-element
  input-elements *input-element*
input-element:
  whitespace
  comment
  token

Five basic elements make up the lexical structure of a C# source file: Line terminators (Section 2.3.1), white space (Section 2.3.2), comments (Section 2.3.3), tokens (Section 2.4), and pre-processing directives (Section 2.5). Of these basic elements, only tokens are significant in the syntactic grammar of a C# program (Section 2.2.3).

The lexical processing of a C# source file consists of reducing the file into a sequence of tokens which becomes the input to the syntactic analysis. Line terminators, white space, and comments can serve to separate tokens, and pre-processing directives can cause sections of the source file to be skipped, but otherwise these lexical elements have no impact on the syntactic structure of a C# program.

When several lexical grammar productions match a sequence of characters in a source file, the lexical processing always forms the longest possible lexical element. For example, the character sequence `//` is processed as the beginning of a single-line comment because that lexical element is longer than a single `/` token.

2.3.1 Line terminators

Line terminators divide the characters of a C# source file into lines.

new-line:
  Carriage return character (U+000D)
  Line feed character (U+000A)
  Carriage return character (U+000D) followed by line feed character (U+000A)
  Line separator character (U+2028)
  Paragraph separator character (U+2029)

For compatibility with source code editing tools that add end-of-file markers, and to enable a source file to be viewed as a sequence of properly terminated lines, the following transformations are applied, in order, to every source file in a C# program:

- If the last character of the source file is a Control-Z character (`U+001A`), this character is deleted.
- A carriage-return character (`U+000D`) is added to the end of the source file if that source file is non-empty and if the last character of the source file is not a carriage return (`U+000D`), a line feed (`U+000A`), a line separator (`U+2028`), or a paragraph separator (`U+2029`).

2.3.2 White space

White space is defined as any character with Unicode class Zs (which includes the space character) as well as the horizontal tab character, the vertical tab character, and the form feed character.

whitespace:
  Any character with Unicode class Zs
  Horizontal tab character (U+0009)
  Vertical tab character (U+000B)
  Form feed character (U+000C)

2.3.3 Comments

Two forms of comments are supported: single-line comments and delimited comments. *Single-line comments* start with the characters `//` and extend to the end of the source line. *Delimited comments* start with the characters `/*` and end with the characters `*/`. Delimited comments may span multiple lines.

comment:
  single-line-comment
  delimited-comment
single-line-comment:
  // *input-characters*$_{opt}$
input-characters:
  input-character
  input-characters *input-character*
input-character:
  Any Unicode character except a *new-line-character*
new-line-character:
  Carriage return character (U+000D)
  Line feed character (U+000A)
  Line separator character (U+2028)
  Paragraph separator character (U+2029)
delimited-comment:
  */** *delimited-comment-characters*$_{opt}$ **/*
delimited-comment-characters:
  delimited-comment-character
  delimited-comment-characters *delimited-comment-character*
delimited-comment-character:
  not-asterisk
  *** *not-slash*
not-asterisk:
  Any Unicode character except *
not-slash:
  Any Unicode character except /

Comments do not nest. The character sequences `/*` and `*/` have no special meaning within a `//` comment, and the character sequences `//` and `/*` have no special meaning within a delimited comment.

Comments are not processed within character and string literals.

The example

```
/* Hello, world program
      This program writes "hello, world" to the console
*/
class Hello
{
   static void Main() {
      System.Console.WriteLine("hello, world");
   }
}
```

includes a delimited comment.

The example

```
// Hello, world program
// This program writes "hello, world" to the console
//
class Hello // any name will do for this class
{
   static void Main() { // this method must be named "Main"
      System.Console.WriteLine("hello, world");
   }
```

```
}
```

shows several single-line comments.

2.4 Tokens

There are several kinds of tokens: identifiers, keywords, literals, operators, and punctuators. White space and comments are not tokens, though they act as separators for tokens.

token:
  identifier
  keyword
  integer-literal
  real-literal
  character-literal
  string-literal
  operator-or-punctuator

2.4.1 Unicode character escape sequences

A Unicode character escape sequence represents a Unicode character. Unicode character escape sequences are processed in identifiers (Section 2.4.2), character literals (Section 2.4.4.4), and regular string literals (Section 2.4.4.5). A Unicode character escape is not processed in any other location (for example, to form an operator, punctuator, or keyword).

unicode-escape-sequence:
  \u *hex-digit* *hex-digit* *hex-digit* *hex-digit*
  \U *hex-digit* *hex-digit* *hex-digit* *hex-digit* *hex-digit* *hex-digit* *hex-digit* *hex-digit*

A Unicode escape sequence represents the single Unicode character formed by the hexadecimal number following the "`\u`" or "`\U`" characters. Since C# uses a 16-bit encoding of Unicode code points in characters and string values, a Unicode character in the range U+10000 to U+10FFFF is not permitted in a character literal and is represented using a Unicode surrogate pair in a string literal. Unicode characters with code points above 0x10FFFF are not supported.

Multiple translations are not performed. For instance, the string literal "`\u005Cu005C`" is equivalent to "`\u005C`" rather than "`\`". The Unicode value `\u005C` is the character "\".

The example

```
class Class1
{
   static void Test(bool \u0066) {
      char c = '\u0066';
      if (\u0066)
         System.Console.WriteLine(c.ToString());
   }
}
```

shows several uses of `\u0066`, which is the escape sequence for the letter "`f`". The program is equivalent to

```
class Class1
{
   static void Test(bool f) {
      char c = 'f';
      if (f)
         System.Console.WriteLine(c.ToString());
   }
}
```

2.4.2 Identifiers

The rules for identifiers given in this section correspond exactly to those recommended by the Unicode Standard Annex 15, except that underscore is allowed as an initial character (as is traditional in the C programming language), Unicode escape sequences are permitted in identifiers, and the "@" character is allowed as a prefix to enable keywords to be used as identifiers.

identifier:
  available-identifier
  @ *identifier-or-keyword*
available-identifier:
  An *identifier-or-keyword* that is not a *keyword*
identifier-or-keyword:
  identifier-start-character *identifier-part-characters*$_{opt}$
identifier-start-character:
  letter-character
  _ (the underscore character `U+005F`)
identifier-part-characters:
  identifier-part-character
  identifier-part-characters *identifier-part-character*
identifier-part-character:
  letter-character
  decimal-digit-character
  connecting-character
  combining-character
  formatting-character
letter-character:
  A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Nl
  A *unicode-escape-sequence* representing a character of classes Lu, Ll, Lt, Lm, Lo, or Nl
combining-character:
  A Unicode character of classes Mn or Mc
  A *unicode-escape-sequence* representing a character of classes Mn or Mc
decimal-digit-character:
  A Unicode character of the class Nd
  A *unicode-escape-sequence* representing a character of the class Nd
connecting-character:
  A Unicode character of the class Pc
  A *unicode-escape-sequence* representing a character of the class Pc
formatting-character:
  A Unicode character of the class Cf
  A *unicode-escape-sequence* representing a character of the class Cf

For information on the Unicode character classes mentioned above, see *The Unicode Standard, Version 3.0,* section 4.5.

Examples of valid identifiers include "`identifier1`", "`_identifier2`", and "`@if`".

An identifier in a conforming program must be in the canonical format defined by Unicode Normalization Form C, as defined by Unicode Standard Annex 15. The behavior when encountering an identifier not in Normalization Form C is implementation-defined; however, a diagnostic is not required.

The prefix "`@`" enables the use of keywords as identifiers, which is useful when interfacing with other programming languages. The character `@` is not actually part of the identifier, so the identifier might be seen in other languages as a normal identifier, without the prefix. An identifier with an `@` prefix is called a verbatim identifier. Use of the `@` prefix for identifiers that are not keywords is permitted, but strongly discouraged as a matter of style.

The example:

```
class @class
{
   public static void @static(bool @bool) {
      if (@bool)
         System.Console.WriteLine("true");
      else
         System.Console.WriteLine("false");
   }
```

```
}
class Class1
{
   static void M() {
      cl\u0061ss.st\u0061tic(true);
   }
}
```

defines a class named "`class`" with a static method named "`static`" that takes a parameter named "`bool`". Note that since Unicode escapes are not permitted in keywords, the token "`cl\u0061ss`" is an identifier, and is the same identifier as "`@class`".

Two identifiers are considered the same if they are identical after the following transformations are applied, in order:

- The prefix "`@`", if used, is removed.
- Each *unicode-escape-sequence* is transformed into its corresponding Unicode character.
- Any *formatting-characters* are removed.

Identifiers containing two consecutive underscore characters (`U+005F`) are reserved for use by the implementation. For example, an implementation might provide extended keywords that begin with two underscores.

2.4.3 Keywords

A keyword is an identifier-like sequence of characters that is reserved, and cannot be used as an identifier except when prefaced by the `@` character.

keyword: one of

abstract	as	base	bool	break	byte	case
catch	char	checked	class	const	continue	decimal
default	delegate	do	double	else	enum	event
explicit	extern	false	finally	fixed	float	for
foreach	goto	if	implicit	in	int	interface
internal	is	lock	long	namespace	new	null
object	operator	out	override	params	private	protected
public	readonly	ref	return	sbyte	sealed	short
sizeof	stackalloc	static	string	struct	switch	this
throw	true	try	typeof	uint	ulong	unchecked
unsafe	ushort	using	virtual	void	volatile	while

In some places in the grammar, specific identifiers have special meaning, but are not keywords. For example, within a property declaration, the "`get`" and "`set`" identifiers have special meaning (Section 10.6.2). An identifier other than `get` or `set` is never permitted in these locations, so this use does not conflict with a use of these words as identifiers.

2.4.4 Literals

A literal is a source code representation of a value.

literal:
  boolean-literal
  integer-literal
  real-literal
  character-literal
  string-literal
  null-literal

2.4.4.1 Boolean literals

There are two Boolean literal values: `true` and `false`.

boolean-literal:
  true
  false

The type of a *boolean-literal* is `bool`.

2.4.4.2 Integer literals

Integer literals are used to write values of types `int`, `uint`, `long`, and `ulong`. Integer literals have two possible forms: decimal and hexadecimal.

integer-literal:
  decimal-integer-literal
  hexadecimal-integer-literal
decimal-integer-literal:
  decimal-digits *integer-type-suffix*$_{opt}$
decimal-digits:
  decimal-digit
  decimal-digits *decimal-digit*
decimal-digit: one of
  0 1 2 3 4 5 6 7 8 9
integer-type-suffix: one of
  U u L l UL Ul uL ul LU Lu lU lu
hexadecimal-integer-literal:
  0x *hex-digits* *integer-type-suffix*$_{opt}$
  0X *hex-digits* *integer-type-suffix*$_{opt}$
hex-digits:
  hex-digit
  hex-digits *hex-digit*
hex-digit: one of
  0 1 2 3 4 5 6 7 8 9 A B C D E F a b c d e f

The type of an integer literal is determined as follows:

- If the literal has no suffix, it has the first of these types in which its value can be represented: `int`, `uint`, `long`, `ulong`.
- If the literal is suffixed by `U` or `u`, it has the first of these types in which its value can be represented: `uint`, `ulong`.
- If the literal is suffixed by `L` or `l`, it has the first of these types in which its value can be represented: `long`, `ulong`.
- If the literal is suffixed by `UL`, `Ul`, `uL`, `ul`, `LU`, `Lu`, `lU`, or `lu`, it is of type `ulong`.

If the value represented by an integer literal is outside the range of the `ulong` type, a compile-time error occurs.

As a matter of style, it is suggested that "`L`" be used instead of "`l`" when writing literals of type `long`, since it is easy to confuse the letter "`l`" with the digit "`1`".

To permit the smallest possible `int` and `long` values to be written as decimal integer literals, the following two rules exist:

- When a *decimal-integer-literal* with the value 2147483648 (2^{31}) and no *integer-type-suffix* appears as the token immediately following a unary minus operator token (Section 7.6.2), the result is a constant of type `int` with the value −2147483648 (-2^{31}). In all other situations, such a *decimal-integer-literal* is of type `uint`.
- When a *decimal-integer-literal* with the value 9223372036854775808 (2^{63}) and no *integer-type-suffix* or the *integer-type-suffix* `L` or `l` appears as the token immediately following a unary minus operator token (Section 7.6.2), the result is a constant of type `long` with the value −9223372036854775808 (-2^{63}). In all other situations, such a *decimal-integer-literal* is of type `ulong`.

2.4.4.3 Real literals

Real literals are used to write values of types `float`, `double`, and `decimal`.

real-literal:
  decimal-digits . *decimal-digits* *exponent-part*$_{opt}$ *real-type-suffix*$_{opt}$
  . *decimal-digits* *exponent-part*$_{opt}$ *real-type-suffix*$_{opt}$
  decimal-digits *exponent-part* *real-type-suffix*$_{opt}$
  decimal-digits *real-type-suffix*
exponent-part:
  e *sign*$_{opt}$ *decimal-digits*
  E *sign*$_{opt}$ *decimal-digits*
sign: one of
  + -
real-type-suffix: one of
  F f D d M m

If no real type suffix is specified, the type of the real literal is `double`. Otherwise, the real type suffix determines the type of the real literal, as follows:

- A real literal suffixed by `F` or `f` is of type `float`. For example, the literals `1f`, `1.5f`, `1e10f`, and `123.456F` are all of type `float`.
- A real literal suffixed by `D` or `d` is of type `double`. For example, the literals `1d`, `1.5d`, `1e10d`, and `123.456D` are all of type `double`.
- A real literal suffixed by `M` or `m` is of type `decimal`. For example, the literals `1m`, `1.5m`, `1e10m`, and `123.456M` are all of type `decimal`. This literal is converted to a `decimal` value by taking the exact value, and, if necessary, rounding to the nearest representable value using banker's rounding (Section 4.1.7). Any scale apparent in the literal is preserved unless the value is rounded or the value is zero (in which latter case the sign and scale will be 0). Hence, the literal `2.900m` will be parsed to form the decimal with sign `0`, coefficient `2900`, and scale `3`.

If the specified literal cannot be represented in the indicated type, then a compile-time error occurs.

The value of a real literal of type `float` or `double` is determined by using the IEEE "round to nearest" mode.

Note that in a real literal, decimal digits are always required after the decimal point. For example, 1.3F is a real literal but 1.F is not.

2.4.4.4 Character literals

A character literal represents a single character, and usually consists of a character in quotes, as in `'a'`.

character-literal:
  ' *character* '
character:
  single-character
  simple-escape-sequence
  hexadecimal-escape-sequence
  unicode-escape-sequence
single-character:
  Any character except ' (U+0027), \ (U+005C), and *new-line-character*
simple-escape-sequence: one of
  \' \" \\ \0 \a \b \f \n \r \t \v
hexadecimal-escape-sequence:
  \x *hex-digit* $\textit{hex-digit}_{opt}$ $\textit{hex-digit}_{opt}$ $\textit{hex-digit}_{opt}$

A character that follows a backslash character (`\`) in a *character* must be one of the following characters: `'`, `"`, `\`, `0`, `a`, `b`, `f`, `n`, `r`, `t`, `u`, `U`, `x`, `v`. Otherwise, a compile-time error occurs.

A hexadecimal escape sequence represents a single Unicode character, with the value formed by the hexadecimal number following "\x".

If the value represented by a character literal is greater than `U+FFFF`, a compile-time error occurs.

A Unicode character escape sequence (Section 2.4.1) in a character literal must be in the range `U+0000` to `U+FFFF`.

A simple escape sequence represents a Unicode character encoding, as described in the table below.

Escape sequence	Character name	Unicode encoding
`\'`	Single quote	`0x0027`
`\"`	Double quote	`0x0022`
`\\`	Backslash	`0x005C`
`\0`	Null	`0x0000`
`\a`	Alert	`0x0007`
`\b`	Backspace	`0x0008`
`\f`	Form feed	`0x000C`
`\n`	New line	`0x000A`
`\r`	Carriage return	`0x000D`
`\t`	Horizontal tab	`0x0009`

`\v`	Vertical tab	`0x000B`

The type of a *character-literal* is `char`.

2.4.4.5 String literals

C# supports two forms of string literals: regular string literals and verbatim string literals.

A regular string literal consists of zero or more characters enclosed in double quotes, as in `"hello"`, and may include both simple escape sequences (such as `\t` for the tab character) and hexadecimal and Unicode escape sequences.

A verbatim string literal consists of an `@` character followed by a double-quote character, zero or more characters, and a closing double-quote character. A simple example is `@"hello"`. In a verbatim string literal, the characters between the delimiters are interpreted verbatim, the only exception being a *quote-escape-sequence*. In particular, simple escape sequences and hexadecimal and Unicode escape sequences are not processed in verbatim string literals. A verbatim string literal may span multiple lines.

string-literal:
  regular-string-literal
  verbatim-string-literal
regular-string-literal:
  " *regular-string-literal-characters*$_{opt}$ "
regular-string-literal-characters:
  regular-string-literal-character
  regular-string-literal-characters *regular-string-literal-character*
regular-string-literal-character:
  single-regular-string-literal-character
  simple-escape-sequence
  hexadecimal-escape-sequence
  unicode-escape-sequence
single-regular-string-literal-character:
  Any character except " (U+0022), \ (U+005C), and *new-line-character*
verbatim-string-literal:
  @" *verbatim -string-literal-characters*$_{opt}$ "
verbatim-string-literal-characters:
  verbatim-string-literal-character
  verbatim-string-literal-characters *verbatim-string-literal-character*
verbatim-string-literal-character:
  single-verbatim-string-literal-character
  quote-escape-sequence
single-verbatim-string-literal-character:
  Any character except "
quote-escape-sequence:
  ""

A character that follows a backslash character (`\`) in a *regular-string-literal-character* must be one of the following characters: `'`, `"`, `\`, `0`, `a`, `b`, `f`, `n`, `r`, `t`, `u`, `U`, `x`, `v`. Otherwise, a compile-time error occurs.

The example

```
string a = "hello, world";                  // hello, world
string b = @"hello, world";               // hello, world
string c = "hello \t world";               // hello     world
string d = @"hello \t world";               // hello \t world
string e = "Joe said \"Hello\" to me";      // Joe said "Hello" to me
string f = @"Joe said ""Hello"" to me";   // Joe said "Hello" to me
string g = "\\\\server\\share\\file.txt";   // \\server\share\file.txt
string h = @"\\server\share\file.txt";      // \\server\share\file.txt
string i = "one\r\ntwo\r\nthree";
string j = @"one
two
three";
```

shows a variety of string literals. The last string literal, `j`, is a verbatim string literal that spans multiple lines. The characters between the quotation marks, including white space such as new line characters, are preserved verbatim.

Since a hexadecimal escape sequence can have a variable number of hex digits, the string literal `"\x123"` contains a single character with hex value 123. To create a string containing the character with hex value 12 followed by the character 3, you could

write `"\x00123"` or `"\x12" + "3"` instead.

The type of a *string-literal* is `string`.

Each string literal does not necessarily result in a new string instance. When two or more string literals that are equivalent according to the string equality operator (Section 7.9.7) appear in the same assembly, these string literals refer to the same string instance. For instance, the output produced by

```
class Test
{
   static void Main() {
      object a = "hello";
      object b = "hello";
      System.Console.WriteLine(a == b);
   }
}
```

is `True` because the two literals refer to the same string instance.

2.4.4.6 The null literal

null-literal:
  null

The type of a *null-literal* is the null type.

2.4.5 Operators and punctuators

There are several kinds of operators and punctuators. Operators are used in expressions to describe operations involving one or more operands. For example, the expression `a + b` uses the `+` operator to add the two operands `a` and `b`. Punctuators are for grouping and separating.

operator-or-punctuator: one of

```
{   }   [   ]   (   )   .   ,   :   ;

+   -   *   /   %   &   |   ^   !   ~

=   <   >   ?   ++  --  &&  ||  <<  >>

==  !=  <=  >=  +=  -=  *=  /=  %=  &=

|=  ^=  <<=  >>=  ->
```

2.5 Pre-processing directives

The pre-processing directives provide the ability to conditionally skip sections of source files, to report error and warning conditions, and to delineate distinct regions of source code. The term "pre-processing directives" is used only for consistency with the C and C++ programming languages. In C#, there is no separate pre-processing step; pre-processing directives are processed as part of the lexical analysis phase.

pp-directive:
  pp-declaration
  pp-conditional
  pp-line
  pp-diagnostic
  pp-region

The following pre-processing directives are available:

- `#define` and `#undef`, which are used to define and undefine, respectively, conditional compilation symbols (Section 2.5.3).
- `#if`, `#elif`, `#else`, and `#endif`, which are used to conditionally skip sections of source code (Section 2.5.4).
- `#line`, which is used to control line numbers emitted for errors and warnings (Section 2.5.7).
- `#error` and `#warning`, which are used to issue errors and warnings, respectively (Section 2.5.5).
- `#region` and `#endregion`, which are used to explicitly mark sections of source code (Section 2.5.6).

A pre-processing directive always occupies a separate line of source code and always begins with a `#` character and a pre-processing directive name. White space may occur before the `#` character and between the `#` character and the directive name.

A source line containing a `#define`, `#undef`, `#if`, `#elif`, `#else`, `#endif`, or `#line` directive may end with a single-line comment. Delimited comments (the `/* */` style of comments) are not permitted on source lines containing pre-processing directives.

Pre-processing directives are not tokens and are not part of the syntactic grammar of C#. However, pre-processing directives can be used to include or exclude sequences of tokens and can in that way affect the meaning of a C# program. For example, when compiled, the program:

```
#define A
#undef B
class C
{
#if A
   void F() {}
#else
   void G() {}
#endif
#if B
   void H() {}
#else
   void I() {}
#endif
}
```

results in the exact same sequence of tokens as the program:

```
class C
{
   void F() {}
   void I() {}
}
```

Thus, whereas the two programs are quite different lexically, they are identical syntactically.

2.5.1 Conditional compilation symbols

The conditional compilation functionality provided by the `#if`, `#elif`, `#else`, and `#endif` directives is controlled through pre-processing expressions (Section 2.5.1) and conditional compilation symbols.

conditional-symbol:
  Any *identifier-or-keyword* except true or false

A conditional compilation symbol has two possible states: defined or undefined. At the beginning of the lexical processing of a source file, a conditional compilation symbol is undefined unless it has been explicitly defined by an external mechanism (such as a command-line compiler option). When a `#define` directive is processed, the conditional compilation symbol named in that directive becomes defined in that source file. The symbol remains defined until an `#undef` directive for that same symbol is processed, or until the end of the source file is reached. An implication of this is that `#define` and `#undef` directives in one source file have no effect on other source files in the same program.

When referenced in a pre-processing expression, a defined conditional compilation symbol has the Boolean value `true`, and an undefined conditional compilation symbol has the Boolean value `false`. There is no requirement that conditional compilation symbols be explicitly declared before they are referenced in pre-processing expressions. Instead, undeclared symbols are simply undefined and thus have the value `false`.

The name space for conditional compilation symbols is distinct and separate from all other named entities in a C# program. Conditional compilation symbols can only be referenced in `#define` and `#undef` directives and in pre-processing expressions.

2.5.2 Pre-processing expressions

Pre-processing expressions can occur in `#if` and `#elif` directives. The operators `!`, `==`, `!=`, `&&` and `||` are permitted in pre-processing expressions, and parentheses may be used for grouping.

pp-expression:
  whitespace$_{opt}$ *pp-or-expression* *whitespace*$_{opt}$
pp-or-expression:
  pp-and-expression
  pp-or-expression *whitespace*$_{opt}$ || *whitespace*$_{opt}$ *pp-and-expression*
pp-and-expression:
  pp-equality-expression
  pp-and-expression *whitespace*$_{opt}$ && *whitespace*$_{opt}$ *pp-equality-expression*
pp-equality-expression:
  pp-unary-expression
  pp-equality-expression *whitespace*$_{opt}$ == *whitespace*$_{opt}$ *pp-unary-expression*
  pp-equality-expression *whitespace*$_{opt}$!= *whitespace*$_{opt}$ *pp-unary-expression*
pp-unary-expression:
  pp-primary-expression
  ! *whitespace*$_{opt}$ *pp-unary-expression*
pp-primary-expression:
  true
  false
  conditional-symbol
  (*whitespace*$_{opt}$ *pp-expression* *whitespace*$_{opt}$)

When referenced in a pre-processing expression, a defined conditional compilation symbol has the Boolean value `true`, and an undefined conditional compilation symbol has the Boolean value `false`.

Evaluation of a pre-processing expression always yields a Boolean value. The rules of evaluation for a pre-processing expression are the same as those for a constant expression (Section 7.15), except that the only user-defined entities that can be referenced are conditional compilation symbols.

2.5.3 Declaration directives

The declaration directives are used to define or undefine conditional compilation symbols.

pp-declaration:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ define *whitespace* *conditional-symbol* *pp-new-line*
  whitespace$_{opt}$ # *whitespace*$_{opt}$ undef *whitespace* *conditional-symbol* *pp-new-line*
pp-new-line:
  whitespace$_{opt}$ *single-line-comment*$_{opt}$ *new-line*

The processing of a `#define` directive causes the given conditional compilation symbol to become defined, starting with the source line that follows the directive. Likewise, the processing of an `#undef` directive causes the given conditional compilation symbol to become undefined, starting with the source line that follows the directive.

Any `#define` and `#undef` directives in a source file must occur before the first *token* (Section 2.4) in the source file; otherwise, a compile-time error occurs. In intuitive terms, `#define` and `#undef` directives must precede any "real code" in the source file.

The example:

```
#define Enterprise
#if Professional || Enterprise
   #define Advanced
#endif
namespace Megacorp.Data
{
   #if Advanced
   class PivotTable {...}
   #endif
}
```

is valid because the `#define` directives precede the first token (the `namespace` keyword) in the source file.

The following example results in a compile-time error because a `#define` directive follows real code:

```
#define A
namespace N
{
   #define B
   #if B
   class Class1 {}
   #endif
}
```

A `#define` directive may define a conditional compilation symbol that is already defined, without there being any intervening `#undef for that` symbol. The example below defines a conditional compilation symbol `A` and then defines it again.

```
#define A
#define A
```

An `#undef` directive may undefine a conditional compilation symbol that is not defined. The example below defines a conditional compilation symbol `A` and then undefines it twice; although the second `#undef` has no effect, it is still valid.

```
#define A
#undef A
#undef A
```

2.5.4 Conditional compilation directives

The conditional compilation directives are used to conditionally include or exclude portions of a source file.

pp-conditional:
  pp-if-section *pp-elif-sections*$_{opt}$ *pp-else-section*$_{opt}$ *pp-endif*
pp-if-section:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ if *whitespace* *pp-expression* *pp-new-line* *conditional-section*$_{opt}$
pp-elif-sections:
  pp-elif-section
  pp-elif-sections *pp-elif-section*
pp-elif-section:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ elif *whitespace* *pp-expression* *pp-new-line* *conditional-section*$_{opt}$
pp-else-section:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ else *pp-new-line* *conditional-section*$_{opt}$
pp-endif:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ endif *pp-new-line*
conditional-section:
  input-section
  skipped-section
skipped-section:
  skipped-section-part
  skipped-section *skipped-section-part*
skipped-section-part:
  skipped-characters$_{opt}$ *new-line*
  pp-directive
skipped-characters:
  whitespace$_{opt}$ *not-number-sign* *input-characters*$_{opt}$
not-number-sign:
  Any *input-character* except #

As indicated by the syntax, conditional compilation directives must be written as sets consisting of, in order, an `#if` directive, zero or more `#elif` directives, zero or one `#else` directive, and an `#endif` directive. Between the directives are conditional sections of source code. Each section is controlled by the immediately preceding directive. A conditional section may itself contain nested conditional compilation directives provided these directives form complete sets.

A *pp-conditional* selects at most one of the contained *conditional-section*s for normal lexical processing:

- The *pp-expression*s of the `#if` and `#elif` directives are evaluated in order until one yields `true`. If an expression yields `true`, the *conditional-section* of the corresponding directive is selected.
- If all *pp-expression*s yield `false`, and if an `#else` directive is present, the *conditional-section* of the `#else` directive is selected.
- Otherwise, no *conditional-section* is selected.

The selected *conditional-section*, if any, is processed as a normal *input-section*: the source code contained in the section must adhere to the lexical grammar; tokens are generated from the source code in the section; and pre-processing directives in the section have the prescribed effects.

The remaining *conditional-section*s, if any, are processed as *skipped-section*s: except for pre-processing directives, the source code in the section need not adhere to the lexical grammar; no tokens are generated from the source code in the section; and pre-processing directives in the section must be lexically correct but are not otherwise processed. Within a *conditional-section* that is being processed as a *skipped-section*, any nested *conditional-section*s (contained in nested `#if`…`#endif` and `#region`…`#endregion` constructs) are also processed as *skipped-section*s.

The following example illustrates how conditional compilation directives can nest:

```
#define Debug      // Debugging on
#undef Trace      // Tracing off
class PurchaseTransaction
{
   void Commit() {
      #if Debug
         CheckConsistency();
```

```
         #if Trace
            WriteToLog(this.ToString());
         #endif
      #endif
      CommitHelper();
   }
}
```

Except for pre-processing directives, skipped source code is not subject to lexical analysis. For example, the following is valid despite the unterminated comment in the `#else` section:

```
#define Debug      // Debugging on
class PurchaseTransaction
{
   void Commit() {
      #if Debug
         CheckConsistency();
      #else
         /* Do something else
      #endif
   }
}
```

Note, however, that pre-processing directives are required to be lexically correct even in skipped sections of source code.

Pre-processing directives are not processed when they appear inside multi-line input elements. For example, the program:

```
class Hello
{
   static void Main() {
      System.Console.WriteLine(@"hello,
#if Debug
      world
#else
      Nebraska
#endif
      ");
   }
}
```

results in the output:

```
hello,
#if Debug
      world
#else
      Nebraska
#endif
```

In peculiar cases, the set of pre-processing directives that is processed might depend on the evaluation of the *pp-expression*. The example:

```
#if X
   /*
#else
   /* */ class Q { }
#endif
```

always produces the same token stream (`class Q { }`), regardless of whether or not `X` is defined. If `X` is defined, the only processed directives are `#if` and `#endif`, due to the multi-line comment. If `X` is undefined, then three directives (`#if`, `#else`, `#endif`) are part of the directive set.

2.5.5 Diagnostic directives

The diagnostic directives are used to explicitly generate error and warning messages that are reported in the same way as other compile-time errors and warnings.

pp-diagnostic:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ error *pp-message*
  whitespace$_{opt}$ # *whitespace*$_{opt}$ warning *pp-message*
pp-message:
  new-line
  whitespace *input-characters*$_{opt}$ *new-line*

The example:

```
#warning Code review needed before check-in
#if Debug && Retail
   #error A build can't be both debug and retail
#endif
class Test {...}
```

always produces a warning ("Code review needed before check-in"), and produces a compile-time error ("A build can't be both debug and retail") if the conditional symbols `Debug` and `Retail` are both defined. Note that a *pp-message* can contain arbitrary text; specifically, it need not contain well-formed tokens, as shown by the single quote in the word `can't`.

2.5.6 Region directives

The region directives are used to explicitly mark regions of source code.

pp-region:
  pp-start-region *conditional-section*$_{opt}$ *pp-end-region*
pp-start-region:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ region *pp-message*
pp-end-region:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ endregion *pp-message*

No semantic meaning is attached to a region; regions are intended for use by the programmer or by automated tools to mark a section of source code. The message specified in a `#region` or `#endregion` directive likewise has no semantic meaning; it merely serves to identify the region. Matching `#region` and `#endregion` directives may have different *pp-messages*.

The lexical processing of a region:

```
#region
...
#endregion
```

corresponds exactly to the lexical processing of a conditional compilation directive of the form:

```
#if true
...
#endif
```

2.5.7 Line directives

Line directives may be used to alter the line numbers and source file names that are reported by the compiler in output such as warnings and errors.

Line directives are most commonly used in meta-programming tools that generate C# source code from some other text input.

pp-line:
  whitespace$_{opt}$ # *whitespace*$_{opt}$ line *whitespace* *line-indicator* *pp-new-line*
line-indicator:
  decimal-digits *whitespace* *file-name*

  decimal-digits

  default

  hidden

file-name:
  " *file-name-characters* "
file-name-characters:
  file-name-character
  file-name-characters *file-name-character*
file-name-character:
  Any *input-character* except "

When no `#line` directives are present, the compiler reports true line numbers and source file names in its output. The `#line` directive is most commonly used in meta-programming tools that generate C# source code from some other text input. When processing a `#line` directive that includes a line-indicator that is not `default`, the compiler treats the line *after* the directive as having the given line number (and file name, if specified).

A `#line default` directive reverses the effect of all preceding `#line` directives. The compiler reports true line information for subsequent lines, precisely as if no `#line` directives had been processed.

A `#line hidden` directive has no effect on the file and line numbers reported in error messages, but does affect source level debugging. When debugging, all lines between a `#line hidden` directive and the subsequent `#line` directive (that is not `#line hidden`) have no line number information. When stepping through code in the debugger, these lines will be skipped entirely.

Note that a *file-name* differs from a regular string literal in that escape characters are not processed; the '\' character simply designates an ordinary backslash character within a *file-name*.

3. Basic concepts

This chapter defines basic concepts that are required for understanding subsequent chapters.

3.1 Application startup

An assembly that has an entry point is called an application. When an application is run, a new application domain is created. Several different instantiations of an application may exist on the same machine at the same time, and each has its own application domain.

An application domain enables application isolation by acting as a container for application state. An application domain acts as a container and boundary for the types defined in the application and the class libraries it uses. Types loaded into one application domain are distinct from the same type loaded into another application domain, and instances of objects are not directly shared between application domains. For instance, each application domain has its own copy of static variables for these types, and a static constructor for a type is run at most once per application domain. Implementations are free to provide implementation-specific policy or mechanisms for the creation and destruction of application domains.

Application startup occurs when the execution environment calls a designated method, which is referred to as the application's entry point. This entry point method is always named `Main`, and can have one of the following signatures:

```
static void Main() {...}
static void Main(string[] args) {...}
static int Main() {...}
static int Main(string[] args) {...}
```

As shown, the entry point may optionally return an `int` value. This return value is used in application termination (Section 3.2).

The entry point may optionally have one formal parameter. The parameter may have any name, but the type of the parameter must be `string[]`. If the formal parameter is present, the execution environment creates and passes a `string[]` argument containing the command-line arguments that were specified when the application was started. The `string[]` argument is never null, but it may have a length of zero if no command-line arguments were specified.

Since C# supports method overloading, a class or struct may contain multiple definitions of some method, provided each has a different signature. However, within a single program, no class or struct may contain more than one method called `Main` whose definition qualifies it to be used as an application entry point. Other overloaded versions of `Main` are permitted, however, provided they have more than one parameter, or their only parameter is other than type `string[]`.

An application can be made up of multiple classes or structs. It is possible for more than one of these classes or structs to contain a method called `Main` whose definition qualifies it to be used as an application entry point. In such cases, an external mechanism (such as a command-line compiler option) must be used to select one of these `Main` methods as the entry point.

In C#, every method must be defined as a member of a class or struct. Ordinarily, the declared accessibility (Section 3.5.1) of a method is determined by the access modifiers (Section 10.2.3) specified in its declaration, and similarly the declared accessibility of a type is determined by the access modifiers specified in its declaration. In order for a given method of a given type to be callable, both the type and the member must be accessible. However, the application entry point is a special case. Specifically, the execution environment can access the application's entry point regardless of its declared accessibility and regardless of the declared accessibility of its enclosing type declarations.

In all other respects, entry point methods behave like those that are not entry points.

3.2 Application termination

Application termination returns control to the execution environment.

If the return type of the application's entry point method is `int`, the value returned serves as the application's termination status code. The purpose of this code is to allow communication of success or failure to the execution environment.

If the return type of the entry point method is `void`, reaching the right brace (`}`) that terminates that method, or executing a `return` statement that has no expression, results in a termination status code of `0`.

Prior to an application's termination, destructors for all of its objects that have not yet been garbage collected are called, unless such cleanup has been suppressed (by a call to the library method `GC.SuppressFinalize`, for example).

3.3 Declarations

Declarations in a C# program define the constituent elements of the program. C# programs are organized using namespaces (Section 9), which can contain type declarations and nested namespace declarations. Type declarations (Section 9.5) are used to define classes (Section 10), structs (Section 11), interfaces (Section 13), enums (Section 14), and delegates (Section 15). The kinds of members permitted in a type declaration depend on the form of the type declaration. For instance, class declarations can contain declarations for constants (Section 10.3), fields (Section 10.4), methods (Section 10.5), properties (Section 10.6), events (Section 10.7), indexers (Section 10.8), operators (Section 10.9), instance constructors (Section 10.10), static constructors (Section 10.11), destructors (Section 10.12), and nested types.

A declaration defines a name in the declaration space to which the declaration belongs. Except for overloaded members (Section 3.6), it is a compile-time error to have two or more declarations that introduce members with the same name in a declaration space. It is never possible for a declaration space to contain different kinds of members with the same name. For example, a declaration space can never contain a field and a method by the same name.

There are several different types of declaration spaces, as described in the following.

- Within all source files of a program, namespace-member-declarations with no enclosing namespace-declaration are members of a single combined declaration space called the global declaration space.
- Within all source files of a program, namespace-member-declarations within namespace-declarations that have the same fully qualified namespace name are members of a single combined declaration space.
- Each class, struct, or interface declaration creates a new declaration space. Names are introduced into this declaration space through class-member-declarations, struct-member-declarations, or interface-member-declarations. Except for overloaded instance constructor declarations and static constructor declarations, a class or struct member declaration cannot introduce a member by the same name as the class or struct. A class, struct, or interface permits the declaration of overloaded methods and indexers. Furthermore, a class or struct permits the declaration of overloaded instance constructors and operators. For example, a class, struct, or interface may contain multiple method declarations with the same name, provided these method declarations differ in their signature (Section 3.6). Note that base classes do not contribute to the declaration space of a class, and base interfaces do not contribute to the declaration space of an interface. Thus, a derived class or interface is allowed to declare a member with the same name as an inherited member. Such a member is said to hide the inherited member.
- Each enumeration declaration creates a new declaration space. Names are introduced into this declaration space through enum-member-declarations.
- Each block or switch-block creates a different declaration space for local variables and constants. Names are introduced into this declaration space through local-variable-declarations and local-constant-declarations. If a block is the body of an instance constructor, method, or operator declaration, or a get or set accessor for an indexer declaration, the parameters declared in such a declaration are members of the block's local variable declaration space. The local variable declaration space of a block includes any nested blocks. Thus, within a nested block it is not possible to declare a local variable with the same name as a local variable in an enclosing block.
- Each block or switch-block creates a separate declaration space for labels. Names are introduced into this declaration space through labeled-statements, and the names are referenced through *goto* statements. The label declaration space of a block includes any nested blocks. Thus, within a nested block it is not possible to declare a label with the same name as a label in an enclosing block.

The textual order in which names are declared is generally of no significance. In particular, textual order is not significant for the declaration and use of namespaces, constants, methods, properties, events, indexers, operators, instance constructors, destructors, static constructors, and types. Declaration order is significant in the following ways:

- Declaration order for field declarations and local variable declarations determines the order in which their initializers (if any) are executed.
- Local variables must be defined before they are used (Section 3.7).
- Declaration order for enum member declarations (Section 14.3) is significant when constant-expression values are omitted.

The declaration space of a namespace is "open ended", and two namespace declarations with the same fully qualified name contribute to the same declaration space. For example

```
namespace Megacorp.Data
{
   class Customer
   {
```

```
      ...
   }
}
namespace Megacorp.Data
{
   class Order
   {
      ...
   }
}
```

The two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names `Megacorp.Data.Customer` and `Megacorp.Data.Order`. Because the two declarations contribute to the same declaration space, it would have caused a compile-time error if each contained a declaration of a class with the same name.

As previously specified, the declaration space of a block includes any nested blocks. Thus, in the following example, the `F` and `G` methods result in a compile-time error because the name `i` is declared in the outer block and cannot be redeclared in the inner block. However, the `H` and `I` methods are valid since the two `i`'s are declared in separate non-nested blocks.

```
class A
{
   void F() {
      int i = 0;
      if (true) {
         int i = 1;
      }
   }
   void G() {
      if (true) {
         int i = 0;
      }
      int i = 1;
   }
   void H() {
      if (true) {
         int i = 0;
      }
      if (true) {
         int i = 1;
      }
   }
   void I() {
      for (int i = 0; i < 10; i++)
         H();
      for (int i = 0; i < 10; i++)
         H();
   }
}
```

3.4 Members

Namespaces and types have members. The members of an entity are generally available through the use of a qualified name that starts with a reference to the entity, followed by a "`.`" token, followed by the name of the member.

Members of a type are either declared in the type or inherited from the base class of the type. When a type inherits from a base class, all members of the base class, except instance constructors, destructors and static constructors, become members of the derived type. The declared accessibility of a base class member does not control whether the member is inherited — inheritance extends to any member that is not an instance constructor, static constructor, or destructor. However, an inherited member may not be accessible in a derived type, either because of its declared accessibility (Section 3.5.1) or because it is hidden by a declaration in the type itself (Section 3.7.1.2).

3.4.1 Namespace members

Namespaces and types that have no enclosing namespace are members of the global namespace. This corresponds directly to the names declared in the global declaration space.

Namespaces and types declared within a namespace are members of that namespace. This corresponds directly to the names declared in the declaration space of the namespace.

Namespaces have no access restrictions. It is not possible to declare private, protected, or internal namespaces, and namespace names are always publicly accessible.

3.4.2 Struct members

The members of a struct are the members declared in the struct and the members inherited from class `object`.

The members of a simple type correspond directly to the members of the struct type aliased by the simple type:

- The members of `sbyte` are the members of the `System.SByte` struct.
- The members of `byte` are the members of the `System.Byte` struct.
- The members of `short` are the members of the `System.Int16` struct.
- The members of `ushort` are the members of the `System.UInt16` struct.
- The members of `int` are the members of the `System.Int32` struct.
- The members of `uint` are the members of the `System.UInt32` struct.
- The members of `long` are the members of the `System.Int64` struct.
- The members of `ulong` are the members of the `System.UInt64` struct.
- The members of `char` are the members of the `System.Char` struct.
- The members of `float` are the members of the `System.Single` struct.
- The members of `double` are the members of the `System.Double` struct.
- The members of `decimal` are the members of the `System.Decimal` struct.
- The members of `bool` are the members of the `System.Boolean` struct.

3.4.3 Enumeration members

The members of an enumeration are the constants declared in the enumeration and the members inherited from class `System.Enum`.

3.4.4 Class members

The members of a class are the members declared in the class and the members inherited from the base class (except for class `object` which has no base class). The members inherited from the base class include the constants, fields, methods, properties, events, indexers, operators, and types of the base class, but not the instance constructors, destructors and static constructors of the base class. Base class members are inherited without regard to their accessibility.

A class declaration may contain declarations of constants, fields, methods, properties, events, indexers, operators, instance constructors, destructors, static constructors and types.

The members of `object` and `string` correspond directly to the members of the class types they alias:

- The members of `object` are the members of the `System.Object` class.
- The members of `string` are the members of the `System.String` class.

3.4.5 Interface members

The members of an interface are the members declared in the interface and in all base interfaces of the interface, and the members inherited from class `object`.

3.4.6 Array members

The members of an array are the members inherited from class `System.Array`.

3.4.7 Delegate members

The members of a delegate are the members inherited from class `System.Delegate`.

3.5 Member access

Declarations of members allow control over member access. The accessibility of a member is established by the declared accessibility (Section 3.5.1) of the member combined with the accessibility of the immediately containing type, if any.

When access to a particular member is allowed, the member is said to be accessible. Conversely, when access to a particular member is disallowed, the member is said to be inaccessible. Access to a member is permitted when the textual location in which the access takes place is included in the accessibility domain (Section 3.5.2) of the member.

3.5.1 Declared accessibility

The declared accessibility of a member can be one of the following:

- Public, which is selected by including a `public` modifier in the member declaration. The intuitive meaning of `public` is "access not limited".
- Protected, which is selected by including a `protected` modifier in the member declaration. The intuitive meaning of `protected` is "access limited to the containing class or types derived from the containing class".
- Internal, which is selected by including an `internal` modifier in the member declaration. The intuitive meaning of `internal` is "access limited to this program".
- Protected internal (meaning protected or internal), which is selected by including both a `protected` and an `internal` modifier in the member declaration. The intuitive meaning of `protected internal` is "access limited to this program or types derived from the containing class".
- Private, which is selected by including a `private` modifier in the member declaration. The intuitive meaning of `private` is "access limited to the containing type".

Depending on the context in which a member declaration takes place, only certain types of declared accessibility are permitted. Furthermore, when a member declaration does not include any access modifiers, the context in which the declaration takes place determines the default declared accessibility.

- Namespaces implicitly have `public` declared accessibility. No access modifiers are allowed on namespace declarations.
- Types declared in compilation units or namespaces can have `public` or `internal` declared accessibility and default to `internal` declared accessibility.
- Class members can have any of the five kinds of declared accessibility and default to `private` declared accessibility. (Note that a type declared as a member of a class can have any of the five kinds of declared accessibility, whereas a type declared as a member of a namespace can have only `public` or `internal` declared accessibility.)
- Struct members can have `public`, `internal`, or `private` declared accessibility and default to `private` declared accessibility because structs are implicitly sealed. Struct members introduced in a struct (that is, not inherited by that struct) cannot have `protected` or `protected internal` declared accessibility. (Note that a type declared as a member of a struct can have `public`, `internal`, or `private` declared accessibility, whereas a type declared as a member of a namespace can have only `public` or `internal` declared accessibility.)
- Interface members implicitly have `public` declared accessibility. No access modifiers are allowed on interface member declarations.
- Enumeration members implicitly have `public` declared accessibility. No access modifiers are allowed on enumeration member declarations.

3.5.2 Accessibility domains

The accessibility domain of a member consists of the (possibly disjoint) sections of program text in which access to the member is permitted. For purposes of defining the accessibility domain of a member, a member is said to be top-level if it is not declared within a type, and a member is said to be nested if it is declared within another type. Furthermore, the program text of a program is defined as all program text contained in all source files of the program, and the program text of a type is defined as all program text contained between the opening and closing "`{`" and "`}`" tokens in the class-body, struct-body, interface-body, or enum-body of the type (including, possibly, types that are nested within the type).

The accessibility domain of a predefined type (such as `object`, `int`, or `double`) is unlimited.

The accessibility domain of a top-level type `T` that is declared in a program `P` is defined as follows:

- If the declared accessibility of `T` is `public`, the accessibility domain of `T` is the program text of `P` and any program that references `P`.
- If the declared accessibility of `T` is `internal`, the accessibility domain of `T` is the program text of `P`.

From these definitions it follows that the accessibility domain of a top-level type is always at least the program text of the program in which that type is declared.

The accessibility domain of a nested member `M` declared in a type `T` within a program `P` is defined as follows (noting that M itself may possibly be a type):

- If the declared accessibility of `M` is `public`, the accessibility domain of `M` is the accessibility domain of `T`.
- If the declared accessibility of `M` is `protected internal`, let `D` be the union of the program text of `P` and the program text of any type derived from `T`, which is declared outside `P`. The accessibility domain of `M` is the intersection of the accessibility domain of `T` with `D`.
- If the declared accessibility of `M` is `protected`, let `D` be the union of the program text of `T` and the program text of any type derived from `T`. The accessibility domain of `M` is the intersection of the accessibility domain of `T` with `D`.
- If the declared accessibility of `M` is `internal`, the accessibility domain of `M` is the intersection of the accessibility domain of `T` with the program text of `P`.
- If the declared accessibility of `M` is `private`, the accessibility domain of `M` is the program text of `T`.

From these definitions it follows that the accessibility domain of a nested member is always at least the program text of the type in which the member is declared. Furthermore, it follows that the accessibility domain of a member is never more inclusive than the accessibility domain of the type in which the member is declared.

In intuitive terms, when a type or member `M` is accessed, the following steps are evaluated to ensure that the access is permitted:

- First, if `M` is declared within a type (as opposed to a compilation unit or a namespace), a compile-time error occurs if that type is not accessible.
- Then, if `M` is `public`, the access is permitted.
- Otherwise, if `M` is `protected internal`, the access is permitted if it occurs within the program in which `M` is declared, or if it occurs within a class derived from the class in which `M` is declared and takes place through the derived class type (Section 3.5.3).
- Otherwise, if `M` is `protected`, the access is permitted if it occurs within the class in which `M` is declared, or if it occurs within a class derived from the class in which `M` is declared and takes place through the derived class type (Section 3.5.3).
- Otherwise, if `M` is `internal`, the access is permitted if it occurs within the program in which `M` is declared.
- Otherwise, if `M` is `private`, the access is permitted if it occurs within the type in which `M` is declared.
- Otherwise, the type or member is inaccessible, and a compile-time error occurs.

In the example

```
public class A
{
   public static int X;
   internal static int Y;
   private static int Z;
}
internal class B
```

```
{
   public static int X;
   internal static int Y;
   private static int Z;
   public class C
   {
      public static int X;
      internal static int Y;
      private static int Z;
   }
   private class D
   {
      public static int X;
      internal static int Y;
      private static int Z;
   }
}
```

the classes and members have the following accessibility domains:

- The accessibility domain of `A` and `A.X` is unlimited.
- The accessibility domain of `A.Y`, `B`, `B.X`, `B.Y`, `B.C`, `B.C.X`, and `B.C.Y` is the program text of the containing program.
- The accessibility domain of `A.Z` is the program text of `A`.
- The accessibility domain of `B.Z` and `B.D` is the program text of `B`, including the program text of `B.C` and `B.D`.
- The accessibility domain of `B.D.X` and `B.D.Y` is the program text of `B`, including the program text of `B.C` and `B.D`.
- The accessibility domain of `B.D.Z` is the program text of `B.D`.

As the example illustrates, the accessibility domain of a member is never larger than that of a containing type. For example, even though all `X` members have public declared accessibility, all but `A.X` have accessibility domains that are constrained by a containing type.

As described in Section 3.4, all members of a base class, except for instance constructors, destructors and static constructors, are inherited by derived types. This includes even private members of a base class. However, the accessibility domain of a private member includes only the program text of the type in which the member is declared. In the example

```
class A
{
   int x;
   static void F(B b) {
      b.x = 1;      // Ok
   }
}
class B: A
{
   static void F(B b) {
      b.x = 1;      // Error, x not accessible
   }
}
```

the `B` class inherits the private member `x` from the `A` class. Because the member is private, it is only accessible within the *class-body* of `A`. Thus, the access to `b.x` succeeds in the `A.F` method, but fails in the `B.F` method.

3.5.3 Protected access for instance members

When a `protected` instance member is accessed outside the program text of the class in which it is declared, and when a `protected internal` instance member is accessed outside the program text of the program in which it is declared, the access is required to take place through an instance of the derived class type in which the access occurs. Let `B` be a base class that declares a protected instance member `M`, and let `D` be a class that derives from `B`. Within the class-body of `D`, access to `M` can take one of the following forms:

- An unqualified type-name or primary-expression of the form `M`.
- A primary-expression of the form `E.M`, provided the type of `E` is `D` or a class derived from `D`.
- A primary-expression of the form `base.M`.

In addition to these forms of access, a derived class can access a protected instance constructor of a base class in a constructor-initializer (Section 10.10.1).

In the example

```
public class A
{
   protected int x;
   static void F(A a, B b) {
      a.x = 1;      // Ok
      b.x = 1;      // Ok
   }
}
public class B: A
{
   static void F(A a, B b) {
      a.x = 1;      // Error, must access through instance of B
      b.x = 1;      // Ok
   }
}
```

within `A`, it is possible to access `x` through instances of both `A` and `B`, since in either case the access takes place through an instance of `A` or a class derived from `A`. However, within `B`, it is not possible to access `x` through an instance of `A`, since `A` does not derive from `B`.

3.5.4 Accessibility constraints

Several constructs in the C# language require a type to be at least as accessible as a member or another type. A type `T` is said to be at least as accessible as a member or type `M` if the accessibility domain of `T` is a superset of the accessibility domain of `M`. In other words, `T` is at least as accessible as `M` if `T` is accessible in all contexts in which `M` is accessible.

The following accessibility constraints exist:

- The direct base class of a class type must be at least as accessible as the class type itself.
- The explicit base interfaces of an interface type must be at least as accessible as the interface type itself.
- The return type and parameter types of a delegate type must be at least as accessible as the delegate type itself.
- The type of a constant must be at least as accessible as the constant itself.
- The type of a field must be at least as accessible as the field itself.
- The return type and parameter types of a method must be at least as accessible as the method itself.
- The type of a property must be at least as accessible as the property itself.
- The type of an event must be at least as accessible as the event itself.
- The type and parameter types of an indexer must be at least as accessible as the indexer itself.
- The return type and parameter types of an operator must be at least as accessible as the operator itself.
- The parameter types of an instance constructor must be at least as accessible as the instance constructor itself.

In the example

```
class A {...}
public class B: A {...}
```

the `B` class results in a compile-time error because `A` is not at least as accessible as `B`.

Likewise, in the example

```
class A {...}
public class B
{
   A F() {...}
   internal A G() {...}
   public A H() {...}
}
```

the `H` method in `B` results in a compile-time error because the return type `A` is not at least as accessible as the method.

3.6 Signatures and overloading

Methods, instance constructors, indexers, and operators are characterized by their signatures:

- The signature of a method consists of the name of the method and the type and kind (value, reference, or output) of each of its formal parameters, considered in the order left to right. The signature of a method specifically does not include the return type, nor does it include the `params` modifier that may be specified for the right-most parameter.
- The signature of an instance constructor consists of the type and kind (value, reference, or output) of each of its formal parameters, considered in the order left to right. The signature of an instance constructor specifically does not include the `params` modifier that may be specified for the right-most parameter.
- The signature of an indexer consists of the type of each of its formal parameters, considered in the order left to right. The signature of an indexer specifically does not include the element type.
- The signature of an operator consists of the name of the operator and the type of each of its formal parameters, considered in the order left to right. The signature of an operator specifically does not include the result type.

Signatures are the enabling mechanism for overloading of members in classes, structs, and interfaces:

- Overloading of methods permits a class, struct, or interface to declare multiple methods with the same name, provided their signatures are unique within that class, struct, or interface.
- Overloading of instance constructors permits a class or struct to declare multiple instance constructors, provided their signatures are unique within that class or struct.
- Overloading of indexers permits a class, struct, or interface to declare multiple indexers, provided their signatures are unique within that class, struct, or interface.
- Overloading of operators permits a class or struct to declare multiple operators with the same name, provided their signatures are unique within that class or struct.

The following example shows a set of overloaded method declarations along with their signatures.

```
interface ITest
{
   void F();                     // F()
   void F(int x);                  // F(int)
   void F(ref int x);            // F(ref int)
   void F(int x, int y);         // F(int, int)
   int F(string s);               // F(string)
   int F(int x);                  // F(int)         error
   void F(string[] a);            // F(string[])
   void F(params string[] a);      // F(string[])      error
}
```

Note that any `ref` and `out` parameter modifiers (Section 10.5.1) are part of a signature. Thus, `F(int)` and `F(ref int)` are unique signatures. Also, note that the return type and the `params` modifier are not part of a signature, so it is not possible to overload solely based on return type or on the inclusion or exclusion of the `params` modifier. As such, the declarations of the methods `F(int)` and `F(params string[])` identified above result in a compile-time error.

3.7 Scopes

The scope of a name is the region of program text within which it is possible to refer to the entity declared by the name without qualification of the name. Scopes can be nested, and an inner scope may redeclare the meaning of a name from an outer scope. (This does not, however, remove the restriction imposed by Section 3.3 that within a nested block it is not possible to declare a local variable with the same name as a local variable in an enclosing block.) The name from the outer scope is then said to be hidden in the region of program text covered by the inner scope, and access to the outer name is only possible by qualifying the name.

- The scope of a namespace member declared by a *namespace-member-declaration* (Section 9.4) with no enclosing namespace-declaration is the entire program text.
- The scope of a namespace member declared by a namespace-member-declaration within a namespace-declaration whose fully qualified name is `N` is the namespace-body of every namespace-declaration whose fully qualified name is `N` or starts with `N`, followed by a period.
- The scope of a name defined or imported by a using-directive (Section 9.3) extends over the namespace-member-declarations of the compilation-unit or namespace-body in which the using-directive occurs. A using-directive may make zero or more namespace or type names available within a particular compilation-unit or namespace-body, but does not contribute any new members to the underlying declaration space. In other words, a using-directive is not transitive but rather affects only the compilation-unit or namespace-body in which it occurs.
- The scope of a member declared by a class-member-declaration (Section 10.2) is the class-body in which the declaration occurs. In addition, the scope of a class member extends to the *class-body* of those derived classes that are included in the accessibility domain (Section 3.5.2) of the member.
- The scope of a member declared by a struct-member-declaration (Section 11.2) is the struct-body in which the declaration occurs.
- The scope of a member declared by an enum-member-declaration (Section 14.3) is the enum-*body* in which the declaration occurs.
- The scope of a parameter declared in a method-declaration (Section 10.5) is the method-body of that method-declaration.
- The scope of a parameter declared in an indexer-declaration (Section 10.8) is the accessor-declarations of that indexer-declaration.
- The scope of a parameter declared in an operator-declaration (Section 10.9) is the block of that operator-declaration.
- The scope of a parameter declared in a constructor-declaration (Section 10.10) is the constructor-initializer and block of that constructor-declaration.
- The scope of a label declared in a labeled-statement (Section 8.4) is the block in which the declaration occurs.
- The scope of a local variable declared in a local-variable-declaration (Section 8.5.1) is the block in which the declaration occurs.
- The scope of a local variable declared in a switch-block of a `switch` statement (Section 8.7.2) is the switch-block.
- The scope of a local variable declared in a for-initializer of a `for` statement (Section 8.8.3) is the for-initializer, the for-condition, the for-iterator, and the contained statement of the `for` statement.
- The scope of a local constant declared in a local-constant-declaration (Section 8.5.2) is the block in which the declaration occurs. It is a compile-time error to refer to a local constant in a textual position that precedes its constant-declarator.

Within the scope of a namespace, class, struct, or enumeration member it is possible to refer to the member in a textual position that precedes the declaration of the member. For example

```
class A
{
   void F() {
      i = 1;
   }
   int i = 0;
}
```

Here, it is valid for `F` to refer to `i` before it is declared.

Within the scope of a local variable, it is a compile-time error to refer to the local variable in a textual position that precedes the *local*-variable-declarator of the local variable. For example

```
class A
{
   int i = 0;
   void F() {
      i = 1;               // Error, use precedes declaration
      int i;
      i = 2;
   }
   void G() {
      int j = (j = 1);      // Valid
   }
   void H() {
      int a = 1, b = ++a;   // Valid
   }
}
```

In the `F` method above, the first assignment to `i` specifically does not refer to the field declared in the outer scope. Rather, it refers to the local variable and it results in a compile-time error because it textually precedes the declaration of the variable. In the `G` method, the use of `j` in the initializer for the declaration of `j` is valid because the use does not precede the *local*-variable-declarator. In the `H` method, a subsequent *local*-variable-declarator correctly refers to a local variable declared in an earlier *local*-variable-declarator within the same local-variable-declaration.

The scoping rules for local variables are designed to guarantee that the meaning of a name used in an expression context is always the same within a block. If the scope of a local variable were to extend only from its declaration to the end of the block, then in the example above, the first assignment would assign to the instance variable and the second assignment would assign to the local variable, possibly leading to compile-time errors if the statements of the block were later to be rearranged.

The meaning of a name within a block may differ based on the context in which the name is used. In the example

```
using System;
class A {}
class Test
{
   static void Main() {
      string A = "hello, world";
      string s = A;                        // expression context
      Type t = typeof(A);                  // type context
      Console.WriteLine(s);               // writes "hello, world"
      Console.WriteLine(t);               // writes "A"
   }
}
```

the name `A` is used in an expression context to refer to the local variable `A` and in a type context to refer to the class `A`.

3.7.1 Name hiding

The scope of an entity typically encompasses more program text than the declaration space of the entity. In particular, the scope of an entity may include declarations that introduce new declaration spaces containing entities of the same name. Such declarations cause the original entity to become hidden. Conversely, an entity is said to be visible when it is not hidden.

Name hiding occurs when scopes overlap through nesting and when scopes overlap through inheritance. The characteristics of the two types of hiding are described in the following sections.

3.7.1.1 Hiding through nesting

Name hiding through nesting can occur as a result of nesting namespaces or types within namespaces, as a result of nesting types within classes or structs, and as a result of parameter and local variable declarations.

In the example

```
class A
{
   int i = 0;
   void F() {
      int i = 1;
   }
   void G() {
      i = 1;
   }
}
```

within the `F` method, the instance variable `i` is hidden by the local variable `i`, but within the `G` method, `i` still refers to the instance variable.

When a name in an inner scope hides a name in an outer scope, it hides all overloaded occurrences of that name. In the example

```
class Outer
{
   static void F(int i) {}
   static void F(string s) {}
   class Inner
   {
      void G() {
         F(1);            // Invokes Outer.Inner.F
         F("Hello");      // Error
      }
      static void F(long l) {}
   }
}
```

the call `F(1)` invokes the `F` declared in `Inner` because all outer occurrences of `F` are hidden by the inner declaration. For the same reason, the call `F("Hello")` results in a compile-time error.

3.7.1.2 Hiding through inheritance

Name hiding through inheritance occurs when classes or structs redeclare names that were inherited from base classes. This type of name hiding takes one of the following forms:

- A constant, field, property, event, or type introduced in a class or struct hides all base class members with the same name.
- A method introduced in a class or struct hides all non-method base class members with the same name, and all base class methods with the same signature (method name and parameter count, modifiers, and types).
- An indexer introduced in a class or struct hides all base class indexers with the same signature (parameter count and types).

The rules governing operator declarations (Section 10.9) make it impossible for a derived class to declare an operator with the same signature as an operator in a base class. Thus, operators never hide one another.

Contrary to hiding a name from an outer scope, hiding an accessible name from an inherited scope causes a warning to be reported. In the example

```
class Base
{
   public void F() {}
}
class Derived: Base
{
   public void F() {}      // Warning, hiding an inherited name
}
```

the declaration of `F` in `Derived` causes a warning to be reported. Hiding an inherited name is specifically not an error, since that would preclude separate evolution of base classes. For example, the above situation might have come about because a later version of `Base` introduced an `F` method that wasn't present in an earlier version of the class. Had the above situation been an error, then *any* change made to a base class in a separately versioned class library could potentially cause derived classes to become invalid.

The warning caused by hiding an inherited name can be eliminated through use of the `new` modifier:

```
class Base
{
   public void F() {}
}
class Derived: Base
{
   new public void F() {}
}
```

The `new` modifier indicates that the `F` in `Derived` is "new", and that it is indeed intended to hide the inherited member.

A declaration of a new member hides an inherited member only within the scope of the new member.

```
class Base
{
   public static void F() {}
}
class Derived: Base
{
   new private static void F() {}   // Hides Base.F in Derived only
}
class MoreDerived: Derived
{
   static void G() { F(); }         // Invokes Base.F
}
```

In the example above, the declaration of `F` in `Derived` hides the `F` that was inherited from `Base`, but since the new `F` in `Derived` has private access, its scope does not extend to `MoreDerived`. Thus, the call `F()` in `MoreDerived.G` is valid and will invoke `Base.F`.

3.8 Namespace and type names

Several contexts in a C# program require a namespace-name or a type-name to be specified. Either form of name is written as one or more identifiers separated by "`.`" tokens.

namespace-name:
  namespace-or-type-name
type-name:
  namespace-or-type-name
namespace-or-type-name:
  identifier
  namespace-or-type-name `.` *identifier*

A type-name is a namespace-or-type-name that refers to a type. Following resolution as described below, the namespace-or-type-name of a type-name must refer to a type, or otherwise a compile-time error occurs.

A namespace-name is a namespace-or-type-name that refers to a namespace. Following resolution as described below, the namespace-or-type-name of a namespace-name must refer to a namespace, or otherwise a compile-time error occurs.

The meaning of a namespace-or-type-name is determined as follows:

- If the namespace-or-type-name consists of a single identifier:
  - If the namespace-or-type-name appears within the body of a class or struct declaration, then starting with that class or struct declaration and continuing with each enclosing class or struct declaration (if any), if a member with the given name exists, is accessible, and denotes a type, then the namespace-or-type-name refers to that member. Note that non-type members (constants, fields, methods, properties, indexers, operators, instance constructors, destructors, and static constructors) are ignored when determining the meaning of a namespace-or-type-name.
  - Otherwise, starting with the namespace in which the namespace-or-type-name occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
  - If the namespace contains a namespace member with the given name, then the namespace-or-type-name refers to that member and, depending on the member, is classified as a namespace or a type.
  - Otherwise, if the namespace has a corresponding namespace declaration enclosing the location where the namespace-or-type-name occurs, then:

    If the namespace declaration contains a using-alias-directive that associates the given name with an imported namespace or type, then the namespace-or-type-name refers to that namespace or type.

    Otherwise, if the namespaces imported by the using-namespace-directives of the namespace declaration contain exactly one type with the given name, then the namespace-or-type-name refers to that type.

    Otherwise, if the namespaces imported by the using-namespace-directives of the namespace declaration contain more than one type with the given name, then the namespace-or-type-name is ambiguous and an error occurs.
  - Otherwise, the namespace-or-type-name is undefined and a compile-time error occurs.
- Otherwise, the namespace-or-type-name is of the form `N.I`, where `N` is a namespace-or-type-name consisting of all identifiers but the rightmost one, and `I` is the rightmost identifier. `N` is first resolved as a namespace-or-type-name. If the resolution of `N` is not successful, a compile-time error occurs. Otherwise, `N.I` is resolved as follows:
  - If `N` is a namespace and `I` is the name of an accessible member of that namespace, then `N.I` refers to that member and, depending on the member, is classified as a namespace or a type.
  - If `N` is a class or struct type and `I` is the name of an accessible type in `N`, then `N.I` refers to that type.
  - Otherwise, `N.I` is an invalid namespace-or-type-name, and a compile-time error occurs.

3.8.1 Fully qualified names

Every namespace and type has a fully qualified name, which uniquely identifies the namespace or type amongst all others. The fully qualified name of a namespace or type `N` is determined as follows:

- If `N` is a member of the global namespace, its fully qualified name is `N`.
- Otherwise, its fully qualified name is `S.N`, where `S` is the fully qualified name of the namespace or type in which `N` is declared.

In other words, the fully qualified name of `N` is the complete hierarchical path of identifiers that lead to `N`, starting from the global namespace. Because every member of a namespace or type must have a unique name, it follows that the fully qualified name of a namespace or type is always unique.

The example below shows several namespace and type declarations along with their associated fully qualified names.

```
class A {}            // A
namespace X            // X
{
   class B            // X.B
   {
      class C {}      // X.B.C
   }
   namespace Y         // X.Y
   {
      class D {}      // X.Y.D
   }
}
namespace X.Y         // X.Y
{
   class E {}         // X.Y.E
}
```

3.9 Automatic memory management

C# employs automatic memory management, which frees developers from manually allocating and freeing the memory occupied by objects. Automatic memory management policies are implemented by a garbage collector. The memory management life cycle of an object is as follows:

1. When the object is created, memory is allocated for it, the constructor is run, and the object is considered live.
2. If the object, or any part of it, cannot be accessed by any possible continuation of execution, other than the running of destructors, the object is considered no longer in use, and it becomes eligible for destruction. The C# compiler and the garbage collector may choose to analyze code to determine which references to an object may be used in the future. For instance, if a local variable that is in scope is the only existing reference to an object, but that local variable is never referred to in any possible continuation of execution from the current execution point in the procedure, the garbage collector may (but is not required to) treat the object as no longer in use.
3. Once the object is eligible for destruction, at some unspecified later time the destructor (Section 10.12) (if any) for the object is run. Unless overridden by explicit calls, the destructor for the object is run once only.
4. Once the destructor for an object is run, if that object, or any part of it, cannot be accessed by any possible continuation of execution, including the running of destructors, the object is considered inaccessible and the object becomes eligible for collection.
5. Finally, at some time after the object becomes eligible for collection, the garbage collector frees the memory associated with that object.

The garbage collector maintains information about object usage, and uses this information to make memory management decisions, such as where in memory to locate a newly created object, when to relocate an object, and when an object is no longer in use or inaccessible.

Like other languages that assume the existence of a garbage collector, C# is designed so that the garbage collector may implement a wide range of memory management policies. For instance, C# does not require that destructors be run or that objects be collected as soon as they are eligible, or that destructors be run in any particular order, or on any particular thread.

The behavior of the garbage collector can be controlled, to some degree, via static methods on the class `System.GC`. This class can be used to request a collection to occur, destructors to be run (or not run), and so forth.

Since the garbage collector is allowed wide latitude in deciding when to collect objects and run destructors, a conforming implementation may produce output that differs from that shown by the following code. The program

```
using System;
class A
{
   ~A() {
      Console.WriteLine("Destruct instance of A");
   }
}
class B
{
   object Ref;
   public B(object o) {
      Ref = o;
   }
   ~B() {
      Console.WriteLine("Destruct instance of B");
   }
}
class Test
{
   static void Main() {
      B b = new B(new A());
      b = null;
      GC.Collect();
      GC.WaitForPendingFinalizers();
   }
}
```

creates an instance of class `A` and an instance of class `B`. These objects become eligible for garbage collection when the variable `b`

is assigned the value `null`, since after this time it is impossible for any user-written code to access them. The output could be either

```
Destruct instance of A
Destruct instance of B
```

or

```
Destruct instance of B
Destruct instance of A
```

because the language imposes no constraints on the order in which objects are garbage collected.

In subtle cases, the distinction between "eligible for destruction" and "eligible for collection" can be important. For example,

```
using System;
class A
{
   ~A() {
      Console.WriteLine("Destruct instance of A");
   }
   public void F() {
      Console.WriteLine("A.F");
      Test.RefA = this;
   }
}
class B
{
   public A Ref;
   ~B() {
      Console.WriteLine("Destruct instance of B");
      Ref.F();
   }
}
class Test
{
   public static A RefA;
   public static B RefB;
   static void Main() {
      RefB = new B();
      RefA = new A();
      RefB.Ref = RefA;
      RefB = null;
      RefA = null;
      // A and B now eligible for destruction
      GC.Collect();
      GC.WaitForPendingFinalizers();
      // B now eligible for collection, but A is not
      if (RefA != null)
         Console.WriteLine("RefA is not null");
   }
}
```

In the above program, if the garbage collector chooses to run the destructor of `A` before the destructor of `B`, then the output of this program might be:

```
Destruct instance of A
Destruct instance of B
A.F
RefA is not null
```

Note that although the instance of `A` was not in use and `A`'s destructor was run, it is still possible for methods of `A` (in this case, `F`) to be called from another destructor. Also, note that running of a destructor may cause an object to become usable from the mainline program again. In this case, the running of `B`'s destructor caused an instance of `A` that was previously not in use to

become accessible from the live reference `Test.RefA`. After the call to `WaitForPendingFinalizers`, the instance of `B` is eligible for collection, but the instance of `A` is not, because of the reference `Test.RefA`.

To avoid confusion and unexpected behavior, it is generally a good idea for destructors to only perform cleanup on data stored in their object's own fields, and not to perform any actions on referenced objects or static fields.

3.10 Execution order

Execution of a C# program proceeds such that the side effects of each executing thread are preserved at critical execution points. A side effect is defined as a read or write of a volatile field, a write to a non-volatile variable, a write to an external resource, and the throwing of an exception. The critical execution points at which the order of these side effects must be preserved are references to volatile fields (Section 10.4.3), lock statements (Section 8.12), and thread creation and termination. The execution environment is free to change the order of execution of a C# program, subject to the following constraints:

- Data dependence is preserved within a thread of execution. That is, the value of each variable is computed as if all statements in the thread were executed in original program order.
- Initialization ordering rules are preserved (Section 10.4.4 and Section 10.4.5).
- The ordering of side effects is preserved with respect to volatile reads and writes (Section 10.4.3). Additionally, the execution environment need not evaluate part of an expression if it can deduce that that expression's value is not used and that no needed side effects are produced (including any caused by calling a method or accessing a volatile field). When program execution is interrupted by an asynchronous event (such as an exception thrown by another thread), it is not guaranteed that the observable side effects are visible in the original program order.

4. Types

The types of the C# language are divided into two main categories: value types and reference types.

type:
  value-type
  reference-type

A third category of types, pointers, is available only in unsafe code. This is discussed further in Section A.2.

Value types differ from reference types in that variables of the value types directly contain their data, whereas variables of the reference types store references to their data, the latter being known as objects. With reference types, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With value types, the variables each have their own copy of the data, and it is not possible for operations on one to affect the other.

C#'s type system is unified such that a value of any type can be treated as an object. Every type in C# directly or indirectly derives from the `object` class type, and `object` is the ultimate base class of all types. Values of reference types are treated as objects simply by viewing the values as type `object`. Values of value types are treated as objects by performing boxing and unboxing operations (Section 4.3).

4.1 Value types

A value type is either a struct type or an enumeration type. C# provides a set of predefined struct types called the simple types. The simple types are identified through reserved words.

value-type:
  struct-type
  enum-type
struct-type:
  type-name
  simple-type
simple-type:
  numeric-type
  bool
numeric-type:
  integral-type
  floating-point-type
  decimal
integral-type:
  sbyte
  byte
  short
  ushort
  int
  uint
  long
  ulong
  char
floating-point-type:
  float
  double
enum-type:
  type-name

A variable of a value type always contains a value of that type. Unlike reference types, it is not possible for a value of a value type to be `null` or to reference an object of a more derived type.

Assignment to a variable of a value type creates a copy of the value being assigned. This differs from assignment to a variable of a reference type, which copies the reference but not the object identified by the reference.

4.1.1 The System.ValueType type

All value types implicitly inherit from the class `System.ValueType`, which, in turn, inherits from class `object`. It is not possible for any type to derive from a value type, and value types are thus implicitly sealed (Section 10.1.1.2).

Note that `System.ValueType` is not itself a *value-type*. Rather, it is a *class-type* from which all *value-types* are automatically derived.

4.1.2 Default constructors

All value types implicitly declare a public parameterless instance constructor called the default constructor. The default constructor returns a zero-initialized instance known as the default value for the value type:

- For all *simple-types*, the default value is the value produced by a bit pattern of all zeros:
  - For `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, and `ulong`, the default value is `0`.
  - For `char`, the default value is `'\x0000'`.
  - For `float`, the default value is `0.0f`.
  - For `double`, the default value is `0.0d`.
  - For `decimal`, the default value is `0.0m`.
  - For `bool`, the default value is `false`.
- For an *enum-type* `E`, the default value is `0`.
- For a *struct-type*, the default value is the value produced by setting all value type fields to their default value and all reference type fields to `null`.

Like any other instance constructor, the default constructor of a value type is invoked using the `new` operator. For efficiency reasons, this requirement is not intended to actually have the implementation generate a constructor call. In the example below, variables `i` and `j` are both initialized to zero.

```
class A
{
   void F() {
      int i = 0;
      int j = new int();
   }
}
```

Because every value type implicitly has a public parameterless instance constructor, it is not possible for a struct type to contain an explicit declaration of a parameterless constructor. A struct type is however permitted to declare parameterized instance constructors (Section 11.3.8).

4.1.3 Struct types

A struct type is a value type that can declare constants, fields, methods, properties, indexers, operators, instance constructors, static constructors, and nested types. Struct types are described in Section 11.

4.1.4 Simple types

C# provides a set of predefined struct types called the simple types. The simple types are identified through reserved words, but these reserved words are simply aliases for predefined struct types in the `System` namespace, as described in the table below.

Reserved word	Aliased type
`sbyte`	`System.SByte`
`byte`	`System.Byte`
`short`	`System.Int16`
`ushort`	`System.UInt16`
`int`	`System.Int32`
`uint`	`System.UInt32`
`long`	`System.Int64`
`ulong`	`System.UInt64`
`char`	`System.Char`
`float`	`System.Single`
`double`	`System.Double`
`bool`	`System.Boolean`
`decimal`	`System.Decimal`

Because a simple type aliases a struct type, every simple type has members. For example, `int` has the members declared in `System.Int32` and the members inherited from `System.Object`, and the following statements are permitted:

```
int i = int.MaxValue;         // System.Int32.MaxValue constant
string s = i.ToString();      // System.Int32.ToString() instance method
string t = 123.ToString();      // System.Int32.ToString() instance method
```

The simple types differ from other struct types in that they permit certain additional operations:

- Most simple types permit values to be created by writing literals (Section 2.4.4). For example, `123` is a literal of type `int` and `'a'` is a literal of type `char`. C# makes no provision for literals of struct types in general, and non-default values of other struct types are ultimately always created through instance constructors of those struct types.
- When the operands of an expression are all simple type constants, it is possible for the compiler to evaluate the expression

at compile-time. Such an expression is known as a constant-expression (Section 7.15). Expressions involving operators defined by other struct types are not considered to be constant expressions.

- Through `const` declarations it is possible to declare constants of the simple types (Section 10.3). It is not possible to have constants of other struct types, but a similar effect is provided by `static readonly` fields.
- Conversions involving simple types can participate in evaluation of conversion operators defined by other struct types, but a user-defined conversion operator can never participate in evaluation of another user-defined operator (Section 6.4.2).

4.1.5 Integral types

C# supports nine integral types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, and `char`. The integral types have the following sizes and ranges of values:

- The `sbyte` type represents signed 8-bit integers with values between –128 and 127.
- The `byte` type represents unsigned 8-bit integers with values between 0 and 255.
- The `short` type represents signed 16-bit integers with values between –32768 and 32767.
- The `ushort` type represents unsigned 16-bit integers with values between 0 and 65535.
- The `int` type represents signed 32-bit integers with values between –2147483648 and 2147483647.
- The `uint` type represents unsigned 32-bit integers with values between 0 and 4294967295.
- The `long` type represents signed 64-bit integers with values between –9223372036854775808 and 9223372036854775807.
- The `ulong` type represents unsigned 64-bit integers with values between 0 and 18446744073709551615.
- The `char` type represents unsigned 16-bit integers with values between 0 and 65535. The set of possible values for the `char` type corresponds to the Unicode character set. Although `char` has the same representation as `ushort`, not all operations permitted on one type are permitted on the other.

The integral-type unary and binary operators always operate with signed 32-bit precision, unsigned 32-bit precision, signed 64-bit precision, or unsigned 64-bit precision:

- For the unary `+` and `~` operators, the operand is converted to type `T`, where `T` is the first of `int`, `uint`, `long`, and `ulong` that can fully represent all possible values of the operand. The operation is then performed using the precision of type `T`, and the type of the result is `T`.
- For the unary `-` operator, the operand is converted to type `T`, where `T` is the first of `int` and `long` that can fully represent all possible values of the operand. The operation is then performed using the precision of type `T`, and the type of the result is `T`. The unary `-` operator cannot be applied to operands of type `ulong`.
- For the binary `+`, `-`, `*`, `/`, `%`, `&`, `^`, `|`, `==`, `!=`, `>`, `<`, `>=`, and `<=` operators, the operands are converted to type `T`, where `T` is the first of `int`, `uint`, `long`, and `ulong` that can fully represent all possible values of both operands. The operation is then performed using the precision of type `T`, and the type of the result is `T` (or `bool` for the relational operators). It is not permitted for one operand to be of type `long` and the other to be of type `ulong` with the binary operators.
- For the binary `<<` and `>>` operators, the left operand is converted to type `T`, where `T` is the first of `int`, `uint`, `long`, and `ulong` that can fully represent all possible values of the operand. The operation is then performed using the precision of type `T`, and the type of the result is `T`.

The `char` type is classified as an integral type, but it differs from the other integral types in two ways:

- There are no implicit conversions from other types to the `char` type. In particular, even though the `sbyte`, `byte`, and `ushort` types have ranges of values that are fully representable using the `char` type, implicit conversions from `sbyte`, `byte`, or `ushort` to `char` do not exist.
- Constants of the `char` type must be written as character-literals or as integer-literals in combination with a cast to type `char`. For example, `(char)10` is the same as `'\x000A'`.

The `checked` and `unchecked` operators and statements are used to control overflow checking for integral-type arithmetic operations and conversions (Section 7.5.12). In a `checked` context, an overflow produces a compile-time error or causes a `System.OverflowException` to be thrown. In an `unchecked` context, overflows are ignored and any high-order bits that do not fit in the destination type are discarded.

4.1.6 Floating point types

C# supports two floating point types: `float` and `double`. The `float` and `double` types are represented using the 32-bit single-precision and 64-bit double-precision IEEE 754 formats, which provide the following sets of values:

- Positive zero and negative zero. In most situations, positive zero and negative zero behave identically as the simple value zero, but certain operations distinguish between the two (Section 7.7.2).
- Positive infinity and negative infinity. Infinities are produced by such operations as dividing a non-zero number by zero. For example, `1.0 / 0.0` yields positive infinity, and `-1.0 / 0.0` yields negative infinity.
- The Not-a-Number value, often abbreviated NaN. NaN's are produced by invalid floating-point operations, such as dividing zero by zero.
- The finite set of non-zero values of the form $s \times m \times 2^e$, where s is 1 or −1, and m and e are determined by the particular floating-point type: For `float`, $0 < m < 2^{24}$ and −149 ≤ e ≤ 104, and for `double`, $0 < m < 2^{53}$ and −1075 ≤ e ≤ 970. Denormalized floating-point numbers are considered valid non-zero values.

The `float` type can represent values ranging from approximately 1.5×10^{-45} to 3.4×10^{38} with a precision of 7 digits.

The `double` type can represent values ranging from approximately 5.0×10^{-324} to 1.7×10^{308} with a precision of 15-16 digits.

If one of the operands of a binary operator is of a floating-point type, then the other operand must be of an integral type or a floating-point type, and the operation is evaluated as follows:

- If one of the operands is of an integral type, then that operand is converted to the floating-point type of the other operand.
- Then, if either of the operands is of type `double`, the other operand is converted to `double`, the operation is performed using at least `double` range and precision, and the type of the result is `double` (or `bool` for the relational operators).
- Otherwise, the operation is performed using at least `float` range and precision, and the type of the result is `float` (or `bool` for the relational operators).

The floating-point operators, including the assignment operators, never produce exceptions. Instead, in exceptional situations, floating-point operations produce zero, infinity, or NaN, as described below:

- If the result of a floating-point operation is too small for the destination format, the result of the operation becomes positive zero or negative zero.
- If the result of a floating-point operation is too large for the destination format, the result of the operation becomes positive infinity or negative infinity.
- If a floating-point operation is invalid, the result of the operation becomes NaN.
- If one or both operands of a floating-point operation is NaN, the result of the operation becomes NaN.

Floating-point operations may be performed with higher precision than the result type of the operation. For example, some hardware architectures support an "extended" or "long double" floating-point type with greater range and precision than the `double` type, and implicitly perform all floating-point operations using this higher precision type. Only at excessive cost in performance can such hardware architectures be made to perform floating-point operations with *less* precision, and rather than require an implementation to forfeit both performance and precision, C# allows a higher precision type to be used for all floating-point operations. Other than delivering more precise results, this rarely has any measurable effects. However, in expressions of the form `x * y / z`, where the multiplication produces a result that is outside the `double` range, but the subsequent division brings the temporary result back into the `double` range, the fact that the expression is evaluated in a higher range format may cause a finite result to be produced instead of an infinity.

4.1.7 The decimal type

The `decimal` type is a 128-bit data type suitable for financial and monetary calculations. The `decimal` type can represent values ranging from $1.0 \times 10-^{28}$ to approximately 7.9×10^{28} with 28-29 significant digits.

The finite set of values of type `decimal` are of the form $(-1)^s$ x *c* x 10^{-e}, where the sign *s* is 0 or 1, the coefficient *c* is given by 0 ≤ *c* < 2^{96}, and the scale *e* is such that 0 ≤ *e ≤* 28. The decimal type does not support signed zeros, infinities, or NaN's. A `decimal` is represented as a 96-bit integer scaled by a power of ten. For `decimal`s with an absolute value less than `1.0m`, the value is exact to the 28th decimal place, but no further. For `decimal`s with an absolute value greater than or equal to `1.0m`, the value is exact to 28 or 29 digits. Contrary to the `float` and `double` data types, decimal fractional numbers such as 0.1 can be represented exactly in the `decimal` representation. In the `float` and `double` representations, such numbers are often infinite fractions, making those representations more prone to round-off errors.

If one of the operands of a binary operator is of type `decimal`, then the other operand must be of an integral type or of type `decimal`. If an integral type operand is present, it is converted to `decimal` before the operation is performed.

The result of an operation on values of type `decimal` is that which would result from calculating an exact result (preserving scale, as defined for each operator) and then rounding to fit the representation. Results are rounded to the nearest representable value, and, when a result is equally close to two representable values, to the value that has an even number in the least significant digit position (this is known as "banker's rounding"). A zero result always has a sign of 0 and a scale of 0.

If a decimal arithmetic operation produces a value less than or equal to 5 x 10^{-29} in absolute value, the result of the operation becomes zero. If a `decimal` arithmetic operation produces a result that is too large for the `decimal` format, a `System.OverflowException` is thrown.

The `decimal` type has greater precision but smaller range than the floating-point types. Thus, conversions from the floating-point types to `decimal` might produce overflow exceptions, and conversions from `decimal` to the floating-point types might cause loss of precision. For these reasons, no implicit conversions exist between the floating-point types and `decimal`, and without explicit casts, it is not possible to mix floating-point and `decimal` operands in the same expression.

4.1.8 The bool type

The `bool` type represents Boolean logical quantities. The possible values of type `bool` are `true` and `false`.

No standard conversions exist between `bool` and other types. In particular, the `bool` type is distinct and separate from the integral types, and a `bool` value cannot be used in place of an integral value, and vice versa.

In the C and C++ languages, a zero integral or floating-point value or a null pointer can be converted to the Boolean value `false`, and a non-zero integral or floating-point value, or a non-null pointer can be converted to the Boolean value `true`. In C#, such conversions are accomplished by explicitly comparing an integral or floating-point value to zero, or by explicitly comparing an object reference to `null`.

4.1.9 Enumeration types

An enumeration type is a distinct type with named constants. Every enumeration type has an underlying type, which must be `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `long` or `ulong`. The set of values of the enumeration type is the same as the set of values of the underlying type. Values of the enumeration type are not restricted to the values of the named constants. Enumeration types are defined through enumeration declarations (Section 14.1).

4.2 Reference types

A reference type is a class type, an interface type, an array type, or a delegate type.

reference-type:
  class-type
  interface-type
  array-type
  delegate-type
class-type:
  type-name
  object
  string
interface-type:
  type-name
array-type:
  non-array-type *rank-specifiers*
non-array-type:
  type
rank-specifiers:
  rank-specifier
  rank-specifiers *rank-specifier*
rank-specifier:
  [*dim-separators*$_{opt}$]
dim-separators:
  ,
  dim-separators ,
delegate-type:
  type-name

A reference type value is a reference to an instance of the type, the latter known as an object. The special value `null` is compatible with all reference types and indicates the absence of an instance.

4.2.1 Class types

A class type defines a data structure that contains data members (constants and fields), function members (methods, properties, events, indexers, operators, instance constructors, destructors and static constructors), and nested types. Class types support inheritance, a mechanism whereby derived classes can extend and specialize base classes. Instances of class types are created using object-creation-expressions (Section 7.5.10.1).

Class types are described in Section 10.

Certain predefined class types have special meaning in the C# language, as described in the following table.

Class type	Description
`System.Object`	The ultimate base class of all other types (Section 4.2.2).
`System.String`	The string type of the C# language (Section 4.2.3).
`System.ValueType`	The base class of all value types (Section 4.1.1).
`System.Enum`	The base class of all enum types (Section 14).
`System.Array`	The base class of all array types (Section 12).
`System.Delegate`	The base class of all delegate types (Section 15).
`System.Exception`	The base class of all exception types (Section 16).

4.2.2 The object type

The `object` class type is the ultimate base class of all other types. Every type in C# directly or indirectly derives from the `object` class type.

The keyword `object` is simply an alias for the predefined class `System.Object`.

4.2.3 The string type

The `string` type is a sealed class type that inherits directly from `object`. Instances of the `string` class represent Unicode character strings.

Values of the `string` type can be written as string literals (Section 2.4.4).

The keyword `string` is simply an alias for the predefined class `System.String`.

4.2.4 Interface types

An interface defines a contract. A class or struct that implements an interface must adhere to its contract. An interface may inherit from multiple base interfaces, and a class or struct may implement multiple interfaces.

Interface types are described in Section 13.

4.2.5 Array types

An array is a data structure that contains zero or more variables that are accessed through computed indices. The variables contained in an array, also called the elements of the array, are all of the same type, and this type is called the element type of the array.

Array types are described in Section 12.

4.2.6 Delegate types

A delegate is a data structure that refers to one or more methods, and for instance methods, it also refers to their corresponding object instances.

The closest equivalent of a delegate in C or C++ is a function pointer, but whereas a function pointer can only reference static functions, a delegate can reference both static and instance methods. In the latter case, the delegate stores not only a reference to the method's entry point, but also a reference to the object instance on which to invoke the method.

Delegate types are described in Section 15.

4.3 Boxing and unboxing

The concept of boxing and unboxing is central to C#'s type system. It provides a bridge between *value-type*s and *reference-type*s by permitting any value of a *value-type* to be converted to and from type `object`. Boxing and unboxing enables a unified view of the type system wherein a value of any type can ultimately be treated as an object.

4.3.1 Boxing conversions

A boxing conversion permits a *value-type* to be implicitly converted to a *reference-type*. The following boxing conversions exist:

- From any *value-type* (including any *enum-type*) to the type `object`.
- From any *value-type* (including any *enum-type*) to the type `System.ValueType`.
- From any *value-type* to any *interface-type* implemented by the *value-type*.
- From any *enum-type* to the type `System.Enum`.

Boxing a value of a *value-type* consists of allocating an object instance and copying the *value-type* value into that instance.

The actual process of boxing a value of a *value-type* is best explained by imagining the existence of a boxing class for that type. For any *value-type* `T`, the boxing class behaves as if it were declared as follows:

```
sealed class T_Box: System.ValueType
{
   T value;
   public T_Box(T t) {
      value = t;
   }
}
```

Boxing of a value `v` of type `T` now consists of executing the expression `new T_Box(v)`, and returning the resulting instance as a value of type `object`. Thus, the statements

```
int i = 123;
object box = i;
```

conceptually correspond to

```
int i = 123;
object box = new int_Box(i);
```

Boxing classes like `T_Box` and `int_Box` above do not actually exist and the dynamic type of a boxed value is not actually a class type. Instead, a boxed value of type `T` has the dynamic type `T`, and a dynamic type check using the `is` operator can simply reference type `T`. For example,

```
int i = 123;
object box = i;
if (box is int) {
   Console.Write("Box contains an int");
}
```

will output the string "`Box contains an int`" on the console.

A boxing conversion implies making a copy of the value being boxed. This is different from a conversion of a *reference-type* to type `object`, in which the value continues to reference the same instance and simply is regarded as the less derived type `object`. For example, given the declaration

```
struct Point
{
   public int x, y;
   public Point(int x, int y) {
      this.x = x;
      this.y = y;
   }
}
```

the following statements

```
Point p = new Point(10, 10);
object box = p;
p.x = 20;
Console.Write(((Point)box).x);
```

will output the value 10 on the console because the implicit boxing operation that occurs in the assignment of `p` to `box` causes the value of `p` to be copied. Had `Point` been declared a `class` instead, the value 20 would be output because `p` and `box` would reference the same instance.

4.3.2 Unboxing conversions

An unboxing conversion permits a *reference-type* to be explicitly converted to a *value-type*. The following unboxing conversions exist:

- From the type `object` to any *value-type* (including any *enum-type*).
- From the type `System.ValueType` to any *value-type* (including any *enum-type*).
- From any *interface-type* to any *value-type* that implements the *interface-type*.
- From the type `System.Enum` to any *enum-type*.

An unboxing operation consists of first checking that the object instance is a boxed value of the given *value-type*, and then copying the value out of the instance.

Referring to the imaginary boxing class described in the previous section, an unboxing conversion of an object `box` to a *value-type* `T` consists of executing the expression `((T_Box)box).value`. Thus, the statements

```
object box = 123;
int i = (int)box;
```

conceptually correspond to

```
object box = new int_Box(123);
int i = ((int_Box)box).value;
```

For an unboxing conversion to a given *value-type* to succeed at run-time, the value of the source operand must be a reference to an object that was previously created by boxing a value of that *value-type*. If the source operand is `null`, a `System.NullReferenceException` is thrown. If the source operand is a reference to an incompatible object, a `System.InvalidCastException` is thrown.

5. Variables

Variables represent storage locations. Every variable has a type that determines what values can be stored in the variable. C# is a type-safe language, and the C# compiler guarantees that values stored in variables are always of the appropriate type. The value of a variable can be changed through assignment or through use of the ++ and -- operators.

A variable must be definitely assigned (Section 5.3) before its value can be obtained.

As described in the following sections, variables are either initially assigned or initially unassigned. An initially assigned variable has a well-defined initial value and is always considered definitely assigned. An initially unassigned variable has no initial value. For an initially unassigned variable to be considered definitely assigned at a certain location, an assignment to the variable must occur in every possible execution path leading to that location.

5.1 Variable categories

C# defines seven categories of variables: static variables, instance variables, array elements, value parameters, reference parameters, output parameters, and local variables. The sections that follow describe each of these categories.

In the example

```
class A
{
   public static int x;
   int y;
   void F(int[] v, int a, ref int b, out int c) {
      int i = 1;
      c = a + b++;
   }
}
```

`x` is a static variable, `y` is an instance variable, `v[0]` is an array element, `a` is a value parameter, `b` is a reference parameter, `c` is an output parameter, and `i` is a local variable.

5.1.1 Static variables

A field declared with the `static` modifier is called a static variable. A static variable comes into existence before execution of the static constructor (Section 10.11) for its containing type, and ceases to exist when the associated application domain ceases to exist.

The initial value of a static variable is the default value (Section 5.2) of the variable's type.

For purposes of definite assignment checking, a static variable is considered initially assigned.

5.1.2 Instance variables

A field declared without the `static` modifier is called an instance variable.

5.1.2.1 Instance variables in classes

An instance variable of a class comes into existence when a new instance of that class is created, and ceases to exist when there are no references to that instance and the instance's destructor (if any) has executed.

The initial value of an instance variable of a class is the default value (Section 5.2) of the variable's type.

For the purpose of definite assignment checking, an instance variable of a class is considered initially assigned.

5.1.2.2 Instance variables in structs

An instance variable of a struct has exactly the same lifetime as the struct variable to which it belongs. In other words, when a variable of a struct type comes into existence or ceases to exist, so too do the instance variables of the struct.

The initial assignment state of an instance variable of a struct is the same as that of the containing struct variable. In other words, when a struct variable is considered initially assigned, so too are its instance variables, and when a struct variable is considered initially unassigned, its instance variables are likewise unassigned.

5.1.3 Array elements

The elements of an array come into existence when an array instance is created, and cease to exist when there are no references to that array instance.

The initial value of each of the elements of an array is the default value (Section 5.2) of the type of the array elements.

For the purpose of definite assignment checking, an array element is considered initially assigned.

5.1.4 Value parameters

A parameter declared without a `ref` or `out` modifier is a value parameter.

A value parameter comes into existence upon invocation of the function member (method, instance constructor, accessor, or operator) (Section 7.4) to which the parameter belongs, and is initialized with the value of the argument given in the invocation. A value parameter ceases to exist upon return of the function member.

For the purpose of definite assignment checking, a value parameter is considered initially assigned.

5.1.5 Reference parameters

A parameter declared with a `ref` modifier is a reference parameter.

A reference parameter does not create a new storage location. Instead, a reference parameter represents the same storage location as the variable given as the argument in the function member invocation. Thus, the value of a reference parameter is always the same as the underlying variable.

The following definite assignment rules apply to reference parameters. Note the different rules for output parameters described in Section 5.1.6.

- A variable must be definitely assigned (Section 5.3) before it can be passed as a reference parameter in a function member invocation.
- Within a function member, a reference parameter is considered initially assigned.

Within an instance method or instance accessor of a struct type, the `this` keyword behaves exactly as a reference parameter of the struct type (Section 7.5.7).

5.1.6 Output parameters

A parameter declared with an `out` modifier is an output parameter.

An output parameter does not create a new storage location. Instead, an output parameter represents the same storage location as the variable given as the argument in the function member invocation. Thus, the value of an output parameter is always the same as the underlying variable.

The following definite assignment rules apply to output parameters. Note the different rules for reference parameters described in Section 5.1.5.

- A variable need not be definitely assigned before it can be passed as an output parameter in a function member invocation.
- Following the normal completion of a function member invocation, each variable that was passed as an output parameter is considered assigned in that execution path.
- Within a function member, an output parameter is considered initially unassigned.
- Every output parameter of a function member must be definitely assigned (Section 5.3) before the function member returns normally.

Within an instance constructor of a struct type, the `this` keyword behaves exactly as an output parameter of the struct type (Section 7.5.7).

5.1.7 Local variables

A local variable is declared by a local-variable-declaration, which may occur in a block, a for-statement, a switch-statement, or a using-statement.

The lifetime of a local variable is the portion of program execution during which storage is guaranteed to be reserved for it. This lifetime extends from entry into the block, for-statement, switch-statement, or using-statement with which it is associated, until execution of that block, for-statement, switch-statement, or using-statement ends in any way. (Entering an enclosed block or calling a method suspends, but does not end, execution of the current block, for-statement, switch-statement, or using-statement.) If the parent block, for-statement, switch-statement, or using-statement is entered recursively, a new instance of the local variable is created each time, and its local-variable-initializer, if any, is evaluated each time.

A local variable is not automatically initialized and thus has no default value. For the purpose of definite assignment checking, a local variable is considered initially unassigned. A *local-variable-declaration* may include a *local-variable-initializer*, in which case the variable is considered definitely assigned in its entire scope, except within the expression provided in the *local-variable-initializer*.

Within the scope of a local variable, it is a compile-time error to refer to that local variable in a textual position that precedes its *local-variable-declarator*.

The actual lifetime of a local variable is implementation-dependent. For example, a compiler might statically determine that a local variable in a block is only used for a small portion of that block. Using this analysis, the compiler could generate code that results in the variable's storage having a shorter lifetime than its containing block.

The storage referred to by a local reference variable is reclaimed independently of the lifetime of that local reference variable (Section 3.9).

A local variable is also declared by a foreach-statement and by a specific-catch-clause for a try-statement. For a foreach-statement, the local variable is an iteration variable (Section 8.8.4). For a specific-catch-clause, the local variable is an exception variable (Section 8.10). A local variable declared by a foreach-statement or specific-catch-clause is considered definitely assigned in its entire scope.

5.2 Default values

The following categories of variables are automatically initialized to their default values:

- Static variables.
- Instance variables of class instances.
- Array elements.

The default value of a variable depends on the type of the variable and is determined as follows:

- For a variable of a *value-type*, the default value is the same as the value computed by the *value-type*'s default constructor (Section 4.1.1).
- For a variable of a *reference-type*, the default value is `null`.

Initialization to default values is typically done by having the memory manager or garbage collector initialize memory to all-bits-zero before it is allocated for use. For this reason, it is convenient to use all-bits-zero to represent the null reference.

5.3 Definite assignment

At a given location in the executable code of a function member, a variable is said to be definitely assigned if the compiler can prove, by static flow analysis, that the variable has been automatically initialized or has been the target of at least one assignment. The rules of definite assignment are:

- An initially assigned variable (Section 5.3.1) is always considered definitely assigned.
- An initially unassigned variable (Section 5.3.2) is considered definitely assigned at a given location if all possible execution paths leading to that location contain at least one of the following:
    - A simple assignment (Section 7.13.1) in which the variable is the left operand.
    - An invocation expression (Section 7.5.5) or object creation expression (Section 7.5.10.1) that passes the variable as an output parameter.
    - For a local variable, a local variable declaration (Section 8.5) that includes a variable initializer.

The definite assignment states of instance variables of a struct-type variable are tracked individually as well as collectively. In additional to the rules above, the following rules apply to struct-type variables and their instance variables:

- An instance variable is considered definitely assigned if its containing struct-type variable is considered definitely assigned.
- A struct-type variable is considered definitely assigned if each of its instance variables is considered definitely assigned.

Definite assignment is a requirement in the following contexts:

- A variable must be definitely assigned at each location where its value is obtained. This ensures that undefined values never occur. The occurrence of a variable in an expression is considered to obtain the value of the variable, except when
    - the variable is the left operand of a simple assignment,
    - the variable is passed as an output parameter, or
    - the variable is a struct-type variable and occurs as the left operand of a member access.
- A variable must be definitely assigned at each location where it is passed as a reference parameter. This ensures that the function member being invoked can consider the reference parameter initially assigned.
- All output parameters of a function member must be definitely assigned at each location where the function member returns (through a `return` statement or through execution reaching the end of the function member body). This ensures that function members do not return undefined values in output parameters, thus enabling the compiler to consider a function member invocation that takes a variable as an output parameter equivalent to an assignment to the variable.
- The `this` variable of a *struct-type* instance constructor must be definitely assigned at each location where that instance constructor returns.

5.3.1 Initially assigned variables

The following categories of variables are classified as initially assigned:

- Static variables.
- Instance variables of class instances.
- Instance variables of initially assigned struct variables.
- Array elements.
- Value parameters.
- Reference parameters.
- Variables declared in a `catch` clause or a `foreach` statement.

5.3.2 Initially unassigned variables

The following categories of variables are classified as initially unassigned:

- Instance variables of initially unassigned struct variables.
- Output parameters, including the `this` variable of struct instance constructors.
- Local variables , except those declared in a catch clause or a foreach statement.

5.3.3 Precise rules for determining definite assignment

In order to determine that each used variable is definitely assigned, the compiler must use a process that is equivalent to the one described in this section.

The compiler processes the body of each function member that has one or more initially unassigned variables. For each initially unassigned variable *v*, the compiler determines a definite assignment state for *v* at each of the following points in the function member:

- At the beginning of each statement
- At the end point (Section 8.1) of each statement
- On each arc that transfers control to another statement or to the end point of a statement
- At the beginning of each expression
- At the end of each expression

The definite assignment state of *v* can be either:

- Definitely assigned. This indicates that on all possible control flows to this point, *v* has been assigned a value.
- Not definitely assigned. For the state of a variable at the end of an expression of type `bool`, the state of a variable that is not definitely assigned may (but does not necessarily) fall into one of the following sub-states:
- Definitely assigned after true expression. This state indicates that *v* is definitely assigned if the Boolean expression evaluated as true, but is not necessarily assigned if the Boolean expression evaluated as false.
- Definitely assigned after false expression. This state indicates that *v* is definitely assigned if the Boolean expression evaluated as false, but is not necessarily assigned if the Boolean expression evaluated as true.

The following rules govern how the state of a variable *v* is determined at each location.

5.3.3.1 General rules for statements

- *v* is not definitely assigned at the beginning of a function member body.
- *v* is definitely assigned at the beginning of any unreachable statement.
- The definite assignment state of *v* at the beginning of any other statement is determined by checking the definite assignment state of *v* on all control flow transfers that target the beginning of that statement. If (and only if) *v* is definitely assigned on all such control flow transfers, then *v* is definitely assigned at the beginning of the statement. The set of possible control flow transfers is determined in the same way as for checking statement reachability (Section 8.1).
- The definite assignment state of *v* at the end point of a block, `checked`, `unchecked`, `if`, `while`, `do`, `for`, `foreach`, `lock`, `using`, or `switch` statement is determined by checking the definite assignment state of *v* on all control flow transfers that target the end point of that statement. If *v* is definitely assigned on all such control flow transfers, then *v* is definitely assigned at the end point of the statement. Otherwise; *v* is not definitely assigned at the end point of the statement. The set of possible control flow transfers is determined in the same way as for checking statement reachability (Section 8.1).

5.3.3.2 Block statements, checked, and unchecked statements

The definite assignment state of *v* on the control transfer to the first statement of the statement list in the block (or to the end point of the block, if the statement list is empty) is the same as the definite assignment statement of *v* before the block, `checked`, or `unchecked` statement.

5.3.3.3 Expression statements

For an expression statement *stmt* that consists of the expression *expr*:

- *v* has the same definite assignment state at the beginning of *expr* as at the beginning of *stmt*.
- If *v* if definitely assigned at the end of *expr*, it is definitely assigned at the end point of *stmt*; otherwise; it is not definitely assigned at the end point of *stmt*.

5.3.3.4 Declaration statements

- If *stmt* is a declaration statement without initializers, then *v* has the same definite assignment state at the end point of *stmt* as at the beginning of *stmt*.
- If *stmt* is a declaration statement with initializers, then the definite assignment state for *v* is determined as if *stmt* were a statement list, with one assignment statement for each declaration with an initializer (in the order of declaration).

5.3.3.5 If statements

For an `if` statement *stmt* of the form:

```
if ( expr ) then-stmt else else-stmt
```

- *v* has the same definite assignment state at the beginning of *expr* as at the beginning of *stmt*.
- If *v* is definitely assigned at the end of *expr*, then it is definitely assigned on the control flow transfer to *then-stmt* and to either *else-stmt* or to the end-point of *stmt* if there is no else clause.
- If *v* has the state "definitely assigned after true expression" at the end of *expr*, then it is definitely assigned on the control flow transfer to *then-stmt*, and not definitely assigned on the control flow transfer to either *else-stmt* or to the end-point of *stmt* if there is no else clause.
- If *v* has the state "definitely assigned after false expression" at the end of *expr*, then it is definitely assigned on the control flow transfer to *else-stmt*, and not definitely assigned on the control flow transfer to *then-stmt*. It is definitely assigned at the end-point of *stmt* if and only if it is definitely assigned at the end-point of *then-stmt*.
- Otherwise, *v* is considered not definitely assigned on the control flow transfer to either the *then-stmt* or *else-stmt*, or to the end-point of *stmt* if there is no else clause.

5.3.3.6 Switch statements

In a `switch` statement *stmt* with a controlling expression *expr*:

- The definite assignment state of *v* at the beginning of *expr* is the same as the state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* on the control flow transfer to a reachable switch block statement list is the same as the definite assignment state of *v* at the end of *expr*.

5.3.3.7 While statements

For a `while` statement *stmt* of the form:

```
while ( expr ) while-body
```

- *v* has the same definite assignment state at the beginning of *expr* as at the beginning of *stmt*.
- If *v* is definitely assigned at the end of *expr*, then it is definitely assigned on the control flow transfer to *while-body* and to the end point of *stmt*.
- If *v* has the state "definitely assigned after true expression" at the end of *expr*, then it is definitely assigned on the control flow transfer to *while-body*, but not definitely assigned at the end-point of *stmt*.
- If *v* has the state "definitely assigned after false expression" at the end of *expr*, then it is definitely assigned on the control flow transfer to the end point of *stmt*, but not definitely assigned on the control flow transfer to *while-body*.

5.3.3.8 Do statements

For a `do` statement *stmt* of the form:

```
do do-body while ( expr ) ;
```

- *v* has the same definite assignment state on the control flow transfer from the beginning of *stmt* to *do-body* as at the beginning of *stmt*.
- *v* has the same definite assignment state at the beginning of *expr* as at the end point of *do-body*.
- If *v* is definitely assigned at the end of *expr*, then it is definitely assigned on the control flow transfer to the end point of *stmt*.
- If *v* has the state "definitely assigned after false expression" at the end of *expr*, then it is definitely assigned on the control flow transfer to the end point of *stmt*.

5.3.3.9 For statements

Definite assignment checking for a `for` statement of the form:

```
for ( for-initializer ; for-condition ; for-iterator ) embedded-statement
```

is done as if the statement were written:

```
{
   for-initializer ;
   while ( for-condition ) {
      embedded-statement ;
      for-iterator ;
   }
}
```

If the *for-condition* is omitted from the `for` statement, then evaluation of definite assignment proceeds as if *for-condition* were replaced with `true` in the above expansion.

5.3.3.10 Break, continue, and goto statements

The definite assignment state of *v* on the control flow transfer caused by a `break`, `continue`, or `goto` statement is the same as the definite assignment state of *v* at the beginning of the statement.

5.3.3.11 Throw statements

For a statement *stmt* of the form

```
throw expr ;
```

The definite assignment state of *v* at the beginning of *expr* is the same as the definite assignment state of *v* at the beginning of *stmt*.

5.3.3.12 Return statements

For a statement *stmt* of the form

```
return expr ;
```

- The definite assignment state of *v* at the beginning of *expr* is the same as the definite assignment state of *v* at the beginning of *stmt*.
- If *v* is an output parameter, then it must be definitely assigned either:
- after *expr*
- or at the end of the `finally` block of a `try-finally` or `try-catch-finally` that encloses the `return` statement.

5.3.3.13 Try-catch statements

For a statement *stmt* of the form:

```
try try-block
catch(...) catch-block-1
...
catch(...) catch-block-n
```

- The definite assignment state of *v* at the beginning of *try-block* is the same as the definite assignment state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* at the beginning of *catch-block-i* (for any *i*) is the same as the definite assignment state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* at the end-point of *stmt* is definitely assigned if (and only if) *v* is definitely assigned at the end-point of *try-block* and every *catch-block-i* (for every *i* from 1 to *n*).

5.3.3.14 Try-finally statements

For a `try` statement *stmt* of the form:

```
try try-block finally finally-block
```

- The definite assignment state of *v* at the beginning of *try-block* is the same as the definite assignment state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* at the beginning of *finally-block* is the same as the definite assignment state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* at the end-point of *stmt* is definitely assigned if (and only if) at least one of the following is true:
    - *v* is definitely assigned at the end-point of *try-block*
    - *v* is definitely assigned at the end-point of *finally-block*

If a control flow transfer (for example, a `goto` statement) is made that begins within *try-block*, and ends outside of *try-block*, then *v* is also considered definitely assigned on that control flow transfer if *v* is definitely assigned at the end-point of *finally-block*. (This is not an only if — if *v* is definitely assigned for another reason on this control flow transfer, then it is still considered definitely assigned.)

5.3.3.15 Try-catch-finally statements

Definite assignment analysis for a `try-catch-finally` statement of the form:

```
try try-block
catch(...) catch-block-1
...
catch(...) catch-block-n
finally finally-block
```

is done as if the statement were a `try-finally` statement enclosing a `try-catch` statement:

```
try {
   try try-block
   catch(...) catch-block-1
   ...
   catch(...) catch-block-n
}
finally finally-block
```

The following example demonstrates how the different blocks of a `try` statement (Section 8.10) affect definite assignment.

```
class A
{
   static void F() {
      int i, j;
      try {
         goto LABEL;
         // neither i nor j definitely assigned
         i = 1;
         // i definitely assigned
      }
      catch {
         // neither i nor j definitely assigned
         i = 3;
         // i definitely assigned
      }
      finally {
         // neither i nor j definitely assigned
         j = 5;
         // j definitely assigned
      }
      // i and j definitely assigned
   LABEL;
      // j definitely assigned

   }
}
```

5.3.3.16 Foreach statements

For a `foreach` statement *stmt* of the form:

```
foreach ( type identifier in expr ) embedded-statement
```

- The definite assignment state of *v* at the beginning of *expr* is the same as the state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* on the control flow transfer to *embedded-statement* or to the end point of *stmt* is the same as the state of *v* at the end of *expr*.

5.3.3.17 Using statements

For a `using` statement *stmt* of the form:

```
using ( resource-acquisition ) embedded-statement
```

- The definite assignment state of *v* at the beginning of *resource-acquisition* is the same as the state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* on the control flow transfer to *embedded-statement* is the same as the state of *v* at the end of *resource-acquisition*.

5.3.3.18 Lock statements

For a `lock` statement *stmt* of the form:

```
lock ( expr ) embedded-statement
```

- The definite assignment state of *v* at the beginning of *expr* is the same as the state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* on the control flow transfer to *embedded-statement* is the same as the state of *v* at the end of *expr*.

5.3.3.19 General rules for simple expressions

The following rule applies to these kinds of expressions: literals (Section 7.5.1), simple names (Section 7.5.2), member access expressions (Section 7.5.4), non-indexed base access expressions (Section 7.5.8), and `typeof` expressions (Section 7.5.11).

The definite assignment state of *v* at the end of such an expression is the same as the definite assignment state of *v* at the beginning of the expression.

5.3.3.20 General rules for expressions with embedded expressions

The following rules apply to these kinds of expressions: parenthesized expressions (Section 7.5.3), element access expressions (Section 7.5.6), base access expressions with indexing (Section 7.5.8), increment and decrement expressions (Section 7.5.9, Section 7.6.5), cast expressions (Section 7.6.6), unary `+`, `-`, `~`, `*` expressions, binary `+`, `-`, `*`, `/`, `%`, `<<`, `>>`, `<`, `<=`, `>`, `>=`, `==`, `!=`, `is`, `as`, `&`, `|`, `^` expressions (Section 7.7, Section 7.8, Section 7.9, Section 7.10), compound assignment expressions (Section 7.13.2), `checked` and `unchecked` expressions (Section 7.5.12), array and delegate creation expressions (Section 7.5.10).

Each of these expressions has one or more sub-expressions that are unconditionally evaluated in a fixed order. For example, the binary `%` operator evaluates the left hand side of the operator, then the right hand side. An indexing operation evaluates the indexed expression, and then evaluates each of the index expressions, in order from left to right. For an expression *expr*, which has sub-expressions *expr1*, *expr2*, ..., *exprn*, evaluated in that order:

- The definite assignment state of *v* at the beginning of *expr1* is the same as the definite assignment state at the beginning of *expr*.
- The definite assignment state of *v* at the beginning of *expri* (*i* greater than one) is the same as the definite assignment state at the end of *expri-1*.
- The definite assignment state of *v* at the end of *expr* is the same as the definite assignment state at the end of *exprn*.

5.3.3.21 Invocation expressions and object creation expressions

For an invocation expression *expr* of the form:

```
primary-expression ( arg1 , arg2 , ... , argn )
```

or an object creation expression of the form:

```
new type ( arg1 , arg2 , ... , argn )
```

- For an invocation expression, the definite assignment state of *v* before *primary-expression* is the same as the state of *v* before *expr*.
- For an invocation expression, the definite assignment state of *v* before *arg1* is the same as the state of *v* after *primary-expression*.
- For an object creation expression, the definite assignment state of *v* before *arg1* is the same as the state of *v* before *expr*.
- For each argument *argi*, the definite assignment state of *v* after *argi* is determined by the normal expression rules, ignoring any `ref` or `out` modifiers.
- For each argument *argi* for any *i* greater than one, the definite assignment state of *v* before *argi* is the same as the state of *v* after *argi-1*.
- If the variable *v* is passed as an `out` argument (i.e., an argument of the form "`out` *v*") in any of the arguments, then the state of *v* after *expr* is definitely assigned. Otherwise; the state of *v* after *expr* is the same as the state of *v* after *argn*.

5.3.3.22 Simple assignment expressions

For an expression *expr* of the form *w* = *expr-rhs*:

- The definite assignment state of *v* before *expr-rhs* is the same as the definite assignment state of *v* before *expr*.
- If *w* is the same variable as *v*, then the definite assignment state of *v* after *expr* is definitely assigned. Otherwise, the definite assignment state of *v* after *expr* is the same as the definite assignment state of *v* after *expr-rhs*.

5.3.3.23 && expressions

For an expression *expr* of the form *expr-first* `&&` *expr-second*:

- The definite assignment state of *v* before *expr-first* is the same as the definite assignment state of *v* before *expr*.
- The definite assignment state of *v* before *expr-second* is definitely assigned if the state of *v* after *expr-first* is either definitely assigned or "definitely assigned after true expression". Otherwise, it is not definitely assigned.
- The definite assignment state of *v* after *expr* is determined by:
- If the state of *v* after *expr-first* is definitely assigned, then the state of *v* after *expr* is definitely assigned.
- Otherwise, if the state of *v* after *expr-second* is definitely assigned, and the state of *v* after *expr-first* is "definitely assigned after false expression", then the state of *v* after *expr* is definitely assigned.
- Otherwise, if the state of *v* after *expr-second* is definitely assigned or "definitely assigned after true expression", then the state of *v* after *expr* is "definitely assigned after true expression".
- Otherwise, if the state of *v* after *expr-first* is "definitely assigned after false expression", and the state of *v* after *expr-second* is "definitely assigned after false expression", then the state of *v* after *expr* is "definitely assigned after false expression".
- Otherwise, the state of *v* after *expr* is not definitely assigned.

In the example

```
class A
{
   static void F(int x, int y) {
      int i;
      if (x >= 0 && (i = y) >= 0) {
         // i definitely assigned
      }
      else {
         // i not definitely assigned
      }
      // i not definitely assigned
   }
}
```

the variable `i` is considered definitely assigned in one of the embedded statements of an `if` statement but not in the other. In the `if` statement in method `F`, the variable `i` is definitely assigned in the first embedded statement because execution of the expression `(i = y)` always precedes execution of this embedded statement. In contrast, the variable `i` is not definitely assigned in the second embedded statement, since `x >= 0` might have tested false, resulting in the variable `i` being unassigned.

5.3.3.24 || expressions

For an expression *expr* of the form *expr-first* `||` *expr-second*:

- The definite assignment state of *v* before *expr-first* is the same as the definite assignment state of *v* before *expr*.
- The definite assignment state of *v* before *expr-second* is definitely assigned if the state of *v* after *expr-first* is either definitely assigned or "definitely assigned after false expression". Otherwise, it is not definitely assigned.
- The definite assignment statement of *v* after *expr* is determined by:
- If the state of *v* after *expr-first* is definitely assigned, then the state of *v* after *expr* is definitely assigned.
- Otherwise, if the state of *v* after *expr-second* is definitely assigned, and the state of *v* after *expr-first* is "definitely assigned after true expression", then the state of *v* after *expr* is definitely assigned.
- Otherwise, if the state of *v* after *expr-second* is definitely assigned or "definitely assigned after false expression", then the state of *v* after *expr* is "definitely assigned after false expression".
- Otherwise, if the state of *v* after *expr-first* is "definitely assigned after true expression", and the state of *v* after *expr-second* is "definitely assigned after true expression", then the state of *v* after *expr* is "definitely assigned after true expression".
- Otherwise, the state of *v* after *expr* is not definitely assigned.

In the example

```
class A
{
   static void G(int x, int y) {
      int i;
      if (x >= 0 || (i = y) >= 0) {
         // i not definitely assigned
      }
      else {
         // i definitely assigned
      }
      // i not definitely assigned
   }
}
```

the variable `i` is considered definitely assigned in one of the embedded statements of an `if` statement but not in the other. In the `if` statement in method `G`, the variable `i` is definitely assigned in the second embedded statement because execution of the expression `(i = y)` always precedes execution of this embedded statement. In contrast, the variable `i` is not definitely assigned in the first embedded statement, since `x >= 0` might have tested true, resulting in the variable `i` being unassigned.

5.3.3.25 ! expressions

For an expression *expr* of the form ！*expr-operand*:

- The definite assignment state of *v* before *expr-operand* is the same as the definite assignment state of *v* before *expr*.
- The definite assignment state of *v* after *expr* is determined by:
- If the state of *v* after *expr-operand* is definitely assigned, then the state of *v* after *expr* is definitely assigned.
- If the state of *v* after *expr-operand* is not definitely assigned, then the state of *v* after *expr* is not definitely assigned.
- If the state of *v* after *expr-operand* is "definitely assigned after false expression", then the state of *v* after *expr* is "definitely assigned after true expression".
- If the state of *v* after *expr-operand* is "definitely assigned after true expression", then the state of *v* after *expr* is "definitely assigned after false expression".

5.3.3.26 ?: expressions

For an expression *expr* of the form *expr-cond* ? *expr-true* : *expr-false*:

- The definite assignment state of *v* before *expr-cond* is the same as the state of *v* before *expr*.
- The definite assignment state of *v* before *expr-true* is definitely assigned if and only if the state of *v* after *expr-cond* is definitely assigned or "definitely assigned after true expression".

The definite assignment state of *v* before *expr-false* is definitely assigned if and only if the state of *v* after *expr-cond* is definitely assigned or "definitely assigned after false expression".

The definite assignment state of *v* after *expr* is determined by:

- If *expr-cond* is a constant expression (Section 7.15) with value true then the state of *v* after *expr* is the same as the state of *v* after *expr-true*.
- Otherwise, if *expr-cond* is a constant expression (Section 7.15) with value false then the state of *v* after *expr* is the same as the state of *v* after *expr-false*.
- Otherwise, if the state of *v* after *expr-true* is definitely assigned and the state of *v* after *expr-false* is definitely assigned, then the state of *v* after *expr* is definitely assigned.
- Otherwise, the state of *v* after *expr* is not definitely assigned.

5.4 Variable references

A *variable-reference* is an *expression* that is classified as a variable. A *variable-reference* denotes a storage location that can be accessed both to fetch the current value and to store a new value.

variable-reference:
  expression

In C and C++, a *variable-reference* is known as an *lvalue*.

5.5 Atomicity of variable references

Reads and writes of the following data types are atomic: `bool`, `char`, `byte`, `sbyte`, `short`, `ushort`, `uint`, `int`, `float`, and reference types. In addition, reads and writes of enum types with an underlying type in the previous list are also atomic. Reads and writes of other types, including `long`, `ulong`, `double`, and `decimal`, as well as user-defined types, are not guaranteed to be atomic. Aside from the library functions designed for that purpose, there is no guarantee of atomic read-modify-write, such as in the case of increment or decrement.

6. Conversions

A conversion enables an expression of one type to be treated as another type. Conversions can be implicit or explicit, and this determines whether an explicit cast is required. For instance, the conversion from type `int` to type `long` is implicit, so expressions of type `int` can implicitly be treated as type `long`. The opposite conversion, from type `long` to type `int`, is explicit and so an explicit cast is required.

```
int a = 123;
long b = a;         // implicit conversion from int to long
int c = (int) b;   // explicit conversion from long to int
```

Some conversions are defined by the language. Programs may also define their own conversions (Section 6.4).

6.1 Implicit conversions

The following conversions are classified as implicit conversions:

- Identity conversions
- Implicit numeric conversions
- Implicit enumeration conversions
- Implicit reference conversions
- Boxing conversions
- Implicit constant expression conversions
- User-defined implicit conversions

Implicit conversions can occur in a variety of situations, including function member invocations (Section 7.4.3), cast expressions (Section 7.6.6), and assignments (Section 7.13).

The pre-defined implicit conversions always succeed and never cause exceptions to be thrown. Properly designed user-defined implicit conversions should exhibit these characteristics as well.

6.1.1 Identity conversion

An identity conversion converts from any type to the same type. This conversion exists only such that an entity that already has a required type can be said to be convertible to that type.

6.1.2 Implicit numeric conversions

The implicit numeric conversions are:

- From `sbyte` to `short`, `int`, `long`, `float`, `double`, or `decimal`.
- From `byte` to `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `float`, `double`, or `decimal`.
- From `short` to `int`, `long`, `float`, `double`, or `decimal`.
- From `ushort` to `int`, `uint`, `long`, `ulong`, `float`, `double`, or `decimal`.
- From `int` to `long`, `float`, `double`, or `decimal`.
- From `uint` to `long`, `ulong`, `float`, `double`, or `decimal`.
- From `long` to `float`, `double`, or `decimal`.
- From `ulong` to `float`, `double`, or `decimal`.
- From `char` to `ushort`, `int`, `uint`, `long`, `ulong`, `float`, `double`, or `decimal`.
- From `float` to `double`.

Conversions from `int`, `uint`, `long`, or `ulong` to `float` and from `long` or `ulong` to `double` may cause a loss of precision, but will never cause a loss of magnitude. The other implicit numeric conversions never lose any information.

There are no implicit conversions to the `char` type, so values of the other integral types do not automatically convert to the `char` type.

6.1.3 Implicit enumeration conversions

An implicit enumeration conversion permits the *decimal-integer-literal* `0` to be converted to any *enum-type*.

6.1.4 Implicit reference conversions

The implicit reference conversions are:

- From any *reference-type* to `object`.
- From any *class-type* `S` to any *class-type* `T`, provided `S` is derived from `T`.
- From any *class-type* `S` to any *interface-type* `T`, provided `S` implements `T`.
- From any *interface-type* `S` to any *interface-type* `T`, provided `S` is derived from `T`.
- From an *array-type* `S` with an element type `SE` to an *array-type* `T` with an element type `TE`, provided all of the following are true:
    - `S` and `T` differ only in element type. In other words, `S` and `T` have the same number of dimensions.
    - Both `SE` and `TE` are *reference-type*s.
    - An implicit reference conversion exists from `SE` to `TE`.
- From any *array-type* to `System.Array`.
- From any *delegate-type* to `System.Delegate`.
- From the null type to any *reference-type*.

The implicit reference conversions are those conversions between *reference-type*s that can be proven to always succeed, and therefore require no checks at run-time.

Reference conversions, implicit or explicit, never change the referential identity of the object being converted. In other words, while a reference conversion may change the type of the reference, it never changes the type or value of the object being referred to.

6.1.5 Boxing conversions

A boxing conversion permits a *value-type* to be implicitly converted to a *reference-type*. Boxing a value of a *value-type* consists of allocating an object instance and copying the *value-type* value into that instance.

Boxing conversions are described further in Section 4.3.1.

6.1.6 Implicit constant expression conversions

An implicit constant expression conversion permits the following conversions:

- A *constant-expression* (Section 7.15) of type `int` can be converted to type `sbyte`, `byte`, `short`, `ushort`, `uint`, or `ulong`, provided the value of the *constant-expression* is within the range of the destination type.
- A *constant-expression* of type `long` can be converted to type `ulong`, provided the value of the *constant-expression* is not negative.

6.1.7 User-defined implicit conversions

A user-defined implicit conversion consists of an optional standard implicit conversion, followed by execution of a user-defined implicit conversion operator, followed by another optional standard implicit conversion. The exact rules for evaluating user-defined conversions are described in Section 6.4.3.

6.2 Explicit conversions

The following conversions are classified as explicit conversions:

- All implicit conversions.
- Explicit numeric conversions.
- Explicit enumeration conversions.
- Explicit reference conversions.
- Explicit interface conversions.
- Unboxing conversions.
- User-defined explicit conversions.

Explicit conversions can occur in cast expressions (Section 7.6.6).

The set of explicit conversions includes all implicit conversions. This means that redundant cast expressions are allowed.

The explicit conversions that are not implicit conversions are conversions that cannot be proven to always succeed, conversions that are known to possibly lose information, and conversions across domains of types sufficiently different to merit explicit notation.

6.2.1 Explicit numeric conversions

The explicit numeric conversions are the conversions from a numeric-type to another numeric-type for which an implicit numeric conversion (Section 6.1.2) does not already exist:

- From `sbyte` to `byte`, `ushort`, `uint`, `ulong`, or `char`.
- From `byte` to `sbyte` and `char`.
- From `short` to `sbyte`, `byte`, `ushort`, `uint`, `ulong`, or `char`.
- From `ushort` to `sbyte`, `byte`, `short`, or `char`.
- From `int` to `sbyte`, `byte`, `short`, `ushort`, `uint`, `ulong`, or `char`.
- From `uint` to `sbyte`, `byte`, `short`, `ushort`, `int`, or `char`.
- From `long` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `ulong`, or `char`.
- From `ulong` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, or `char`.
- From `char` to `sbyte`, `byte`, or `short`.
- From `float` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, or `decimal`.
- From `double` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, or `decimal`.
- From `decimal` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, or `double`.

Because the explicit conversions include all implicit and explicit numeric conversions, it is always possible to convert from any numeric-type to any other numeric-type using a cast expression (Section 7.6.6).

The explicit numeric conversions possibly lose information or possibly cause exceptions to be thrown. An explicit numeric conversion is processed as follows:

- For a conversion from an integral type to another integral type, the processing depends on the overflow checking context (Section 7.5.12) in which the conversion takes place:
  - In a `checked` context, the conversion succeeds if the value of the source operand is within the range of the destination type, but throws a `System.OverflowException` if the value of the source operand is outside the range of the destination type.
  - In an `unchecked` context, the conversion always succeeds, and proceeds as follows.

    If the source type is larger than the destination type, then the source value is truncated by discarding its "extra" most significant bits. The result is then treated as a value of the destination type.

    If the source type is smaller than the destination type, then the source value is either sign-extended or zero-extended so that it is the same size as the destination type. Sign-extension is used if the source type is signed; zero-extension is used if the source type is unsigned. The result is then treated as a value of the destination type.

    If the source type is the same size as the destination type, then the source value is treated as a value of the destination type.
- For a conversion from `decimal` to an integral type, the source value is rounded towards zero to the nearest integral value, and this integral value becomes the result of the conversion. If the resulting integral value is outside the range of the destination type, a `System.OverflowException` is thrown.
- For a conversion from `float` or `double` to an integral type, the processing depends on the overflow checking context (Section 7.5.12) in which the conversion takes place:
  - In a `checked` context, the conversion proceeds as follows:

    If the value of the operand is NaN or infinite, a `System.OverflowException` is thrown.

    Otherwise, the source operand is rounded towards zero to the nearest integral value. If this integral value is within the range of the destination type then this value is the result of the conversion.

    Otherwise, a `System.OverflowException` is thrown.
  - In an unchecked context, the conversion always succeeds, and proceeds as follows.

    If the value of the operand is NaN or infinite, the result of the conversion is an unspecified value of the destination type.

Otherwise, the source operand is rounded towards zero to the nearest integral value. If this integral value is within the range of the destination type then this value is the result of the conversion.

Otherwise, the result of the conversion is an unspecified value of the destination type.

- For a conversion from `double` to `float`, the `double` value is rounded to the nearest `float` value. If the `double` value is too small to represent as a `float`, the result becomes positive zero or negative zero. If the `double` value is too large to represent as a `float`, the result becomes positive infinity or negative infinity. If the `double` value is NaN, the result is also NaN.
- For a conversion from `float` or `double` to `decimal`, the source value is converted to `decimal` representation and rounded to the nearest number after the 28th decimal place if required (Section 4.1.7). If the source value is too small to represent as a `decimal`, the result becomes zero. If the source value is NaN, infinity, or too large to represent as a `decimal`, a `System.OverflowException` is thrown.
- For a conversion from `decimal` to `float` or `double`, the `decimal` value is rounded to the nearest `double` or `float` value. While this conversion may lose precision, it never causes an exception to be thrown.

6.2.2 Explicit enumeration conversions

The explicit enumeration conversions are:

- From `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, or `decimal` to any *enum-type*.
- From any *enum-type* to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, or `decimal`.
- From any *enum-type* to any other *enum-type*.

An explicit enumeration conversion between two types is processed by treating any participating *enum-type* as the underlying type of that *enum-type*, and then performing an implicit or explicit numeric conversion between the resulting types. For example, given an *enum-type* `E` with and underlying type of `int`, a conversion from `E` to `byte` is processed as an explicit numeric conversion (Section 6.2.1) from `int` to `byte`, and a conversion from `byte` to `E` is processed as an implicit numeric conversion (Section 6.1.2) from `byte` to `int`.

6.2.3 Explicit reference conversions

The explicit reference conversions are:

- From `object` to any other *reference-type*.
- From any *class-type* `S` to any *class-type* `T`, provided `S` is a base class of `T`.
- From any *class-type* `S` to any *interface-type* `T`, provided `S` is not sealed and provided `S` does not implement `T`.
- From any *interface-type* `S` to any *class-type* `T`, provided `T` is not sealed or provided `T` implements `S`.
- From any *interface-type* `S` to any *interface-type* `T`, provided `S` is not derived from `T`.
- From an *array-type* `S` with an element type `SE` to an *array-type* `T` with an element type `TE`, provided all of the following are true:
- `S` and `T` differ only in element type. In other words, `S` and `T` have the same number of dimensions.
- Both `SE` and `TE` are *reference-types*.
- An explicit reference conversion exists from `SE` to `TE`.
- From `System.Array` and the interfaces it implements to any *array-type*.
- From `System.Delegate` and the interfaces it implements to any *delegate-type*.

The explicit reference conversions are those conversions between *reference-types* that require run-time checks to ensure they are correct.

For an explicit reference conversion to succeed at run-time, the value of the source operand must be `null`, or the actual type of the object referenced by the source operand must be a type that can be converted to the destination type by an implicit reference conversion (Section 6.1.4). If an explicit reference conversion fails, a `System.InvalidCastException` is thrown.

Reference conversions, implicit or explicit, never change the referential identity of the object being converted. In other words, while a reference conversion may change the type of the reference, it never changes the type or value of the object being referred to.

6.2.4 Unboxing conversions

An unboxing conversion permits a *reference-type* to be explicitly converted to a *value-type*. An unboxing operation consists of first checking that the object instance is a boxed value of the given *value-type*, and then copying the value out of the instance.

Unboxing conversions are described further in Section 4.3.2.

6.2.5 User-defined explicit conversions

A user-defined explicit conversion consists of an optional standard explicit conversion, followed by execution of a user-defined implicit or explicit conversion operator, followed by another optional standard explicit conversion. The exact rules for evaluating user-defined conversions are described in Section 6.4.4.

6.3 Standard conversions

The standard conversions are those pre-defined conversions that can occur as part of a user-defined conversion.

6.3.1 Standard implicit conversions

The following implicit conversions are classified as standard implicit conversions:

- Identity conversions (Section 6.1.1).
- Implicit numeric conversions (Section 6.1.2).
- Implicit reference conversions (Section 6.1.4).
- Boxing conversions (Section 6.1.5).
- Implicit constant expression conversions (Section 6.1.6).

The standard implicit conversions specifically exclude user-defined implicit conversions.

6.3.2 Standard explicit conversions

The standard explicit conversions are all standard implicit conversions plus the subset of the explicit conversions for which an opposite standard implicit conversion exists. In other words, if a standard implicit conversion exists from a type `A` to a type `B`, then a standard explicit conversion exists from type `A` to type `B` and from type `B` to type `A`.

6.4 User-defined conversions

C# allows the pre-defined implicit and explicit conversions to be augmented by user-defined conversions. User-defined conversions are introduced by declaring conversion operators (Section 10.9.3) in class and struct types.

6.4.1 Permitted user-defined conversions

C# permits only certain user-defined conversions to be declared. In particular, it is not possible to redefine an already existing implicit or explicit conversion. A class or struct is permitted to declare a conversion from a source type `S` to a target type `T` only if all of the following are true:

- `S` and `T` are different types.
- Either `S` or `T` is the class or struct type in which the operator declaration takes place.
- Neither `S` nor `T` is `object` or an *interface-type*.
- `T` is not a base class of `S`, and `S` is not a base class of `T`.

The restrictions that apply to user-defined conversions are discussed further in Section 10.9.3.

6.4.2 Evaluation of user-defined conversions

A user-defined conversion converts a value from its type, called the source type, to another type, called the target type. Evaluation of a user-defined conversion centers on finding the most specific user-defined conversion operator for the particular source and target types. This determination is broken into several steps:

- Finding the set of classes and structs from which user-defined conversion operators will be considered. This set consists of the source type and its base classes and the target type and its base classes (with the implicit assumptions that only classes and structs can declare user-defined operators, and that non-class types have no base classes).
- From that set of types, determining which user-defined conversion operators are applicable. For a conversion operator to be applicable, it must be possible to perform a standard conversion (Section 6.3) from the source type to the operand type of the operator, and it must be possible to perform a standard conversion from the result type of the operator to the target type.
- From the set of applicable user-defined operators, determining which operator is unambiguously the most specific. In general terms, the most specific operator is the operator whose operand type is "closest" to the source type and whose result type is "closest" to the target type. The exact rules for establishing the most specific user-defined conversion operator are defined in the following sections.

Once a most specific user-defined conversion operator has been identified, the actual execution of the user-defined conversion involves up to three steps:

- First, if required, performing a standard conversion from the source type to the operand type of the user-defined conversion operator.
- Next, invoking the user-defined conversion operator to perform the conversion.
- Finally, if required, performing a standard conversion from the result type of the user-defined conversion operator to the target type.

Evaluation of a user-defined conversion never involves more than one user-defined conversion operator. In other words, a conversion from type `S` to type `T` will never first execute a user-defined conversion from `S` to `X` and then execute a user-defined conversion from `X` to `T`.

Exact definitions of evaluation of user-defined implicit or explicit conversions are given in the following sections. The definitions make use of the following terms:

- If a standard implicit conversion (Section 6.3.1) exists from a type `A` to a type `B`, and if neither `A` nor `B` are *interface-types*, then `A` is said to be encompassed by `B`, and `B` is said to encompass `A`.
- The most encompassing type in a set of types is the one type that encompasses all other types in the set. If no single type encompasses all other types, then the set has no most encompassing type. In more intuitive terms, the most encompassing type is the "largest" type in the set — the one type to which each of the other types can be implicitly converted.
- The most encompassed type in a set of types is the one type that is encompassed by all other types in the set. If no single type is encompassed by all other types, then the set has no most encompassed type. In more intuitive terms, the most encompassed type is the "smallest" type in the set — the one type that can be implicitly converted to each of the other types.

6.4.3 User-defined implicit conversions

A user-defined implicit conversion from type `S` to type `T` is processed as follows:

- Find the set of types, `D`, from which user-defined conversion operators will be considered. This set consists of `S` (if `S` is a class or struct), the base classes of `S` (if `S` is a class), and `T` (if `T` is a class or struct).
- Find the set of applicable user-defined conversion operators, `U`. This set consists of the user-defined implicit conversion operators declared by the classes or structs in `D` that convert from a type encompassing `S` to a type encompassed by `T`. If `U` is empty, the conversion is undefined and a compile-time error occurs.
- Find the most specific source type, `SX`, of the operators in `U`:
  - If any of the operators in `U` convert from `S`, then `SX` is `S`.
  - Otherwise, `SX` is the most encompassed type in the combined set of target types of the operators in `U`. If no most encompassed type can be found, then the conversion is ambiguous and a compile-time error occurs.
- Find the most specific target type, `TX`, of the operators in `U`:
  - If any of the operators in `U` convert to `T`, then `TX` is `T`.
  - Otherwise, `TX` is the most encompassing type in the combined set of target types of the operators in `U`. If no most encompassing type can be found, then the conversion is ambiguous and a compile-time error occurs.
- If `U` contains exactly one user-defined conversion operator that converts from `SX` to `TX`, then this is the most specific conversion operator. If no such operator exists, or if more than one such operator exists, then the conversion is ambiguous and a compile-time error occurs. Otherwise, the user-defined conversion is applied:
  - If `S` is not `SX`, then a standard implicit conversion from `S` to `SX` is performed.
  - The most specific user-defined conversion operator is invoked to convert from `SX` to `TX`.
  - If `TX` is not `T`, then a standard implicit conversion from `TX` to `T` is performed.

6.4.4 User-defined explicit conversions

A user-defined explicit conversion from type `S` to type `T` is processed as follows:

- Find the set of types, `D`, from which user-defined conversion operators will be considered. This set consists of `S` (if `S` is a class or struct), the base classes of `S` (if `S` is a class), `T` (if `T` is a class or struct), and the base classes of `T` (if `T` is a class).
- Find the set of applicable user-defined conversion operators, `U`. This set consists of the user-defined implicit or explicit conversion operators declared by the classes or structs in `D` that convert from a type encompassing or encompassed by `S` to a type encompassing or encompassed by `T`. If `U` is empty, the conversion is undefined and a compile-time error occurs.
- Find the most specific source type, `SX`, of the operators in `U`:
  - If any of the operators in `U` convert from `S`, then `SX` is `S`.
  - Otherwise, if any of the operators in `U` convert from types that encompass `S`, then `SX` is the most encompassed type in the combined set of source types of those operators. If no most encompassed type can be found, then the conversion is ambiguous and a compile-time error occurs.
  - Otherwise, `SX` is the most encompassing type in the combined set of source types of the operators in `U`. If no most encompassing type can be found, then the conversion is ambiguous and a compile-time error occurs.
- Find the most specific target type, `TX`, of the operators in `U`:
  - If any of the operators in `U` convert to `T`, then `TX` is `T`.
  - Otherwise, if any of the operators in `U` convert to types that are encompassed by `T`, then `TX` is the most encompassing type in the combined set of source types of those operators. If no most encompassing type can be found, then the conversion is ambiguous and a compile-time error occurs.
  - Otherwise, `TX` is the most encompassed type in the combined set of target types of the operators in `U`. If no most encompassed type can be found, then the conversion is ambiguous and a compile-time error occurs.
- If `U` contains exactly one user-defined conversion operator that converts from `SX` to `TX`, then this is the most specific conversion operator. If no such operator exists, or if more than one such operator exists, then the conversion is ambiguous and a compile-time error occurs. Otherwise, the user-defined conversion is applied:
  - If `S` is not `SX`, then a standard explicit conversion from `S` to `SX` is performed.
  - The most specific user-defined conversion operator is invoked to convert from `SX` to `TX`.
  - If `TX` is not `T`, then a standard explicit conversion from `TX` to `T` is performed.

7. Expressions

An expression is a sequence of operators and operands. This chapter defines the syntax, order of evaluation of operands and operators, and meaning of expressions.

7.1 Expression classifications

An expression is classified as one of the following:

- A value. Every value has an associated type.
- A variable. Every variable has an associated type, namely the declared type of the variable.
- A namespace. An expression with this classification can only appear as the left hand side of a member-access (Section 7.5.4). In any other context, an expression classified as a namespace causes a compile-time error.
- A type. An expression with this classification can only appear as the left hand side of a member-access (Section 7.5.4), or as an operand for the `as` operator (Section 7.9.10), the `is` operator (Section 7.9.9), or the `typeof` operator (Section 7.5.11). In any other context, an expression classified as a type causes a compile-time error.
- A method group, which is a set of overloaded methods resulting from a member lookup (Section 7.3). A method group may have an associated instance expression. When an instance method is invoked, the result of evaluating the instance expression becomes the instance represented by `this` (Section 7.5.7). A method group is only permitted in an invocation-expression (Section 7.5.5) or a delegate-creation-expression (Section 7.5.10.3). In any other context, an expression classified as a method group causes a compile-time error.
- A property access. Every property access has an associated type, namely the type of the property. Furthermore, a property access may have an associated instance expression. When an accessor (the `get` or `set` block) of an instance property access is invoked, the result of evaluating the instance expression becomes the instance represented by `this` (Section 7.5.7).
- An event access. Every event access has an associated type, namely the type of the event. Furthermore, an event access may have an associated instance expression. An event access may appear as the left hand operand of the `+=` and `-=` operators (Section 7.13.3). In any other context, an expression classified as an event access causes a compile-time error.
- An indexer access. Every indexer access has an associated type, namely the element type of the indexer. Furthermore, an indexer access has an associated instance expression and an associated argument list. When an accessor (the `get` or `set` block) of an indexer access is invoked, the result of evaluating the instance expression becomes the instance represented by `this` (Section 7.5.7), and the result of evaluating the argument list becomes the parameter list of the invocation.
- Nothing. This occurs when the expression is an invocation of a method with a return type of `void`. An expression classified as nothing is only valid in the context of a statement-expression (Section 8.6).

The final result of an expression is never a namespace, type, method group, or event access. Rather, as noted above, these categories of expressions are intermediate constructs that are only permitted in certain contexts.

A property access or indexer access is always reclassified as a value by performing an invocation of the get-accessor or the set-accessor. The particular accessor is determined by the context of the property or indexer access: If the access is the target of an assignment, the set-accessor is invoked to assign a new value (Section 7.13.1). Otherwise, the get-accessor is invoked to obtain the current value (Section 7.1.1).

7.1.1 Values of expressions

Most of the constructs that involve an expression ultimately require the expression to denote a value. In such cases, if the actual expression denotes a namespace, a type, a method group, or nothing, a compile-time error occurs. However, if the expression denotes a property access, an indexer access, or a variable, the value of the property, indexer, or variable is implicitly substituted:

- The value of a variable is simply the value currently stored in the storage location identified by the variable. A variable must be considered definitely assigned (Section 5.3) before its value can be obtained, or otherwise a compile-time error occurs.
- The value of a property access expression is obtained by invoking the get-accessor of the property. If the property has no get-accessor, a compile-time error occurs. Otherwise, a function member invocation (Section 7.4.3) is performed, and the result of the invocation becomes the value of the property access expression.
- The value of an indexer access expression is obtained by invoking the get-accessor of the indexer. If the indexer has no get-accessor, a compile-time error occurs. Otherwise, a function member invocation (Section 7.4.3) is performed with the argument list associated with the indexer access expression, and the result of the invocation becomes the value of the indexer access expression.

7.2 Operators

Expressions are constructed from operands and operators. The operators of an expression indicate which operations to apply to the operands. Examples of operators include `+`, `-`, `*`, `/`, and `new`. Examples of operands include literals, fields, local variables, and expressions.

There are three kinds of operators:

- Unary operators. The unary operators take one operand and use either prefix notation (such as `-x`) or postfix notation (such as `x++`).
- Binary operators. The binary operators take two operands and all use infix notation (such as `x + y`).
- Ternary operator. Only one ternary operator, `?:`, exists; it takes three operands and uses infix notation (`c? x: y`).

The order of evaluation of operators in an expression is determined by the precedence and associativity of the operators (Section 7.2.1).

Operands in an expression are evaluated from left to right. For example, in `F(i) + G(i++) * H(i)`, method `F` is called using the old value of `i`, then method `G` is called with the old value of `i`, and, finally, method `H` is called with the new value of `i`. This is separate from and unrelated to operator precedence.

Certain operators can be overloaded. Operator overloading permits user-defined operator implementations to be specified for operations where one or both of the operands are of a user-defined class or struct type (Section 7.2.2).

7.2.1 Operator precedence and associativity

When an expression contains multiple operators, the precedence of the operators controls the order in which the individual operators are evaluated. For example, the expression `x + y * z` is evaluated as `x + (y * z)` because the `*` operator has higher precedence than the binary `+` operator. The precedence of an operator is established by the definition of its associated grammar production. For example, an additive-expression consists of a sequence of multiplicative-expressions separated by `+` or `-` operators, thus giving the `+` and `-` operators lower precedence than the `*`, `/`, and `%` operators.

The following table summarizes all operators in order of precedence from highest to lowest:

Section	Category	Operators
Section 7.5	Primary	`x.y  f(x)  a[x]  x++  x--  new  typeof  checked  unchecked`
Section 7.6	Unary	`+  -  !  ~  ++x  --x  (T)x`
Section 7.7	Multiplicative	`*  /  %`
Section 7.7	Additive	`+  -`
Section 7.8	Shift	`<<  >>`
Section 7.9	Relational and type testing	`<  >  <=  >=  is  as`
Section 7.9	Equality	`==  !=`
Section 7.10	Logical AND	`&`
Section 7.10	Logical XOR	`^`
Section 7.10	Logical OR	`|`
Section 7.11	Conditional AND	`&&`
Section 7.11	Conditional OR	`||`
Section 7.12	Conditional	`?:`
Section 7.13	Assignment	`=  *=  /=  %=  +=  -=  <<=  >>=  &=  ^=  |=`

When an operand occurs between two operators with the same precedence, the associativity of the operators controls the order in which the operations are performed:

- Except for the assignment operators, all binary operators are left-associative, meaning that operations are performed from

left to right. For example, `x + y + z` is evaluated as `(x + y) + z`.

- The assignment operators and the conditional operator (`?:`) are right-associative, meaning that operations are performed from right to left. For example, `x = y = z` is evaluated as `x = (y = z)`.

Precedence and associativity can be controlled using parentheses. For example, `x + y * z` first multiplies `y` by `z` and then adds the result to `x`, but `(x + y) * z` first adds `x` and `y` and then multiplies the result by `z`.

7.2.2 Operator overloading

All unary and binary operators have predefined implementations that are automatically available in any expression. In addition to the predefined implementations, user-defined implementations can be introduced by including `operator` declarations in classes and structs (Section 10.9). User-defined operator implementations always take precedence over predefined operator implementations: Only when no applicable user-defined operator implementations exist will the predefined operator implementations be considered.

The overloadable unary operators are:

```
+   -   !   ~   ++   --   true   false
```

Although `true` and `false` are not used explicitly in expressions, they are considered operators because they are invoked in several expression contexts: Boolean expressions (Section 7.16) and expressions involving the conditional (Section 7.12), and conditional logical operators (Section 7.11).

The overloadable binary operators are:

```
+   -   *   /   %   &   |   ^   <<   >>   ==   !=   >   <   >=   <=
```

Only the operators listed above can be overloaded. In particular, it is not possible to overload member access, method invocation, or the `=`, `&&`, `||`, `?:`, `checked`, `unchecked`, `new`, `typeof`, `as`, and `is` operators.

When a binary operator is overloaded, the corresponding assignment operator (if any) is also implicitly overloaded. For example, an overload of operator `*` is also an overload of operator `*=`. This is described further in Section 7.13. Note that the assignment operator itself (`=`) cannot be overloaded. An assignment always performs a simple bit-wise copy of a value into a variable.

Cast operations, such as `(T)x`, are overloaded by providing user-defined conversions (Section 6.4).

Element access, such as `a[x]`, is not considered an overloadable operator. Instead, user-defined indexing is supported through indexers (Section 10.8).

In expressions, operators are referenced using operator notation, and in declarations, operators are referenced using functional notation. The following table shows the relationship between operator and functional notations for unary and binary operators. In the first entry, *op* denotes any overloadable unary prefix operator. In the second entry, *op* denotes the unary postfix `++` and `--` operators. In the third entry, *op* denotes any overloadable binary operator.

Operator notation	Functional notation
op `x`	`operator` *op* `(x)`
`x` *op*	`operator` *op* `(x)`
`x` *op* `y`	`operator` *op* `(x, y)`

User-defined operator declarations always require at least one of the parameters to be of the class or struct type that contains the operator declaration. Thus, it is not possible for a user-defined operator to have the same signature as a predefined operator.

User-defined operator declarations cannot modify the syntax, precedence, or associativity of an operator. For example, the `/` operator is always a binary operator, always has the precedence level specified in Section 7.2.1, and is always left-associative.

While it is possible for a user-defined operator to perform any computation it pleases, implementations that produce results other than those that are intuitively expected are strongly discouraged. For example, an implementation of `operator ==` should compare the two operands for equality and return an appropriate `bool` result.

The descriptions of individual operators in Section 7.5 through Section 7.13 specify the predefined implementations of the operators and any additional rules that apply to each operator. The descriptions make use of the terms unary operator overload resolution, binary operator overload resolution, and numeric promotion, definitions of which are found in the following sections.

7.2.3 Unary operator overload resolution

An operation of the form *op* `x` or `x` *op*, where *op* is an overloadable unary operator, and `x` is an expression of type `X`, is processed as follows:

- The set of candidate user-defined operators provided by `X` for the operation `operator` *op* `(x)` is determined using the rules of Section 7.2.5.
- If the set of candidate user-defined operators is not empty, then this becomes the set of candidate operators for the operation. Otherwise, the predefined unary `operator` *op* implementations become the set of candidate operators for the operation. The predefined implementations of a given operator are specified in the description of the operator (Section 7.5 and Section 7.6).
- The overload resolution rules of Section 7.4.2 are applied to the set of candidate operators to select the best operator with respect to the argument list `(x)`, and this operator becomes the result of the overload resolution process. If overload resolution fails to select a single best operator, a compile-time error occurs.

7.2.4 Binary operator overload resolution

An operation of the form `x` *op* `y`, where *op* is an overloadable binary operator, `x` is an expression of type `X`, and `y` is an expression of type `Y`, is processed as follows:

- The set of candidate user-defined operators provided by `X` and `Y` for the operation `operator` *op* `(x, y)` is determined. The set consists of the union of the candidate operators provided by `X` and the candidate operators provided by `Y`, each determined using the rules of Section 7.2.5. If `X` and `Y` are the same type, or if `X` and `Y` are derived from a common base type, then shared candidate operators only occur in the combined set once.
- If the set of candidate user-defined operators is not empty, then this becomes the set of candidate operators for the operation. Otherwise, the predefined binary `operator` *op* implementations become the set of candidate operators for the operation. The predefined implementations of a given operator are specified in the description of the operator (Section 7.7 through Section 7.13).
- The overload resolution rules of Section 7.4.2 are applied to the set of candidate operators to select the best operator with respect to the argument list `(x, y)`, and this operator becomes the result of the overload resolution process. If overload resolution fails to select a single best operator, a compile-time error occurs.

7.2.5 Candidate user-defined operators

Given a type `T` and an operation `operator` *op* `(A)`, where *op* is an overloadable operator and `A` is an argument list, the set of candidate user-defined operators provided by `T` for `operator` *op* `(A)` is determined as follows:

- For all `operator` *op* declarations in `T`, if at least one operator is applicable (Section 7.4.2.1) with respect to the argument list `A`, then the set of candidate operators consists of all applicable `operator` *op* declarations in `T`.
- Otherwise, if `T` is `object`, the set of candidate operators is empty.
- Otherwise, the set of candidate operators provided by `T` is the set of candidate operators provided by the direct base class of `T`.

7.2.6 Numeric promotions

Numeric promotion consists of automatically performing certain implicit conversions of the operands of the predefined unary and binary numeric operators. Numeric promotion is not a distinct mechanism, but rather an effect of applying overload resolution to the predefined operators. Numeric promotion specifically does not affect evaluation of user-defined operators, although user-defined operators can be implemented to exhibit similar effects.

As an example of numeric promotion, consider the predefined implementations of the binary `*` operator:

```
int operator *(int x, int y);
uint operator *(uint x, uint y);
long operator *(long x, long y);
ulong operator *(ulong x, ulong y);
float operator *(float x, float y);
double operator *(double x, double y);
decimal operator *(decimal x, decimal y);
```

When overload resolution rules (Section 7.4.2) are applied to this set of operators, the effect is to select the first of the operators for which implicit conversions exist from the operand types. For example, for the operation `b * s`, where `b` is a `byte` and `s` is a `short`, overload resolution selects `operator *(int, int)` as the best operator. Thus, the effect is that `b` and `s` are converted to `int`, and the type of the result is `int`. Likewise, for the operation `i * d`, where `i` is an `int` and `d` is a `double`, overload resolution selects `operator *(double, double)` as the best operator.

7.2.6.1 Unary numeric promotions

Unary numeric promotion occurs for the operands of the predefined `+`, `–`, and `~` unary operators. Unary numeric promotion simply consists of converting operands of type `sbyte`, `byte`, `short`, `ushort`, or `char` to type `int`. Additionally, for the unary `–` operator, unary numeric promotion converts operands of type `uint` to type `long`.

7.2.6.2 Binary numeric promotions

Binary numeric promotion occurs for the operands of the predefined `+`, `-`, `*`, `/`, `%`, `&`, `|`, `^`, `==`, `!=`, `>`, `<`, `>=`, and `<=` binary operators. Binary numeric promotion implicitly converts both operands to a common type which, in case of the non-relational operators, also becomes the result type of the operation. Binary numeric promotion consists of applying the following rules, in the order they appear here:

- If either operand is of type `decimal`, the other operand is converted to type `decimal`, or a compile-time error occurs if the other operand is of type `float` or `double`.
- Otherwise, if either operand is of type `double`, the other operand is converted to type `double`.
- Otherwise, if either operand is of type `float`, the other operand is converted to type `float`.
- Otherwise, if either operand is of type `ulong`, the other operand is converted to type `ulong`, or a compile-time error occurs if the other operand is of type `sbyte`, `short`, `int`, or `long`.
- Otherwise, if either operand is of type `long`, the other operand is converted to type `long`.
- Otherwise, if either operand is of type `uint` and the other operand is of type `sbyte`, `short`, or `int`, both operands are converted to type `long`.
- Otherwise, if either operand is of type `uint`, the other operand is converted to type `uint`.
- Otherwise, both operands are converted to type `int`.

Note that the first rule disallows any operations that mix the `decimal` type with the `double` and `float` types. The rule follows from the fact that there are no implicit conversions between the `decimal` type and the `double` and `float` types.

Also note that it is not possible for an operand to be of type `ulong` when the other operand is of a signed integral type. The reason is that no integral type exists that can represent the full range of `ulong` as well as the signed integral types.

In both of the above cases, a cast expression can be used to explicitly convert one operand to a type that is compatible with the other operand.

In the example

```
decimal AddPercent(decimal x, double percent) {
   return x * (1.0 + percent / 100.0);
}
```

a compile-time error occurs because a `decimal` cannot be multiplied by a `double`. The error is resolved by explicitly converting the second operand to `decimal`, as follows:

```
decimal AddPercent(decimal x, double percent) {
   return x * (decimal)(1.0 + percent / 100.0);
}
```

7.3 Member lookup

A member lookup is the process whereby the meaning of a name in the context of a type is determined. A member lookup may occur as part of evaluating a simple-name (Section 7.5.2) or a member-access (Section 7.5.4) in an expression.

A member lookup of a name `N` in a type `T` is processed as follows:

- First, the set of all accessible (Section 3.5) members named `N` declared in `T` and the base types (Section 7.3.1) of `T` is constructed. Declarations that include an `override` modifier are excluded from the set. If no members named `N` exist and are accessible, then the lookup produces no match, and the following steps are not evaluated.
- Next, members that are hidden by other members are removed from the set. For every member `S.M` in the set, where `S` is the type in which the member `M` is declared, the following rules are applied:
    - If `M` is a constant, field, property, event, type, or enumeration member, then all members declared in a base type of `S` are removed from the set.
    - If `M` is a method, then all non-method members declared in a base type of `S` are removed from the set, and all methods with the same signature as `M` declared in a base type of `S` are removed from the set.
- Finally, having removed hidden members, the result of the lookup is determined:
    - If the set consists of a single non-method member, then this member is the result of the lookup.
    - Otherwise, if the set contains only methods, then this group of methods is the result of the lookup.
    - Otherwise, the lookup is ambiguous, and a compile-time error occurs (this situation can only occur for a member lookup in an interface that has multiple direct base interfaces).

For member lookups in types other than interfaces, and member lookups in interfaces that are strictly single-inheritance (each interface in the inheritance chain has exactly zero or one direct base interface), the effect of the lookup rules is simply that derived members hide base members with the same name or signature. Such single-inheritance lookups are never ambiguous. The ambiguities that can possibly arise from member lookups in multiple-inheritance interfaces are described in Section 13.2.5.

7.3.1 Base types

For purposes of member lookup, a type `T` is considered to have the following base types:

- If `T` is `object`, then `T` has no base type.
- If `T` is a *value-type*, the base type of `T` is the class type `object`.
- If `T` is a *class-type*, the base types of `T` are the base classes of `T`, including the class type `object`.
- If `T` is an *interface-type*, the base types of `T` are the base interfaces of `T` and the class type `object`.
- If `T` is an *array-type*, the base types of `T` are the class types `System.Array` and `object`.
- If `T` is a *delegate-type*, the base types of `T` are the class types `System.Delegate` and `object`.

7.4 Function members

Function members are members that contain executable statements. Function members are always members of types and cannot be members of namespaces. C# defines the following categories of function members:

- Methods
- Properties
- Events
- Indexers
- User-defined operators
- Instance constructors
- Static constructors
- Destructors

Except for destructors and static constructors (which cannot be invoked explicitly), the statements contained in function members are executed through function member invocations. The actual syntax for writing a function member invocation depends on the particular function member category.

The argument list (Section 7.4.1) of a function member invocation provides actual values or variable references for the parameters of the function member.

Invocations of methods, indexers, operators and instance constructors employ overload resolution to determine which of a candidate set of function members to invoke. This process is described in Section 7.4.2.

Once a particular function member has been identified at compile-time, possibly through overload resolution, the actual run-time process of invoking the function member is described in Section 7.4.3.

The following table summarizes the processing that takes place in constructs involving the six categories of function members that can be explicitly invoked. In the table, `e`, `x`, `y`, and `value` indicate expressions classified as variables or values, `T` indicates an expression classified as a type, `F` is the simple name of a method, and `P` is the simple name of a property.

Construct	Example	Description
Method invocation	`F(x, y)`	Overload resolution is applied to select the best method `F` in the containing class or struct. The method is invoked with the argument list `(x, y)`. If the method is not `static`, the instance expression is `this`.
Method invocation	`T.F(x, y)`	Overload resolution is applied to select the best method `F` in the class or struct `T`. A compile-time error occurs if the method is not `static`. The method is invoked with the argument list `(x, y)`.
Method invocation	`e.F(x, y)`	Overload resolution is applied to select the best method F in the class, struct, or interface given by the type of `e`. A compile-time error occurs if the method is `static`. The method is invoked with the instance expression `e` and the argument list `(x, y)`.
Property access	`P`	The `get` accessor of the property `P` in the containing class or struct is invoked. A compile-time error occurs if `P` is write-only. If `P` is not `static`, the instance expression is `this`.
Property access	`P = value`	The `set` accessor of the property `P` in the containing class or struct is invoked with the argument list `(value)`. A compile-time error occurs if `P` is read-only. If `P` is not `static`, the instance expression is `this`.
Property access	`T.P`	The `get` accessor of the property `P` in the class or struct `T` is invoked. A compile-time error occurs if `P` is not `static` or if `P` is write-only.
Property access	`T.P = value`	The `set` accessor of the property `P` in the class or struct `T` is invoked with the argument list `(value)`. A compile-time error occurs if `P` is not `static` or if `P` is read-only.

Property access	`e.P`	The `get` accessor of the property `P` in the class, struct, or interface given by the type of `e` is invoked with the instance expression `e`. A compile-time error occurs if `P` is `static` or if `P` is write-only.
Property access	`e.P = value`	The `set` accessor of the property `P` in the class, struct, or interface given by the type of `e` is invoked with the instance expression `e` and the argument list `(value)`. A compile-time error occurs if `P` is `static` or if `P` is read-only.
Event access	`E += value`	The `add` accessor of the event `E` in the containing class or struct is invoked. If `E` is not static, the instance expression is `this`.
Event access	`E -= value`	The `remove` accessor of the event `E` in the containing class or struct is invoked. If `E` is not static, the instance expression is `this`.
Event access	`T.E += value`	The `add` accessor of the event `E` in the class or struct `T` is invoked. A compile-time error occurs if `E` is not static.
Event access	`T.E -= value`	The remove accessor of the event `E` in the class or struct `T` is invoked. A compile-time error occurs if `E` is not static.
Event access	`e.E += value`	The `add` accessor of the event `E` in the class, struct, or interface given by the type of `e` is invoked with the instance expression `e`. A compile-time error occurs if `E` is static.
Event access	`e.E -= value`	The `remove` accessor of the event `E` in the class, struct, or interface given by the type of `e` is invoked with the instance expression `e`. A compile-time error occurs if `E` is static.
Indexer access	`e[x, y]`	Overload resolution is applied to select the best indexer in the class, struct, or interface given by the type of e. The `get` accessor of the indexer is invoked with the instance expression `e` and the argument list `(x, y)`. A compile-time error occurs if the indexer is write-only.
Indexer access	`e[x, y] = value`	Overload resolution is applied to select the best indexer in the class, struct, or interface given by the type of `e`. The `set` accessor of the indexer is invoked with the instance expression `e` and the argument list `(x, y, value)`. A compile-time error occurs if the indexer is read-only.
Operator invocation	`-x`	Overload resolution is applied to select the best unary operator in the class or struct given by the type of `x`. The selected operator is invoked with the argument list `(x)`.
Operator invocation	`x + y`	Overload resolution is applied to select the best binary operator in the classes or structs given by the types of x and y. The selected operator is invoked with the argument list `(x, y)`.
Instance constructor	`new T(x, y)`	Overload resolution is applied to select the best instance constructor in the class or struct `T`. The instance constructor is invoked with the argument list `(x, y)`.

7.4.1 Argument lists

Every function member invocation includes an argument list which provides actual values or variable references for the parameters of the function member. The syntax for specifying the argument list of a function member invocation depends on the function member category:

- For instance constructors, methods, and delegates, the arguments are specified as an argument-list, as described below.
- For properties, the argument list is empty when invoking the `get` accessor, and consists of the expression specified as the right operand of the assignment operator when invoking the `set` accessor.
- For events, the argument list consists of the expression specified as the right operand of the `+=` or `-=` operator.
- For indexers, the argument list consists of the expressions specified between the square brackets in the indexer access. When invoking the `set` accessor, the argument list additionally includes the expression specified as the right operand of the assignment operator.
- For user-defined operators, the argument list consists of the single operand of the unary operator or the two operands of the binary operator.

The arguments of properties (Section 10.6), events (Section 10.7), indexers (Section 10.8), and user-defined operators (Section 10.9) are always passed as value parameters (Section 10.5.1.1). Reference and output parameters are not supported for these categories of function members.

The arguments of an instance constructor, method, or delegate invocation are specified as an argument-list:

argument-list:
  argument
  argument-list , *argument*
argument:
  expression
  ref *variable-reference*
  out *variable-reference*

An argument-list consists of one or more arguments, separated by commas. Each argument can take one of the following forms:

- An expression, indicating that the argument is passed as a value parameter (Section 10.5.1.1).
- The keyword `ref` followed by a variable-reference (Section 5.3.3), indicating that the argument is passed as a reference parameter (Section 10.5.1.2). A variable must be definitely assigned (Section 5.3) before it can be passed as a reference parameter. A volatile field (Section 10.4.3) cannot be passed as a reference parameter.
- The keyword `out` followed by a variable-reference (Section 5.3.3), indicating that the argument is passed as an output parameter (Section 10.5.1.3). A variable is considered definitely assigned (Section 5.3) following a function member invocation in which the variable is passed as an output parameter. A volatile field (Section 10.4.3) cannot be passed as an output parameter.

During the run-time processing of a function member invocation (Section 7.4.3), the expressions or variable references of an argument list are evaluated in order, from left to right, as follows:

- For a value parameter, the argument expression is evaluated and an implicit conversion (Section 6.1) to the corresponding parameter type is performed. The resulting value becomes the initial value of the value parameter in the function member invocation.
- For a reference or output parameter, the variable reference is evaluated and the resulting storage location becomes the storage location represented by the parameter in the function member invocation. If the variable reference given as a reference or output parameter is an array element of a *reference-type*, a run-time check is performed to ensure that the element type of the array is identical to the type of the parameter. If this check fails, a `System.ArrayTypeMismatchException` is thrown.

Methods, indexers, and instance constructors may declare their right-most parameter to be a parameter array (Section 10.5.1.4). Such function members are invoked either in their normal form or in their expanded form depending on which is applicable (Section 7.4.2.1):

- When a function member with a parameter array is invoked in its normal form, the argument given for the parameter array must be a single expression of a type that is implicitly convertible (Section 6.1) to the parameter array type. In this case, the parameter array acts precisely like a value parameter.
- When a function member with a parameter array is invoked in its expanded form, the invocation must specify zero or more

arguments for the parameter array, where each argument is an expression of a type that is implicitly convertible (Section 6.1) to the element type of the parameter array. In this case, the invocation creates an instance of the parameter array type with a length corresponding to the number of arguments, initializes the elements of the array instance with the given argument values, and uses the newly created array instance as the actual argument.

The expressions of an argument list are always evaluated in the order they are written. Thus, the example

```
class Test
{
   static void F(int x, int y, int z) {
      System.Console.WriteLine("x = {0}, y = {1}, z = {2}", x, y, z);
   }
   static void Main() {
      int i = 0;
      F(i++, i++, i++);
   }
}
```

produces the output

```
x = 0, y = 1, z = 2
```

The array co-variance rules (Section 12.5) permit a value of an array type `A[]` to be a reference to an instance of an array type `B[]`, provided an implicit reference conversion exists from `B` to `A`. Because of these rules, when an array element of a *reference-type* is passed as a reference or output parameter, a run-time check is required to ensure that the actual element type of the array is identical to that of the parameter. In the example

```
class Test
{
   static void F(ref object x) {...}
   static void Main() {
      object[] a = new object[10];
      object[] b = new string[10];
      F(ref a[0]);      // Ok
      F(ref b[1]);      // ArrayTypeMismatchException
   }
}
```

the second invocation of `F` causes a `System.ArrayTypeMismatchException` to be thrown because the actual element type of `b` is `string` and not `object`.

When a function member with a parameter array is invoked in its expanded form, the invocation is processed exactly as if an array creation expression with an array initializer (Section 7.5.10.2) was inserted around the expanded parameters. For example, given the declaration

```
void F(int x, int y, params object[] args);
```

the following invocations of the expanded form of the method

```
F(10, 20);
F(10, 20, 30, 40);
F(10, 20, 1, "hello", 3.0);
```

correspond exactly to

```
F(10, 20, new object[] {});
F(10, 20, new object[] {30, 40});
F(10, 20, new object[] {1, "hello", 3.0});
```

In particular, note that an empty array is created when there are zero arguments given for the parameter array.

7.4.2 Overload resolution

Overload resolution is a compile-time mechanism for selecting the best function member to invoke given an argument list and a set of candidate function members. Overload resolution selects the function member to invoke in the following distinct contexts within C#:

- Invocation of a method named in an invocation-expression (Section 7.5.5).
- Invocation of an instance constructor named in an object-creation-expression (Section 7.5.10.1).
- Invocation of an indexer accessor through an element-access (Section 7.5.6).
- Invocation of a predefined or user-defined operator referenced in an expression (Section 7.2.3 and Section 7.2.4).

Each of these contexts defines the set of candidate function members and the list of arguments in its own unique way, as described in detail in the sections listed above. For example, the set of candidates for a method invocation does not include methods marked `override` (Section 7.3), and methods in a base class are not candidates if any method in a derived class is applicable (Section 7.5.5.1).

Once the candidate function members and the argument list have been identified, the selection of the best function member is the same in all cases:

- Given the set of applicable candidate function members, the best function member in that set is located.
- If the set contains only one function member, then that function member is the best function member.
- Otherwise, the best function member is the one function member that is better than all other function members with respect to the given argument list, provided that each function member is compared to all other function members using the rules in Section 7.4.2.2.
- If there is not exactly one function member that is better than all other function members, then the function member invocation is ambiguous and a compile-time error occurs.

The following sections define the exact meanings of the terms applicable function member and better function member.

7.4.2.1 Applicable function member

A function member is said to be an applicable function member with respect to an argument list `A` when all of the following are true:

- The number of arguments in `A` is identical to the number of parameters in the function member declaration.
- For each argument in `A`, the parameter passing mode of the argument (that is, value, `ref`, or `out`) is identical to the parameter passing mode of the corresponding parameter, and
  - for a value parameter or a parameter array, an implicit conversion (Section 6.1) exists from the type of the argument to the type of the corresponding parameter, or
  - for a `ref` or `out` parameter, the type of the argument is identical to the type of the corresponding parameter. After all, a `ref` or `out` parameter is an alias for the argument passed.

For a function member that includes a parameter array, if the function member is applicable by the above rules, it is said to be applicable in its normal form. If a function member that includes a parameter array is not applicable in its normal form, the function member may instead be applicable in its expanded form:

- The expanded form is constructed by replacing the parameter array in the function member declaration with zero or more value parameters of the element type of the parameter array such that the number of arguments in the argument list `A` matches the total number of parameters. If `A` has fewer arguments than the number of fixed parameters in the function member declaration, the expanded form of the function member cannot be constructed and is thus not applicable.
- If the class, struct, or interface in which the function member is declared already contains another applicable function member with the same signature as the expanded form, the expanded form is not applicable.
- Otherwise, the expanded form is applicable if for each argument in `A` the parameter passing mode of the argument is identical to the parameter passing mode of the corresponding parameter, and
  - for a fixed value parameter or a value parameter created by the expansion, an implicit conversion (Section 6.1) exists from the type of the argument to the type of the corresponding parameter, or
  - for a `ref` or `out` parameter, the type of the argument is identical to the type of the corresponding parameter.

7.4.2.2 Better function member

Given an argument list `A` with a set of argument types `{A1, A2, ..., AN}` and two applicable function members `MP` and `MQ` with parameter types `{P1, P2, ..., PN}` and `{Q1, Q2, ..., QN}`, `MP` is defined to be a better function member than `MQ` if

- for each argument, the implicit conversion from `AX` to `PX` is not worse than the implicit conversion from `AX` to `QX`, and
- for at least one argument, the conversion from `AX` to `PX` is better than the conversion from `AX` to `QX`.

When performing this evaluation, if `MP` or `MQ` is applicable in its expanded form, then `PX` or `QX` refers to a parameter in the expanded form of the parameter list.

7.4.2.3 Better conversion

Given an implicit conversion `C1` that converts from a type `S` to a type `T1`, and an implicit conversion `C2` that converts from a type `S` to a type `T2`, the better conversion of the two conversions is determined as follows:

- If `T1` and `T2` are the same type, neither conversion is better.
- If `S` is `T1`, `C1` is the better conversion.
- If `S` is `T2`, `C2` is the better conversion.
- If an implicit conversion from `T1` to `T2` exists, and no implicit conversion from `T2` to `T1` exists, `C1` is the better conversion.
- If an implicit conversion from `T2` to `T1` exists, and no implicit conversion from `T1` to `T2` exists, `C2` is the better conversion.
- If `T1` is `sbyte` and `T2` is `byte`, `ushort`, `uint`, or `ulong`, `C1` is the better conversion.
- If `T2` is `sbyte` and `T1` is `byte`, `ushort`, `uint`, or `ulong`, `C2` is the better conversion.
- If `T1` is `short` and `T2` is `ushort`, `uint`, or `ulong`, `C1` is the better conversion.
- If `T2` is `short` and `T1` is `ushort`, `uint`, or `ulong`, `C2` is the better conversion.
- If `T1` is `int` and `T2` is `uint`, or `ulong`, `C1` is the better conversion.
- If `T2` is `int` and `T1` is `uint`, or `ulong`, `C2` is the better conversion.
- If `T1` is `long` and `T2` is `ulong`, `C1` is the better conversion.
- If `T2` is `long` and `T1` is `ulong`, `C2` is the better conversion.
- Otherwise, neither conversion is better.

If an implicit conversion `C1` is defined by these rules to be a better conversion than an implicit conversion `C2`, then it is also the case that `C2` is a worse conversion than `C1`.

7.4.3 Function member invocation

This section describes the process that takes place at run-time to invoke a particular function member. It is assumed that a compile-time process has already determined the particular member to invoke, possibly by applying overload resolution to a set of candidate function members.

For purposes of describing the invocation process, function members are divided into two categories:

- Static function members. These are instance constructors, static methods, static property accessors, and user-defined operators. Static function members are always non-virtual.
- Instance function members. These are instance methods, instance property accessors, and indexer accessors. Instance function members are either non-virtual or virtual, and are always invoked on a particular instance. The instance is computed by an instance expression, and it becomes accessible within the function member as `this` (Section 7.5.7).

The run-time processing of a function member invocation consists of the following steps, where `M` is the function member and, if `M` is an instance member, `E` is the instance expression:

- If `M` is a static function member:
  - The argument list is evaluated as described in Section 7.4.1.
  - `M` is invoked.
- If `M` is an instance function member declared in a *value-type*:
  - `E` is evaluated. If this evaluation causes an exception, then no further steps are executed.
  - If `E` is not classified as a variable, then a temporary local variable of `E`'s type is created and the value of `E` is assigned to that variable. `E` is then reclassified as a reference to that temporary local variable. The temporary variable is accessible as `this` within `M`, but not in any other way. Thus, only when `E` is a true variable is it possible for the caller to observe the changes that `M` makes to `this`.
  - The argument list is evaluated as described in Section 7.4.1.
  - `M` is invoked. The variable referenced by `E` becomes the variable referenced by `this`.
- If `M` is an instance function member declared in a *reference-type*:
  - `E` is evaluated. If this evaluation causes an exception, then no further steps are executed.
  - The argument list is evaluated as described in Section 7.4.1.
  - If the type of `E` is a *value-type*, a boxing conversion (Section 4.3.1) is performed to convert `E` to type `object`, and `E` is considered to be of type `object` in the following steps. In this case, `M` could only be a member of `System.Object`.
  - The value of `E` is checked to be valid. If the value of `E` is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
  - The function member implementation to invoke is determined:

    If the compile-time type of `E` is an interface, the function member to invoke is the implementation of `M` provided by the run-time type of the instance referenced by `E`. This function member is determined by applying the interface mapping rules (Section 13.4.2) to determine the implementation of `M` provided by the run-time type of the instance referenced by `E`.

    Otherwise, if `M` is a virtual function member, the function member to invoke is the implementation of `M` provided by the run-time type of the instance referenced by `E`. This function member is determined by applying the rules for determining the most derived implementation (Section 10.5.3) of `M` with respect to the run-time type of the instance referenced by `E`.

    Otherwise, `M` is a non-virtual function member, and the function member to invoke is `M` itself.

  - The function member implementation determined in the step above is invoked. The object referenced by `E` becomes the object referenced by `this`.

7.4.3.1 Invocations on boxed instances

A function member implemented in a *value-type* can be invoked through a boxed instance of that *value-type* in the following situations:

- When the function member is an `override` of a method inherited from type `object` and is invoked through an instance expression of type `object`.
- When the function member is an implementation of an interface function member and is invoked through an instance expression of an *interface-type*.
- When the function member is invoked through a delegate.

In these situations, the boxed instance is considered to contain a variable of the *value-type*, and this variable becomes the variable referenced by `this` within the function member invocation. In particular, this means that when a function member is invoked on a boxed instance, it is possible for the function member to modify the value contained in the boxed instance.

7.5 Primary expressions

Primary expressions include the simplest forms of expressions.

primary-expression:
  primary-no-array-creation-expression
  array-creation-expression
primary-no-array-creation-expression:
  literal
  simple-name
  parenthesized-expression
  member-access
  invocation-expression
  element-access
  this-access
  base-access
  post-increment-expression
  post-decrement-expression
  object-creation-expression
  delegate-creation-expression
  typeof-expression
  checked-expression
  unchecked-expression

Primary expressions are divided between array-creation-expressions and primary-no-array-creation-expressions. Treating array-creation-expression in this way, rather than listing it along with the other simple expression forms, enables the grammar to disallow potentially confusing code such as

```
object o = new int[3][1];
```

which would otherwise be interpreted as

```
object o = (new int[3])[1];
```

7.5.1 Literals

A primary-expression that consists of a literal (Section 2.4.4) is classified as a value.

7.5.2 Simple names

A simple-name consists of a single identifier.

simple-name:
  identifier

A simple-name is evaluated and classified as follows:

- If the simple-name appears within a block and if the block's (or an enclosing block's) local variable declaration space (Section 3.3) contains a local variable or parameter with the given name, then the simple-name refers to that local variable or parameter and is classified as a variable.
- Otherwise, for each type `T`, starting with the immediately enclosing class, struct, or enumeration declaration and continuing with each enclosing outer class or struct declaration (if any), if a member lookup of the simple-name in `T` produces a match:
- If `T` is the immediately enclosing class or struct type and the lookup identifies one or more methods, the result is a method group with an associated instance expression of `this`.
- If `T` is the immediately enclosing class or struct type, if the lookup identifies an instance member, and if the reference occurs within the block of an instance constructor, an instance method, or an instance accessor, the result is the same as a member access (Section 7.5.4) of the form `this.E`, where `E` is the simple-name.
- Otherwise, the result is the same as a member access (Section 7.5.4) of the form `T.E`, where `E` is the simple-name. In this case, it is a compile-time error for the simple-name to refer to an instance member.
- Otherwise, starting with the namespace in which the simple-name occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
- If the namespace contains a namespace member with the given name, then the simple-name refers to that member and, depending on the member, is classified as a namespace or a type.
- Otherwise, if the namespace has a corresponding namespace declaration enclosing the location where the simple-name occurs, then:
- If the namespace declaration contains a using-alias-directive that associates the given name with an imported namespace or type, then the simple-name refers to that namespace or type.
- Otherwise, if the namespaces imported by the using-namespace-directives of the namespace declaration contain exactly one type with the given name, then the simple-name refers to that type.
- Otherwise, if the namespaces imported by the using-namespace-directives of the namespace declaration contain more than one type with the given name, then the simple-name is ambiguous and a compile-time error occurs.
- Otherwise, the name given by the simple-name is undefined and a compile-time error occurs.

7.5.2.1 Invariant meaning in blocks

For each occurrence of a given identifier as a simple-name in an expression, every other occurrence of the same identifier as a simple-name in an expression within the immediately enclosing block (Section 8.2) or switch-block (Section 8.7.2) must refer to the same entity. This rule ensures that the meaning of a name in the context of an expression is always the same within a block.

The example

```
class Test
{
   double x;
   void F(bool b) {
      x = 1.0;
      if (b) {
         int x;
         x = 1;
      }
   }
}
```

results in a compile-time error because `x` refers to different entities within the outer block (the extent of which includes the nested block in the `if` statement). In contrast, the example

```
class Test
{
   double x;
   void F(bool b) {
      if (b) {
         x = 1.0;
      }
      else {
         int x ;
         x = 1;
      }
   }
}
```

is permitted because the name `x` is never used in the outer block.

> **Note** The rule of *invariant meaning* applies only to simple names. It is perfectly valid for the same identifier to have one meaning as a simple name and another meaning as right operand of a member access (Section 7.5.4). For example:

```
struct Point
{
   int x, y;
   public Point(int x, int y) {
      this.x = x;
      this.y = y;
   }
}
```

The example above illustrates a common pattern of using the names of fields as parameter names in an instance constructor. In the example, the simple names `x` and `y` refer to the parameters, but that does not prevent the member access expressions `this.x` and `this.y` from accessing the fields.

7.5.3 Parenthesized expressions

A parenthesized-expression consists of an expression enclosed in parentheses.

parenthesized-expression:
(*expression*)

A parenthesized-expression is evaluated by evaluating the *expression* within the parentheses. If the expression within the parentheses denotes a namespace, type, or method group, a compile-time error occurs. Otherwise, the result of the parenthesized-expression is the result of the evaluation of the contained expression.

7.5.4 Member access

A member-access consists of a primary-expression or a predefined-type, followed by a "`.`" token, followed by an identifier.

member-access:
  primary-expression `.` *identifier*
  predefined-type `.` *identifier*
predefined-type: one of
  bool byte char decimal double float int long
  object sbyte short string uint ulong ushort

A member-access of the form `E.I`, where `E` is a primary-expression or a predefined-type and `I` is an identifier, is evaluated and classified as follows:

- If `E` is a namespace and `I` is the name of an accessible member of that namespace, then the result is that member and, depending on the member, is classified as a namespace or a type.
- If `E` is a predefined-type or a primary-expression classified as a type, and a member lookup (Section 7.3) of `I` in `E` produces a match, then `E.I` is evaluated and classified as follows:
  - If `I` identifies a type, then the result is that type.
  - If `I` identifies one or more methods, then the result is a method group with no associated instance expression.
  - If `I` identifies a `static` property, then the result is a property access with no associated instance expression.
  - If `I` identifies a `static` field:

    If the field is `readonly` and the reference occurs outside the static constructor of the class or struct in which the field is declared, then the result is a value, namely the value of the static field `I` in `E`.

    Otherwise, the result is a variable, namely the static field `I` in `E`.

  - If `I` identifies a `static` event:

    If the reference occurs within the class or struct in which the event is declared, and the event was declared without event-accessor-declarations (Section 10.7), then `E.I` is processed exactly as if `I` was a static field.

    Otherwise, the result is an event access with no associated instance expression.

  - If `I` identifies a constant, then the result is a value, namely the value of that constant.
  - If `I` identifies an enumeration member, then the result is a value, namely the value of that enumeration member.
  - Otherwise, `E.I` is an invalid member reference, and a compile-time error occurs.
- If `E` is a property access, indexer access, variable, or value, the type of which is `T`, and a member lookup (Section 7.3) of `I` in `T` produces a match, then `E.I` is evaluated and classified as follows:
  - First, if `E` is a property or indexer access, then the value of the property or indexer access is obtained (Section 7.1.1) and `E` is reclassified as a value.
  - If `I` identifies one or more methods, then the result is a method group with an associated instance expression of `E`.
  - If `I` identifies an instance property, then the result is a property access with an associated instance expression of `E`.
  - If `T` is a *class-type* and `I` identifies an instance field of that *class-type*:

    If the value of `E` is `null`, then a `System.NullReferenceException` is thrown.

    Otherwise, if the field is `readonly` and the reference occurs outside an instance constructor of the class in which the field is declared, then the result is a value, namely the value of the field `I` in the object referenced by `E`.

    Otherwise, the result is a variable, namely the field `I` in the object referenced by `E`.

  - If `T` is a struct-type and `I` identifies an instance field of that struct-type:

    If `E` is a value, or if the field is `readonly` and the reference occurs outside an instance constructor of the struct in which the field is declared, then the result is a value, namely the value of the field `I` in the struct instance given by `E`.

    Otherwise, the result is a variable, namely the field `I` in the struct instance given by `E`.

  - If `I` identifies an instance event:

If the reference occurs within the class or struct in which the event is declared, and the event was declared without event-accessor-declarations (Section 10.7), then `E.I` is processed exactly as if `I` was an instance field.

Otherwise, the result is an event access with an associated instance expression of `E`.

- Otherwise, `E.I` is an invalid member reference, and a compile-time error occurs.

7.5.4.1 Identical simple names and type names

In a member access of the form `E.I`, if `E` is a single identifier, and if the meaning of `E` as a simple-name (Section 7.5.2) is a constant, field, property, local variable, or parameter with the same type as the meaning of `E` as a type-name (Section 3.8), then both possible meanings of `E` are permitted. The two possible meanings of `E.I` are never ambiguous, since `I` must necessarily be a member of the type `E` in both cases. In other words, the rule simply permits access to the static members and nested types of `E` where a compile-time error would otherwise have occurred. For example:

```
struct Color
{
   public static readonly Color White = new Color(...);
   public static readonly Color Black = new Color(...);
   public Color Complement() {...}
}
class A
{
   public Color Color;               // Field Color of type Color
   void F() {
      Color = Color.Black;          // References Color.Black static member
      Color = Color.Complement();   // Invokes Complement() on Color field
   }
   static void G() {
      Color c = Color.White;         // References Color.White static member
   }
}
```

Within the `A` class, those occurrences of the `Color` identifier that reference the `Color` type are underlined, and those that reference the `Color` field are not underlined.

7.5.5 Invocation expressions

An invocation-expression is used to invoke a method.

invocation-expression:
  primary-expression (*argument-list*$_{opt}$)

The primary-expression of an invocation-expression must be a method group or a value of a *delegate-type*. If the primary-expression is a method group, the invocation-expression is a method invocation (Section 7.5.5.1). If the primary-expression is a value of a *delegate-type*, the invocation-expression is a delegate invocation (Section 7.5.5.2). If the primary-expression is neither a method group nor a value of a *delegate-type*, a compile-time error occurs.

The optional argument-list (Section 7.4.1) provides values or variable references for the parameters of the method.

The result of evaluating an invocation-expression is classified as follows:

- If the invocation-expression invokes a method or delegate that returns `void`, the result is nothing. An expression that is classified as nothing cannot be an operand of any operator, and is permitted only in the context of a statement-expression (Section 8.6).
- Otherwise, the result is a value of the type returned by the method or delegate.

7.5.5.1 Method invocations

For a method invocation, the primary-expression of the invocation-expression must be a method group. The method group identifies the one method to invoke or the set of overloaded methods from which to choose a specific method to invoke. In the latter case, determination of the specific method to invoke is based on the context provided by the types of the arguments in the argument-list.

The compile-time processing of a method invocation of the form `M(A)`, where `M` is a method group and `A` is an optional argument-list, consists of the following steps:

- The set of candidate methods for the method invocation is constructed. Starting with the set of methods associated with `M`, which were found by a previous member lookup (Section 7.3), the set is reduced to those methods that are applicable with respect to the argument list `A`. The set reduction consists of applying the following rules to each method `T.N` in the set, where `T` is the type in which the method `N` is declared:
  - If `N` is not applicable with respect to `A` (Section 7.4.2.1), then `N` is removed from the set.
  - If `N` is applicable with respect to `A` (Section 7.4.2.1), then all methods declared in a base type of `T` are removed from the set.
- If the resulting set of candidate methods is empty, then no applicable methods exist, and a compile-time error occurs. If the candidate methods are not all declared in the same type, the method invocation is ambiguous, and a compile-time error occurs (this latter situation can only occur for an invocation of a method in an interface that has multiple direct base interfaces, as described in Section 13.2.5).
- The best method of the set of candidate methods is identified using the overload resolution rules of Section 7.4.2. If a single best method cannot be identified, the method invocation is ambiguous, and a compile-time error occurs.
- Given a best method, the invocation of the method is validated in the context of the method group: If the best method is a static method, the method group must have resulted from a simple-name or a member-access through a type. If the best method is an instance method, the method group must have resulted from a simple-name, a member-access through a variable or value, or a base-access. If neither requirement is true, a compile-time error occurs.

Once a method has been selected and validated at compile-time by the above steps, the actual run-time invocation is processed according to the rules of function member invocation described in Section 7.4.3.

The intuitive effect of the resolution rules described above is as follows: To locate the particular method invoked by a method invocation, start with the type indicated by the method invocation and proceed up the inheritance chain until at least one applicable, accessible, non-override method declaration is found. Then perform overload resolution on the set of applicable, accessible, non-override methods declared in that type and invoke the method thus selected.

7.5.5.2 Delegate invocations

For a delegate invocation, the primary-expression of the invocation-expression must be a value of a *delegate-type*. Furthermore, considering the *delegate-type* to be a function member with the same parameter list as the *delegate-type*, the *delegate-type* must be applicable (Section 7.4.2.1) with respect to the argument-list of the invocation-expression.

The run-time processing of a delegate invocation of the form `D(A)`, where `D` is a primary-expression of a *delegate-type* and `A` is an optional argument-list, consists of the following steps:

- `D` is evaluated. If this evaluation causes an exception, no further steps are executed.
- The value of `D` is checked to be valid. If the value of `D` is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
- Otherwise, `D` is a reference to a delegate instance. Function member invocations (Section 7.4.3) are performed on each of the callable entities in the invocation list of the delegate. For callable entities consisting of an instance and instance method, the instance for the invocation is the instance contained in the callable entity.

7.5.6 Element access

An element-access consists of a primary-no-array-creation-expression, followed by a "[" token, followed by an expression-list, followed by a "]" token. The expression-list consists of one or more expressions, separated by commas.

element-access:
  primary-no-array-creation-expression [*expression-list*]
expression-list:
  expression
  expression-list , *expression*

If the primary-no-array-creation-expression of an element-access is a value of an *array-type*, the element-access is an array access (Section 7.5.6.1). Otherwise, the primary-no-array-creation-expression must be a variable or value of a class, struct, or interface type that has one or more indexer members, in which case the element-access is an indexer access (Section 7.5.6.2).

7.5.6.1 Array access

For an array access, the primary-no-array-creation-expression of the element-access must be a value of an *array-type*. The number of expressions in the expression-list must be the same as the rank of the *array-type*, and each expression must be of type `int`, `uint`, `long`, `ulong`, or of a type that can be implicitly converted to one or more of these types.

The result of evaluating an array access is a variable of the element type of the array, namely the array element selected by the value(s) of the expression(s) in the expression-list.

The run-time processing of an array access of the form `P[A]`, where `P` is a primary-no-array-creation-expression of an *array-type* and `A` is an expression-list, consists of the following steps:

- `P` is evaluated. If this evaluation causes an exception, no further steps are executed.
- The index expressions of the expression-list are evaluated in order, from left to right. Following evaluation of each index expression, an implicit conversion (Section 6.1) to one of the following types is performed: `int`, `uint`, `long`, `ulong`. The first type in this list for which an implicit conversion exists is chosen. For instance, if the index expression is of type `short` then an implicit conversion to `int` is performed, since implicit conversions from `short` to `int` and from `short` to `long` are possible. If evaluation of an index expression or the subsequent implicit conversion causes an exception, then no further index expressions are evaluated and no further steps are executed.
- The value of `P` is checked to be valid. If the value of `P` is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
- The value of each expression in the *expression-list* is checked against the actual bounds of each dimension of the array instance referenced by `P`. If one or more values are out of range, a `System.IndexOutOfRangeException` is thrown and no further steps are executed.
- The location of the array element given by the index expression(s) is computed, and this location becomes the result of the array access.

7.5.6.2 Indexer access

For an indexer access, the primary-no-array-creation-expression of the element-access must be a variable or value of a class, struct, or interface type, and this type must implement one or more indexers that are applicable with respect to the expression-list of the element-access.

The compile-time processing of an indexer access of the form `P[A]`, where `P` is a primary-no-array-creation-expression of a class, struct, or interface type `T`, and `A` is an expression-list, consists of the following steps:

- The set of indexers provided by `T` is constructed. The set consists of all indexers declared in `T` or a base type of `T` that are not `override` declarations and are accessible in the current context (Section 3.5).
- The set is reduced to those indexers that are applicable and not hidden by other indexers. The following rules are applied to each indexer `S.I` in the set, where `S` is the type in which the indexer `I` is declared:
  - If `I` is not applicable with respect to `A` (Section 7.4.2.1), then `I` is removed from the set.
  - If `I` is applicable with respect to `A` (Section 7.4.2.1), then all indexers declared in a base type of `S` are removed from the set.
- If the resulting set of candidate indexers is empty, then no applicable indexers exist, and a compile-time error occurs. If the candidate indexers are not all declared in the same type, the indexer access is ambiguous, and a compile-time error occurs (this latter situation can only occur for an indexer access on an instance of an interface that has multiple direct base interfaces).
- The best indexer of the set of candidate indexers is identified using the overload resolution rules of Section 7.4.2. If a single best indexer cannot be identified, the indexer access is ambiguous, and a compile-time error occurs.
- The index expressions of the expression-list are evaluated in order, from left to right. The result of processing the indexer access is an expression classified as an indexer access. The indexer access expression references the indexer determined in the step above, and has an associated instance expression of `P` and an associated argument list of `A`.

Depending on the context in which it is used, an indexer access causes invocation of either the get-accessor or the set-accessor of the indexer. If the indexer access is the target of an assignment, the set-accessor is invoked to assign a new value (Section 7.13.1). In all other cases, the get-accessor is invoked to obtain the current value (Section 7.1.1).

7.5.7 This access

A this-access consists of the reserved word `this`.

this-access:
  this

A this-access is permitted only in the *block* of an instance constructor, an instance method, or an instance accessor. It has one of the following meanings:

- When `this` is used in a *primary-expression* within an instance constructor of a class, it is classified as a value. The type of the value is the class within which the usage occurs, and the value is a reference to the object being constructed.
- When `this` is used in a *primary-expression* within an instance method or instance accessor of a class, it is classified as a value. The type of the value is the class within which the usage occurs, and the value is a reference to the object for which the method or accessor was invoked.
- When `this` is used in a *primary-expression* within an instance constructor of a struct, it is classified as a variable. The type of the variable is the struct within which the usage occurs, and the variable represents the struct being constructed. The `this` variable of an instance constructor of a struct behaves exactly the same as an `out` parameter of the struct type — in particular, this means that the variable must be definitely assigned in every execution path of the instance constructor.
- When `this` is used in a *primary-expression* within an instance method or instance accessor of a struct, it is classified as a variable. The type of the variable is the struct within which the usage occurs, and the variable represents the struct for which the method or accessor was invoked. The `this` variable of an instance method of a struct behaves exactly the same as a `ref` parameter of the struct type.

Use of `this` in a *primary-expression* in a context other than the ones listed above is a compile-time error. In particular, it is not possible to refer to `this` in a static method, a static property accessor, or in a *variable-initializer* of a field declaration.

7.5.8 Base access

A *base-access* consists of the reserved word `base` followed by either a "`.`" token and an identifier or an expression-list enclosed in square brackets:

base-access:
  base . *identifier*
  base [*expression-list*]

A *base-access* is used to access base class members that are hidden by similarly named members in the current class or struct. A *base-access* is permitted only in the block of an instance constructor, an instance method, or an instance accessor. When `base.I` occurs in a class or struct, `I` must denote a member of the base class of that class or struct. Likewise, when `base[E]` occurs in a class, an applicable indexer must exist in the base class.

At compile-time, *base-access* expressions of the form `base.I` and `base[E]` are evaluated exactly as if they were written `((B)this).I` and `((B)this)[E]`, where `B` is the base class of the class or struct in which the construct occurs. Thus, `base.I` and `base[E]` correspond to `this.I` and `this[E]`, except `this` is viewed as an instance of the base class.

When a *base-access* references a virtual function member (a method, property, or indexer), the determination of which function member to invoke at run-time (Section 7.4.3) is changed. The function member that is invoked is determined by finding the most derived implementation (Section 10.5.3) of the function member with respect to `B` (instead of with respect to the run-time type of `this`, as would be usual in a non-base access). Thus, within an `override` of a `virtual` function member, a *base-access* can be used to invoke the inherited implementation of the function member. If the function member referenced by a *base-access* is abstract, a compile-time error occurs.

7.5.9 Postfix increment and decrement operators

post-increment-expression:
  primary-expression `++`
post-decrement-expression:
  primary-expression `--`

The operand of a postfix increment or decrement operation must be an expression classified as a variable, a property access, or an indexer access. The result of the operation is a value of the same type as the operand.

If the operand of a postfix increment or decrement operation is a property or indexer access, the property or indexer must have both a `get` and a `set` accessor. If this is not the case, a compile-time error occurs.

Unary operator overload resolution (Section 7.2.3) is applied to select a specific operator implementation. Predefined `++` and `--` operators exist for the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type. The predefined `++` operators return the value produced by adding 1 to the operand, and the predefined `--` operators return the value produced by subtracting 1 from the operand.

The run-time processing of a postfix increment or decrement operation of the form `x++` or `x--` consists of the following steps:

- If `x` is classified as a variable:
  - `x` is evaluated to produce the variable.
  - The value of `x` is saved.
  - The selected operator is invoked with the saved value of `x` as its argument.
  - The value returned by the operator is stored in the location given by the evaluation of `x`.
  - The saved value of `x` becomes the result of the operation.
- If `x` is classified as a property or indexer access:
  - The instance expression (if `x` is not `static`) and the argument list (if `x` is an indexer access) associated with `x` are evaluated, and the results are used in the subsequent `get` and `set` accessor invocations.
  - The `get` accessor of `x` is invoked and the returned value is saved.
  - The selected operator is invoked with the saved value of `x` as its argument.
  - The `set` accessor of `x` is invoked with the value returned by the operator as its `value` argument.
  - The saved value of `x` becomes the result of the operation.

The `++` and `--` operators also support prefix notation, as described in Section 7.6.5. The result of `x++` or `x--` is the value of `x` *before* the operation, whereas the result of `++x` or `--x` is the value of `x` *after* the operation. In either case, `x` itself has the same value after the operation.

An `operator ++` or `operator --` implementation can be invoked using either postfix or prefix notation. It is not possible to have separate operator implementations for the two notations.

7.5.10 The new operator

The `new` operator is used to create new instances of types.

There are three forms of `new` expressions:

- Object creation expressions are used to create new instances of class types and value types.
- Array creation expressions are used to create new instances of array types.
- Delegate creation expressions are used to create new instances of delegate types.

The `new` operator implies creation of an instance of a type, but does not necessarily imply dynamic allocation of memory. In particular, instances of value types require no additional memory beyond the variables in which they reside, and no dynamic allocations occur when `new` is used to create instances of value types.

7.5.10.1 Object creation expressions

An *object-creation-expression* is used to create a new instance of a *class-type* or a *value-type*.

object-creation-expression:
  new *type* (*argument-list*$_{opt}$)

The type of an object-creation-expression must be a *class-type* or a *value-type*. The type cannot be an `abstract` *class-type*.

The optional argument-list (Section 7.4.1) is permitted only if the type is a *class-type* or a struct-type.

The compile-time processing of an object-creation-expression of the form `new T(A)`, where `T` is a *class-type* or a *value-type* and `A` is an optional argument-list, consists of the following steps:

- If `T` is a *value-type* and `A` is not present:
  - The object-creation-expression is a default constructor invocation. The result of the object-creation-expression is a value of type `T`, namely the default value for `T` as defined in Section 4.1.1.
- Otherwise, if `T` is a *class-type* or a struct-type:
  - If `T` is an `abstract` *class-type*, a compile-time error occurs.
  - The instance constructor to invoke is determined using the overload resolution rules of Section 7.4.2. The set of candidate instance constructors consists of all accessible instance constructors declared in `T`, which are applicable with respect to `A` (Section 7.4.2.1). If the set of candidate instance constructors is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs.
  - The result of the object-creation-expression is a value of type `T`, namely the value produced by invoking the instance constructor determined in the step above.
- Otherwise, the object-creation-expression is invalid, and a compile-time error occurs.

The run-time processing of an object-creation-expression of the form `new T(A)`, where `T` is *class-type* or a struct-type and `A` is an optional argument-list, consists of the following steps:

- If `T` is a *class-type*:
  - A new instance of class `T` is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
  - All fields of the new instance are initialized to their default values (Section 5.2).
  - The instance constructor is invoked according to the rules of function member invocation (Section 7.4.3). A reference to the newly allocated instance is automatically passed to the instance constructor and the instance can be accessed from within that constructor as `this`.
- If `T` is a struct-type:
  - An instance of type `T` is created by allocating a temporary local variable. Since an instance constructor of a struct-type is required to definitely assign a value to each field of the instance being created, no initialization of the temporary variable is necessary.
  - The instance constructor is invoked according to the rules of function member invocation (Section 7.4.3). A reference to the newly allocated instance is automatically passed to the instance constructor and the instance can be accessed from within that constructor as `this`.

7.5.10.2 Array creation expressions

An array-creation-expression is used to create a new instance of an *array-type*.

array-creation-expression:
  new *non-array-type* [*expression-list*] *rank-specifiers*$_{opt}$ *array-initializer*$_{opt}$
  new *array-type* *array-initializer*

An array creation expression of the first form allocates an array instance of the type that results from deleting each of the individual expressions from the expression list. For example, the array creation expression `new int[10, 20]` produces an array instance of type `int[,]`, and the array creation expression `new int[10][,]` produces an array of type `int[][,]`. Each expression in the expression list must be of type `int`, `uint`, `long`, or `ulong`, or of a type that can be implicitly converted to one or more of these types. The value of each expression determines the length of the corresponding dimension in the newly allocated array instance. Since the length of an array dimension must be nonnegative, it is a compile-time error to have a constant-expression with a negative value in the expression list.

Except in an unsafe context (Section A.1), the layout of arrays is unspecified.

If an array creation expression of the first form includes an array initializer, each expression in the expression list must be a constant and the rank and dimension lengths specified by the expression list must match those of the array initializer.

In an array creation expression of the second form, the rank of the specified array type must match that of the array initializer. The individual dimension lengths are inferred from the number of elements in each of the corresponding nesting levels of the array initializer. Thus, the expression

```
new int[,] {{0, 1}, {2, 3}, {4, 5}}
```

exactly corresponds to

```
new int[3, 2] {{0, 1}, {2, 3}, {4, 5}}
```

Array initializers are described further in Section 12.6.

The result of evaluating an array creation expression is classified as a value, namely a reference to the newly allocated array instance. The run-time processing of an array creation expression consists of the following steps:

- The dimension length expressions of the expression-list are evaluated in order, from left to right. Following evaluation of each expression, an implicit conversion (Section 6.1) to one of the following types is performed: `int`, `uint`, `long`, `ulong`. The first type in this list for which an implicit conversion exists is chosen. If evaluation of an expression or the subsequent implicit conversion causes an exception, then no further expressions are evaluated and no further steps are executed.
- The computed values for the dimension lengths are validated as follows. If one or more of the values are less than zero, a `System.OverflowException` is thrown and no further steps are executed.
- An array instance with the given dimension lengths is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
- All elements of the new array instance are initialized to their default values (Section 5.2).
- If the array creation expression contains an array initializer, then each expression in the array initializer is evaluated and assigned to its corresponding array element. The evaluations and assignments are performed in the order the expressions are written in the array initializer — in other words, elements are initialized in increasing index order, with the rightmost dimension increasing first. If evaluation of a given expression or the subsequent assignment to the corresponding array element causes an exception, then no further elements are initialized (and the remaining elements will thus have their default values).

An array creation expression permits instantiation of an array with elements of an array type, but the elements of such an array must be manually initialized. For example, the statement

```
int[][] a = new int[100][];
```

creates a single-dimensional array with 100 elements of type `int[]`. The initial value of each element is `null`. It is not possible for the same array creation expression to also instantiate the sub-arrays, and the statement

```
int[][] a = new int[100][5];      // Error
```

results in a compile-time error. Instantiation of the sub-arrays must instead be performed manually, as in

```
int[][] a = new int[100][];
for (int i = 0; i < 100; i++) a[i] = new int[5];
```

When an array of arrays has a "rectangular" shape, that is when the sub-arrays are all of the same length, it is more efficient to use a multi-dimensional array. In the example above, instantiation of the array of arrays creates 101 objects — one outer array and 100 sub-arrays. In contrast,

```
int[,] = new int[100, 5];
```

creates only a single object, a two-dimensional array, and accomplishes the allocation in a single statement.

7.5.10.3 Delegate creation expressions

A delegate-creation-expression is used to create a new instance of a *delegate-type*.

delegate-creation-expression:
  new *delegate-type* (*expression*)

The argument of a delegate creation expression must be a method group (Section 7.1) or a value of a *delegate-type*. If the argument is a method group, it identifies the method and, for an instance method, the object for which to create a delegate. If the argument is a value of a *delegate-type*, it identifies a delegate instance of which to create a copy.

The compile-time processing of a delegate-creation-expression of the form `new D(E)`, where `D` is a *delegate-type* and `E` is an expression, consists of the following steps:

- If `E` is a method group:
  - The set of methods identified by `E` must include exactly one method that is compatible (Section 15.1) with `D`, and this method becomes the one to which the newly created delegate refers. If no matching method exists, or if more than one matching method exists, a compile-time error occurs. If the selected method is an instance method, the instance expression associated with `E` determines the target object of the delegate.
  - As in a method invocation, the selected method must be compatible with the context of the method group: If the method is a static method, the method group must have resulted from a simple-name or a member-access through a type. If the method is an instance method, the method group must have resulted from a simple-name or a member-access through a variable or value. If the selected method does not match the context of the method group, a compile-time error occurs.
  - The result is a value of type `D`, namely a newly created delegate that refers to the selected method and target object.
- Otherwise, if `E` is a value of a *delegate-type*:
  - `D` and `E` must be compatible (Section 15.1); otherwise, a compile-time error occurs.
  - The result is a value of type `D`, namely a newly created delegate that refers to the same invocation list as `E`.
- Otherwise, the delegate creation expression is invalid, and a compile-time error occurs.

The run-time processing of a delegate-creation-expression of the form `new D(E)`, where `D` is a *delegate-type* and `E` is an expression, consists of the following steps:

- If `E` is a method group:
  - If the method selected at compile-time is a static method, the target object of the delegate is `null`. Otherwise, the selected method is an instance method, and the target object of the delegate is determined from the instance expression associated with `E`:

    The instance expression is evaluated. If this evaluation causes an exception, no further steps are executed.

    If the instance expression is of a *reference-type*, the value computed by the instance expression becomes the target object. If the target object is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.

    If the instance expression is of a *value-type*, a boxing operation (Section 4.3.1) is performed to convert the value to an object, and this object becomes the target object.
  - A new instance of the delegate type `D` is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
  - The new delegate instance is initialized with a reference to the method that was determined at compile-time and a reference to the target object computed above.
- If `E` is a value of a *delegate-type*:
  - `E` is evaluated. If this evaluation causes an exception, no further steps are executed.
  - If the value of `E` is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
  - A new instance of the delegate type `D` is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
  - The new delegate instance is initialized with the same invocation list as the delegate instance given by `E`.

The invocation list of a delegate is determined when the delegate is instantiated and then remains constant for the entire lifetime of the delegate. In other words, it is not possible to change the target callable entities of a delegate once it has been created. When

two delegates are combined or one is removed from another (Section 15.1), a new delegate results; no existing delegate has its contents changed.

It is not possible to create a delegate that refers to a property, indexer, user-defined operator, instance constructor, destructor, or static constructor.

As described above, when a delegate is created from a method group, the formal parameter list and return type of the delegate determine which of the overloaded methods to select. In the example

```
delegate double DoubleFunc(double x);
class A
{
   DoubleFunc f = new DoubleFunc(Square);
   static float Square(float x) {
      return x * x;
   }
   static double Square(double x) {
      return x * x;
   }
}
```

the `A.f` field is initialized with a delegate that refers to the second `Square` method because that method exactly matches the formal parameter list and return type of `DoubleFunc`. Had the second `Square` method not been present, a compile-time error would have occurred.

7.5.11 The typeof operator

The `typeof` operator is used to obtain the `System.Type` object for a type.

typeof-expression:
  typeof (*type*)
  typeof (void)

The first form of typeof-expression consists of a `typeof` keyword followed by a parenthesized *type*. The result of an expression of this form is the `System.Type` object for the indicated type. There is only one `System.Type` object for any given type. This means that for type `T`, `typeof(T) == typeof(T)` is always true.

The second form of typeof-expression consists of a `typeof` keyword followed by a parenthesized `void` keyword. The result of an expression of this form is the `System.Type` object that represents the absence of a type. The type object returned by `typeof(void)` is distinct from the type object returned for any type. This special type object is useful in class libraries that allow reflection onto methods in the language, where those methods wish to have a way to represent the return type of any method, including void methods, with an instance of `System.Type`.

The example

```
using System;
class Test
{
   static void Main() {
      Type[] t = {
         typeof(int),
         typeof(System.Int32),
         typeof(string),
         typeof(double[]),
         typeof(void)
      };
      for (int i = 0; i < t.Length; i++) {
         Console.WriteLine(t[i].FullName);
      }
   }
}
```

produces the following output:

```
System.Int32
System.Int32
System.String
System.Double[]
System.Void
```

Note that `int` and `System.Int32` are the same type.

7.5.12 The checked and unchecked operators

The `checked` and `unchecked` operators are used to control the overflow checking context for integral-type arithmetic operations and conversions.

checked-expression:
  checked (*expression*)
unchecked-expression:
  unchecked (*expression*)

The `checked` operator evaluates the contained expression in a checked context, and the `unchecked` operator evaluates the contained expression in an unchecked context. A checked-expression or unchecked-expression corresponds exactly to a parenthesized-expression (Section 7.5.3), except that the contained expression is evaluated in the given overflow checking context.

The overflow checking context can also be controlled through the `checked` and `unchecked` statements (Section 8.11).

The following operations are affected by the overflow checking context established by the `checked` and `unchecked` operators and statements:

- The predefined `++` and `--` unary operators (Section 7.5.9 and Section 7.6.5), when the operand is of an integral type.
- The predefined `-` unary operator (Section 7.6.2), when the operand is of an integral type.
- The predefined `+`, `-`, `*`, and `/` binary operators (Section 7.7), when both operands are of integral types.
- Explicit numeric conversions (Section 6.2.1) from one integral type to another integral type, or from `float` or `double` to an integral type.

When one of the above operations produce a result that is too large to represent in the destination type, the context in which the operation is performed controls the resulting behavior:

- In a `checked` context, if the operation is a constant expression (Section 7.15), a compile-time error occurs. Otherwise, when the operation is performed at run-time, a `System.OverflowException` is thrown.
- In an `unchecked` context, the result is truncated by discarding any high-order bits that do not fit in the destination type.

For non-constant expressions (expressions that are evaluated at run-time) that are not enclosed by any `checked` or `unchecked` operators or statements, the default overflow checking context is `unchecked` unless external factors (such as compiler switches and execution environment configuration) call for `checked` evaluation.

For constant expressions (expressions that can be fully evaluated at compile-time), the default overflow checking context is always `checked`. Unless a constant expression is explicitly placed in an `unchecked` context, overflows that occur during the compile-time evaluation of the expression always cause compile-time errors.

In the example

```
class Test
{
   static readonly int x = 1000000;
   static readonly int y = 1000000;
   static int F() {
      return checked(x * y);      // Throws OverflowException
   }
   static int G() {
      return unchecked(x * y);   // Returns -727379968
   }
   static int H() {
      return x * y;               // Depends on default
   }
}
```

no compile-time errors are reported since neither of the expressions can be evaluated at compile-time. At run-time, the `F` method throws a `System.OverflowException`, and the `G` method returns –727379968 (the lower 32 bits of the out-of-range result). The behavior of the `H` method depends on the default overflow checking context for the compilation, but it is either the same as `F` or the same as `G`.

In the example

```
class Test
{
   const int x = 1000000;
   const int y = 1000000;
   static int F() {
      return checked(x * y);      // Compile error, overflow
   }
   static int G() {
      return unchecked(x * y);   // Returns -727379968
   }
   static int H() {
      return x * y;               // Compile error, overflow
   }
}
```

the overflows that occur when evaluating the constant expressions in `F` and `H` cause compile-time errors to be reported because the expressions are evaluated in a `checked` context. An overflow also occurs when evaluating the constant expression in `G`, but since the evaluation takes place in an `unchecked` context, the overflow is not reported.

The `checked` and `unchecked` operators only affect the overflow checking context for those operations that are textually contained within the "`(`" and "`)`" tokens. The operators have no effect on function members that are invoked as a result of evaluating the contained expression. In the example

```
class Test
{
   static int Multiply(int x, int y) {
      return x * y;
   }
   static int F() {
      return checked(Multiply(1000000, 1000000));
   }
}
```

the use of `checked` in `F` does not affect the evaluation of `x * y` in `Multiply`, so `x * y` is evaluated in the default overflow checking context.

The `unchecked` operator is convenient when writing constants of the signed integral types in hexadecimal notation. For example:

```
class Test
{
   public const int AllBits = unchecked((int)0xFFFFFFFF);
   public const int HighBit = unchecked((int)0x80000000);
}
```

Both of the hexadecimal constants above are of type `uint`. Because the constants are outside the `int` range, without the `unchecked` operator, the casts to `int` would produce compile-time errors.

The `checked` and `unchecked` operators and statements allow programmers to control certain aspects of some numeric calculations. However, the behavior of some numeric operators depends on their operands' data types. For example, multiplying two decimals always results in an exception on overflow even within an explicitly `unchecked` construct. Similarly, multiplying two floats never results in an exception on overflow even within an explicitly `checked` construct. In addition, other operators are *never* affected by the mode of checking, whether default or explicit.

7.6 Unary operators

The +, –, !, ~, ++, ––, and cast operators are called the unary operators.

unary-expression:
  primary-expression
  + *unary-expression*
  - *unary-expression*
  ! *unary-expression*
  ~ *unary-expression*
  pre-increment-expression
  pre-decrement-expression
  cast-expression

7.6.1 Unary plus operator

For an operation of the form `+x`, unary operator overload resolution (Section 7.2.3) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined unary plus operators are:

```
int operator +(int x);
uint operator +(uint x);
long operator +(long x);
ulong operator +(ulong x);
float operator +(float x);
double operator +(double x);
decimal operator +(decimal x);
```

For each of these operators, the result is simply the value of the operand.

7.6.2 Unary minus operator

For an operation of the form `-x`, unary operator overload resolution (Section 7.2.3) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined negation operators are:

- Integer negation:

```
int operator -(int x);
long operator -(long x);
```

The result is computed by subtracting `x` from zero. If the value of `x` is the smallest representable value of the operand type (-2^{31} for `int` or -2^{63} for `long`), then the mathematical negation of x is not representable within the operand type. If this occurs within a `checked` context, a `System.OverflowException` is thrown; if it occurs within an `unchecked` context, the result is the value of the operand and the overflow is not reported.

If the operand of the negation operator is of type `uint`, it is converted to type `long`, and the type of the result is `long`. An exception is the rule that permits the `int` value −2147483648 (-2^{31}) to be written as a decimal integer literal (Section 2.4.4.2).

If the operand of the negation operator is of type `ulong`, a compile-time error occurs. An exception is the rule that permits the `long` value −9223372036854775808 (-2^{63}) to be written as a decimal integer literal (Section 2.4.4.2).

- Floating-point negation:

```
float operator -(float x);
double operator -(double x);
```

The result is the value of `x` with its sign inverted. If `x` is NaN, the result is also NaN.

- Decimal negation:

```
decimal operator -(decimal x);
```

The result is computed by subtracting `x` from zero. Decimal negation is equivalent to using the unary minus operator of type `System.Decimal`.

7.6.3 Logical negation operator

For an operation of the form `!x`, unary operator overload resolution (Section 7.2.3) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. Only one predefined logical negation operator exists:

```
bool operator !(bool x);
```

This operator computes the logical negation of the operand: If the operand is `true`, the result is `false`. If the operand is `false`, the result is `true`.

7.6.4 Bitwise complement operator

For an operation of the form `~x`, unary operator overload resolution (Section 7.2.3) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined bitwise complement operators are:

```
int operator ~(int x);
uint operator ~(uint x);
long operator ~(long x);
ulong operator ~(ulong x);
```

For each of these operators, the result of the operation is the bitwise complement of `x`.

Every enumeration type `E` implicitly provides the following bitwise complement operator:

```
E operator ~(E x);
```

The result of evaluating `~x`, where `x` is an expression of an enumeration type `E` with an underlying type `U`, is exactly the same as evaluating (E) `(~(U)x)`.

7.6.5 Prefix increment and decrement operators

pre-increment-expression:
  `++` *unary-expression*
pre-decrement-expression:
  `--` *unary-expression*

The operand of a prefix increment or decrement operation must be an expression classified as a variable, a property access, or an indexer access. The result of the operation is a value of the same type as the operand.

If the operand of a prefix increment or decrement operation is a property or indexer access, the property or indexer must have both a `get` and a `set` accessor. If this is not the case, a compile-time error occurs.

Unary operator overload resolution (Section 7.2.3) is applied to select a specific operator implementation. Predefined `++` and `--` operators exist for the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type. The predefined `++` operators return the value produced by adding 1 to the operand, and the predefined `--` operators return the value produced by subtracting 1 from the operand.

The run-time processing of a prefix increment or decrement operation of the form `++x` or `--x` consists of the following steps:

- If `x` is classified as a variable:
  - `x` is evaluated to produce the variable.
  - The selected operator is invoked with the value of `x` as its argument.
  - The value returned by the operator is stored in the location given by the evaluation of `x`.
  - The value returned by the operator becomes the result of the operation.
- If `x` is classified as a property or indexer access:
  - The instance expression (if `x` is not `static`) and the argument list (if `x` is an indexer access) associated with `x` are evaluated, and the results are used in the subsequent `get` and `set` accessor invocations.
  - The `get` accessor of `x` is invoked.
  - The selected operator is invoked with the value returned by the `get` accessor as its argument.
  - The `set` accessor of `x` is invoked with the value returned by the operator as its `value` argument.
  - The value returned by the operator becomes the result of the operation.

The `++` and `--` operators also support postfix notation, (Section 7.5.9). The result of `x++` or `x--` is the value of `x` *before* the operation, whereas the result of `++x` or `--x` is the value of `x` *after* the operation. In either case, `x` itself has the same value after the operation.

An `operator ++` or `operator --` implementation can be invoked using either postfix or prefix notation. It is not possible to have separate operator implementations for the two notations.

7.6.6 Cast expressions

A cast-expression is used to explicitly convert an expression to a given type.

cast-expression:
  (*type*) *unary-expression*

A cast-expression of the form `(T)E`, where `T` is a *type* and `E` is a unary-expression, performs an explicit conversion (Section 6.2) of the value of `E` to type `T`. If no explicit conversion exists from the type of `E` to `T`, a compile-time error occurs. Otherwise, the result is the value produced by the explicit conversion. The result is always classified as a value, even if `E` denotes a variable.

The grammar for a cast-expression leads to certain syntactic ambiguities. For example, the expression `(x)-y` could either be interpreted as a cast-expression (a cast of `-y` to type `x`) or as an additive-expression combined with a parenthesized-expression (which computes the value `x - y)`.

To resolve cast-expression ambiguities, the following rule exists: A sequence of one or more tokens (Section 2.4) enclosed in parentheses is considered the start of a cast-expression only if at least one of the following are true:

- The sequence of tokens is correct grammar for a type, but not for an expression.
- The sequence of tokens is correct grammar for a type, and the token immediately following the closing parentheses is the token "`~`", the token "`!`", the token "`(`", an identifier (Section 2.4.1), a literal (Section 2.4.4), or any keyword (Section 2.4.3) except `as` and `is`.

The term "correct grammar" above means only that the sequence of tokens must conform to the particular grammatical production. It specifically does not consider the actual meaning of any constituent identifiers. For example, if `x` and `y` are identifiers, then `x.y` is correct grammar for a type, even if `x.y` doesn't actually denote a type.

From the disambiguation rule it follows that, if `x` and `y` are identifiers, `(x)y`, `(x)(y)`, and `(x)(-y)` are cast-expressions, but `(x)-y` is not, even if `x` identifies a type. However, if `x` is a keyword that identifies a predefined type (such as `int`), then all four forms are cast-expressions (because such a keyword could not possibly be an expression by itself).

7.7 Arithmetic operators

The `*`, `/`, `%`, `+`, and `–` operators are called the arithmetic operators.

multiplicative-expression:
  unary-expression
  multiplicative-expression `*` *unary-expression*
  multiplicative-expression `/` *unary-expression*
  multiplicative-expression `%` *unary-expression*
additive-expression:
  multiplicative-expression
  additive-expression `+` *multiplicative-expression*
  additive-expression `–` *multiplicative-expression*

7.7.1 Multiplication operator

For an operation of the form `x * y`, binary operator overload resolution (Section 7.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined multiplication operators are listed below. The operators all compute the product of `x` and `y`.

- Integer multiplication:

```
int operator *(int x, int y);
uint operator *(uint x, uint y);
long operator *(long x, long y);
ulong operator *(ulong x, ulong y);
```

In a `checked` context, if the product is outside the range of the result type, a `System.OverflowException` is thrown. In an `unchecked` context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- Floating-point multiplication:

```
float operator *(float x, float y);
double operator *(double x, double y);
```

The product is computed according to the rules of IEEE 754 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are positive finite values. `z` is the result of `x * y`. If the result is too large for the destination type, `z` is infinity. If the result is too small for the destination type, `z` is zero.

	+y	**–y**	**+0**	**–0**	**+∞**	**–∞**	**NaN**
+x	+z	-z	+0	-0	+8	-8	NaN
–x	-z	+z	-0	+0	-8	+8	NaN
+0	+0	-0	+0	-0	NaN	NaN	NaN
–0	-0	+0	-0	+0	NaN	NaN	NaN
+∞	+8	-8	NaN	NaN	+8	-8	NaN
–∞	-8	+8	NaN	NaN	-8	+8	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal multiplication:

```
decimal operator *(decimal x, decimal y);
```

If the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. If the result value is too small to represent in the `decimal` format, the result is zero. The scale of the result, before any rounding, is the sum of the scales of the two operands.

Decimal multiplication is equivalent to using the multiplication operator of type `System.Decimal`.

7.7.2 Division operator

For an operation of the form `x / y`, binary operator overload resolution (Section 7.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined division operators are listed below. The operators all compute the quotient of `x` and `y`.

- Integer division:

```
int operator /(int x, int y);
uint operator /(uint x, uint y);
long operator /(long x, long y);
ulong operator /(ulong x, ulong y);
```

If the value of the right operand is zero, a `System.DivideByZeroException` is thrown.

The division rounds the result towards zero, and the absolute value of the result is the largest possible integer that is less than the absolute value of the quotient of the two operands. The result is zero or positive when the two operands have the same sign and zero or negative when the two operands have opposite signs.

If the left operand is the smallest representable `int` or `long` value and the right operand is `-1`, an overflow occurs. A `System.OverflowException` is always thrown in this situation, regardless of whether the operation occurs in a `checked` or an `unchecked` context.

- Floating-point division:

```
float operator /(float x, float y);
double operator /(double x, double y);
```

The quotient is computed according to the rules of IEEE 754 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are positive finite values. `z` is the result of `x / y`. If the result is too large for the destination type, `z` is infinity. If the result is too small for the destination type, `z` is zero.

	+y	**–y**	**+0**	**–0**	**+∞**	**–∞**	**NaN**
+x	+z	-z	+8	-8	+0	-0	NaN
–x	-z	+z	-8	+8	-0	+0	NaN
+0	+0	-0	NaN	NaN	+0	-0	NaN
–0	-0	+0	NaN	NaN	-0	+0	NaN
+∞	+8	-8	+8	-8	NaN	NaN	NaN
–∞	-8	+8	-8	+8	NaN	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal division:

```
decimal operator /(decimal x, decimal y);
```

If the value of the right operand is zero, a `System.DivideByZeroException` is thrown. If the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. If the result value is too small to represent in the `decimal` format, the result is zero. The scale of the result is the smallest scale that will preserve a result equal to the nearest representable decimal value to the true mathematical result.

Decimal division is equivalent to using the division operator of type `System.Decimal`.

7.7.3 Remainder operator

For an operation of the form `x % y`, binary operator overload resolution (Section 7.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined remainder operators are listed below. The operators all compute the remainder of the division between `x` and `y`.

- Integer remainder:

```
int operator %(int x, int y);
uint operator %(uint x, uint y);
long operator %(long x, long y);
ulong operator %(ulong x, ulong y);
```

The result of `x % y` is the value produced by `x - (x / y) * y`. If `y` is zero, a `System.DivideByZeroException` is thrown. The remainder operator never causes an overflow.

- Floating-point remainder:

```
float operator %(float x, float y);
double operator %(double x, double y);
```

The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are positive finite values. `z` is the result of `x % y` and is computed as `x - n * y`, where `n` is the largest possible integer that is less than or equal to `x / y`. This method of computing the remainder is analogous to that used for integer operands, but differs from the IEEE 754 definition (in which `n` is the integer closest to `x / y`).

	+y	**–y**	**+0**	**–0**	**+∞**	**–∞**	**NaN**
+x	+z	+z	NaN	NaN	x	x	NaN
–x	-z	-z	NaN	NaN	-x	-x	NaN
+0	+0	+0	NaN	NaN	+0	+0	NaN
–0	-0	-0	NaN	NaN	-0	-0	NaN
+∞	NaN	NaN	NaN	NaN	NaN	NaN	NaN
–∞	NaN	NaN	NaN	NaN	NaN	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal remainder:

```
decimal operator %(decimal x, decimal y);
```

If the value of the right operand is zero, a `System.DivideByZeroException` is thrown. The scale of the result, before any rounding, is the larger of the scales of the two operands, and the sign of the result, if non-zero, is the same as that of `x`.

Decimal remainder is equivalent to using the remainder operator of type `System.Decimal`.

7.7.4 Addition operator

For an operation of the form `x + y`, binary operator overload resolution (Section 7.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined addition operators are listed below. For numeric and enumeration types, the predefined addition operators compute the sum of the two operands. When one or both operands are of type string, the predefined addition operators concatenate the string representation of the operands.

- Integer addition:

```
int operator +(int x, int y);
uint operator +(uint x, uint y);
long operator +(long x, long y);
ulong operator +(ulong x, ulong y);
```

In a `checked` context, if the sum is outside the range of the result type, a `System.OverflowException` is thrown. In an `unchecked` context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- Floating-point addition:

```
float operator +(float x, float y);
double operator +(double x, double y);
```

The sum is computed according to the rules of IEEE 754 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are nonzero finite values, and `z` is the result of `x + y`. If `x` and `y` have the same magnitude but opposite signs, `z` is positive zero. If `x + y` is too large to represent in the destination type, `z` is an infinity with the same sign as `x + y`.

	y	**+0**	**–0**	**+∞**	**–∞**	**NaN**
x	z	x	x	+∞	–∞	NaN
+0	y	+0	+0	+∞	–∞	NaN
–0	y	+0	–0	+∞	–∞	NaN
+∞	+∞	+∞	+∞	+∞	NaN	NaN
–∞	–∞	–∞	–∞	NaN	–∞	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal addition:

```
decimal operator +(decimal x, decimal y);
```

If the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. The scale of the result, before any rounding, is the larger of the scales of the two operands.

Decimal addition is equivalent to using the addition operator of type `System.Decimal`.

- Enumeration addition. Every enumeration type implicitly provides the following predefined operators, where `E` is the enum type, and `U` is the underlying type of `E`:

```
E operator +(E x, U y);
E operator +(U x, E y);
```

The operators are evaluated exactly as `(E)((U)x + (U)y)`.

- String concatenation:

```
string operator +(string x, string y);
string operator +(string x, object y);
string operator +(object x, string y);
```

The binary `+` operator performs string concatenation when one or both operands are of type `string`. If an operand of string concatenation is `null`, an empty string is substituted. Otherwise, any non-string argument is converted to its string representation by invoking the virtual `ToString` method inherited from type `object`. If `ToString` returns `null`, an empty string is substituted.

```
using System;
class Test
{
   static void Main() {
      string s = null;
      Console.WriteLine("s = >" + s + "<"); // displays s = ><
      int i = 1;
      Console.WriteLine("i = " + i);        // displays i = 1
      float f = 1.2300E+15F;
      Console.WriteLine("f = " + f);        // displays f = 1.23+E15
      decimal d = 2.900m;
      Console.WriteLine("d = " + d);        // displays d = 2.900
   }
}
```

The result of the string concatenation operator is a string that consists of the characters of the left operand followed by the characters of the right operand. The string concatenation operator never returns a `null` value. A `System.OutOfMemoryException` may be thrown if there is not enough memory available to allocate the resulting string.

- Delegate combination. Every delegate type implicitly provides the following predefined operator, where `D` is the delegate type:

```
D operator +(D x, D y);
```

The binary `+` operator performs delegate combination when both operands are of some delegate type `D`. (If the operands have different delegate types, a compile-time error occurs.) If the first operand is `null`, the result of the operation is the value of the second operand (even if that is also `null`). Otherwise, if the second operand is `null`, then the result of the operation is the value of the first operand. Otherwise, the result of the operation is a new delegate instance that, when invoked, invokes the first operand and then invokes the second operand. For examples of delegate combination, see Section 7.7.5 and Section 15.3. Since `System.Delegate` is not a delegate type, `operator +` is not defined for it.

7.7.5 Subtraction operator

For an operation of the form `x - y`, binary operator overload resolution (Section 7.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined subtraction operators are listed below. The operators all subtract `y` from `x`.

- Integer subtraction:

```
int operator -(int x, int y);
uint operator -(uint x, uint y);
long operator -(long x, long y);
ulong operator -(ulong x, ulong y);
```

In a `checked` context, if the difference is outside the range of the result type, a `System.OverflowException` is thrown. In an `unchecked` context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- Floating-point subtraction:

```
float operator -(float x, float y);
double operator -(double x, double y);
```

The difference is computed according to the rules of IEEE 754 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are nonzero finite values, and `z` is the result of `x - y`. If `x` and `y` are equal, `z` is positive zero. If `x - y` is too large to represent in the destination type, `z` is an infinity with the same sign as `x - y`.

	y	**+0**	**–0**	**+∞**	**–∞**	**NaN**
x	z	x	x	-8	+8	NaN
+0	-y	+0	+0	-8	+8	NaN
–0	-y	-0	+0	-8	+8	NaN
+∞	+8	+8	+8	NaN	+8	NaN
–∞	-8	-8	-8	-8	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal subtraction:

```
decimal operator -(decimal x, decimal y);
```

If the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. The scale of the result, before any rounding, is the larger of the scales of the two operands.

Decimal subtraction is equivalent to using the subtraction operator of type `System.Decimal`.

- Enumeration subtraction. Every enumeration type implicitly provides the following predefined operator, where `E` is the enum type, and `U` is the underlying type of `E`:

```
U operator -(E x, E y);
```

This operator is evaluated exactly as `(U)((U)x - (U)y)`. In other words, the operator computes the difference between the ordinal values of `x` and `y`, and the type of the result is the underlying type of the enumeration.

```
E operator -(E x, U y);
```

This operator is evaluated exactly as `(E)((U)x - y)`. In other words, the operator subtracts a value from the underlying type of the enumeration, yielding a value of the enumeration.

- Delegate removal. Every delegate type implicitly provides the following predefined operator, where `D` is the delegate type:

```
D operator -(D x, D y);
```

The binary `-` operator performs delegate removal when both operands are of some delegate type `D`. If the operands have different delegate types, a compile-time error occurs. If the first operand is `null`, the result of the operation is `null`. Otherwise, if the second operand is `null`, then the result of the operation is the value of the first operand. Otherwise, both operands represent invocation lists (Section 15.1) having one or more entries, and the result is a new invocation list consisting of the first operand's list with the second operand's entries removed from it, provided the second operand's list is a proper contiguous sublist of the first's. (To determine sublist equality, corresponding entries are compared as for the delegate equality operator; see Section 7.9.8). Otherwise, the result is the value of the left operand. Neither of the operands' lists is changed in the process. If the second operand's list matches multiple sublists of contiguous entries in the first operand's list, the right-most matching sublist of contiguous entries is removed. If removal results in an empty list, the result is `null`. For example:

```
delegate void D(int x);
class C
{
   public static void M1(int i) { /* ... */ }
   public static void M2(int i) { /* ... */ }
}
class Test
{
   static void Main() {
      D cd1 = new D(C.M1);
      D cd2 = new D(C.M2);
      D cd3 = cd1 + cd2 + cd2 + cd1;   // M1 + M2 + M2 + M1
      cd3 -= cd1;                        // => M1 + M2 + M2
      cd3 = cd1 + cd2 + cd2 + cd1;      // M1 + M2 + M2 + M1
      cd3 -= cd1 + cd2;                  // => M2 + M1
      cd3 = cd1 + cd2 + cd2 + cd1;      // M1 + M2 + M2 + M1
      cd3 -= cd2 + cd2;                  // => M1 + M1
      cd3 = cd1 + cd2 + cd2 + cd1;      // M1 + M2 + M2 + M1
      cd3 -= cd2 + cd1;                  // => M1 + M2
      cd3 = cd1 + cd2 + cd2 + cd1;      // M1 + M2 + M2 + M1
      cd3 -= cd1 + cd1;                  // => M1 + M2 + M2 + M1
   }
}
```

7.8 Shift operators

The << and >> operators are used to perform bit shifting operations.

shift-expression:
  additive-expression
  shift-expression << *additive-expression*
  shift-expression >> *additive-expression*

For an operation of the form `x << count` or `x >> count`, binary operator overload resolution (Section 7.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

When declaring an overloaded shift operator, the type of the first operand must always be the class or struct containing the operator declaration, and the type of the second operand must always be `int`.

The predefined shift operators are listed below.

- Shift left:

```
int operator <<(int x, int count);
uint operator <<(uint x, int count);
long operator <<(long x, int count);
ulong operator <<(ulong x, int count);
```

The << operator shifts `x` left by a number of bits computed as described below.

The high-order bits outside the range of the result type of `x` are discarded, the remaining bits are shifted left, and the low-order empty bit positions are set to zero.

- Shift right:

```
int operator >>(int x, int count);
uint operator >>(uint x, int count);
long operator >>(long x, int count);
ulong operator >>(ulong x, int count);
```

The >> operator shifts `x` right by a number of bits computed as described below.

When `x` is of type `int` or `long`, the low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero if `x` is non-negative and set to one if `x` is negative.

When `x` is of type `uint` or `ulong`, the low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero.

For the predefined operators, the number of bits to shift is computed as follows:

- When the type of `x` is `int` or `uint`, the shift count is given by the low-order five bits of `count`. In other words, the shift count is computed from `count & 0x1F`.
- When the type of `x` is `long` or `ulong`, the shift count is given by the low-order six bits of `count`. In other words, the shift count is computed from `count & 0x3F`.

If the resulting shift count is zero, the shift operators simply return the value of `x`.

Shift operations never cause overflows and produce the same results in `checked` and `unchecked` contexts.

When the left operand of the >> operator is of a signed integral type, the operator performs an arithmetic shift right wherein the value of the most significant bit (the sign bit) of the operand is propagated to the high-order empty bit positions. When the left operand of the >> operator is of an unsigned integral type, the operator performs a logical shift right wherein high-order empty bit positions are always set to zero. To perform the opposite operation of that inferred from the operand type, explicit casts can be used. For example, if `x` is a variable of type `int`, the operation `unchecked((int)((uint)x >> y))` performs a logical shift right of `x`.

7.9 Relational and type-testing operators

The `==`, `!=`, `<`, `>`, `<=`, `>=`, `is` and `as` operators are called the relational and type-testing operators.

relational-expression:
  shift-expression
  relational-expression `<` *shift-expression*
  relational-expression `>` *shift-expression*
  relational-expression `<=` *shift-expression*
  relational-expression `>=` *shift-expression*
  relational-expression `is` *type*
  relational-expression `as` *type*
equality-expression:
  relational-expression
  equality-expression `==` *relational-expression*
  equality-expression `!=` *relational-expression*

The `is` operator is described in Section 7.9.9 and the `as` operator is described in Section 7.9.10.

The `==`, `!=`, `<`, `>`, `<=` and `>=` operators are comparison operators. For an operation of the form `x` *op* `y`, where *op* is a comparison operator, overload resolution (Section 7.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined comparison operators are described in the following sections. All predefined comparison operators return a result of type `bool`, as described in the following table.

Operation	Result
`x == y`	`true` if `x` is equal to `y`, `false` otherwise
`x != y`	`true` if `x` is not equal to `y`, `false` otherwise
`x < y`	`true` if `x` is less than `y`, `false` otherwise
`x > y`	`true` if `x` is greater than `y`, `false` otherwise
`x <= y`	`true` if `x` is less than or equal to `y`, `false` otherwise
`x >= y`	`true` if `x` is greater than or equal to `y`, `false` otherwise

7.9.1 Integer comparison operators

The predefined integer comparison operators are:

```
bool operator ==(int x, int y);
bool operator ==(uint x, uint y);
bool operator ==(long x, long y);
bool operator ==(ulong x, ulong y);
bool operator !=(int x, int y);
bool operator !=(uint x, uint y);
bool operator !=(long x, long y);
bool operator !=(ulong x, ulong y);
bool operator <(int x, int y);
bool operator <(uint x, uint y);
bool operator <(long x, long y);
bool operator <(ulong x, ulong y);
bool operator >(int x, int y);
bool operator >(uint x, uint y);
bool operator >(long x, long y);
bool operator >(ulong x, ulong y);
bool operator <=(int x, int y);
bool operator <=(uint x, uint y);
bool operator <=(long x, long y);
bool operator <=(ulong x, ulong y);
bool operator >=(int x, int y);
bool operator >=(uint x, uint y);
bool operator >=(long x, long y);
bool operator >=(ulong x, ulong y);
```

Each of these operators compares the numeric values of the two integer operands and returns a `bool` value that indicates whether the particular relation is `true` or `false`.

7.9.2 Floating-point comparison operators

The predefined floating-point comparison operators are:

```
bool operator ==(float x, float y);
bool operator ==(double x, double y);
bool operator !=(float x, float y);
bool operator !=(double x, double y);
bool operator <(float x, float y);
bool operator <(double x, double y);
bool operator >(float x, float y);
bool operator >(double x, double y);
bool operator <=(float x, float y);
bool operator <=(double x, double y);
bool operator >=(float x, float y);
bool operator >=(double x, double y);
```

The operators compare the operands according to the rules of the IEEE 754 standard:

- If either operand is NaN, the result is `false` for all operators except `!=`, for which the result is `true`. For any two operands, `x != y` always produces the same result as `!(x == y)`. However, when one or both operands are NaN, the `<`, `>`, `<=`, and `>=` operators do not produce the same results as the logical negation of the opposite operator. For example, if either of `x` and `y` is NaN, then `x < y` is `false`, but `!(x >= y)` is `true`.
- When neither operand is NaN, the operators compare the values of the two floating-point operands with respect to the ordering

  ```
  -8 < -max < ... < -min < -0.0 == +0.0 < +min < ... < +max < +8
  ```

where `min` and `max` are the smallest and largest positive finite values that can be represented in the given floating-point format. Notable effects of this ordering are:

- Negative and positive zeros are considered equal.
- A negative infinity is considered less than all other values, but equal to another negative infinity.
- A positive infinity is considered greater than all other values, but equal to another positive infinity.

7.9.3 Decimal comparison operators

The predefined decimal comparison operators are:

```
bool operator ==(decimal x, decimal y);
bool operator !=(decimal x, decimal y);
bool operator <(decimal x, decimal y);
bool operator >(decimal x, decimal y);
bool operator <=(decimal x, decimal y);
bool operator >=(decimal x, decimal y);
```

Each of these operators compares the numeric values of the two decimal operands and returns a `bool` value that indicates whether the particular relation is `true` or `false`. Each decimal comparison is equivalent to using the corresponding relational or equality operator of type `System.Decimal`.

7.9.4 Boolean equality operators

The predefined Boolean equality operators are:

```
bool operator ==(bool x, bool y);
bool operator !=(bool x, bool y);
```

The result of `==` is `true` if both `x` and `y` are `true` or if both `x` and `y` are `false`. Otherwise, the result is `false`.

The result of `!=` is `false` if both `x` and `y` are `true` or if both `x` and `y` are `false`. Otherwise, the result is `true`. When the operands are of type `bool`, the `!=` operator produces the same result as the `^` operator.

7.9.5 Enumeration comparison operators

Every enumeration type implicitly provides the following predefined comparison operators:

```
bool operator ==(E x, E y);
bool operator !=(E x, E y);
bool operator <(E x, E y);
bool operator >(E x, E y);
bool operator <=(E x, E y);
bool operator >=(E x, E y);
```

The result of evaluating `x` *op* `y`, where `x` and `y` are expressions of an enumeration type `E` with an underlying type `U`, and *op* is one of the comparison operators, is exactly the same as evaluating `((U)x)` *op* `((U)y)`. In other words, the enumeration type comparison operators simply compare the underlying integral values of the two operands.

7.9.6 Reference type equality operators

The predefined reference type equality operators are:

```
bool operator ==(object x, object y);
bool operator !=(object x, object y);
```

The operators return the result of comparing the two references for equality or non-equality.

Since the predefined reference type equality operators accept operands of type `object`, they apply to all types that do not declare applicable `operator ==` and `operator !=` members. Conversely, any applicable user-defined equality operators effectively hide the predefined reference type equality operators.

The predefined reference type equality operators require the operands to be *reference-type* values or the value `null`; furthermore, they require that a standard implicit conversion (Section 6.3.1) exists from the type of either operand to the type of the other operand. Unless both of these conditions are true, a compile-time error occurs. Notable implications of these rules are:

- It is a compile-time error to use the predefined reference type equality operators to compare two references that are known to be different at compile-time. For example, if the compile-time types of the operands are two class types `A` and `B`, and if neither `A` nor `B` derives from the other, then it would be impossible for the two operands to reference the same object. Thus, the operation is considered a compile-time error.
- The predefined reference type equality operators do not permit value type operands to be compared. Therefore, unless a struct type declares its own equality operators, it is not possible to compare values of that struct type.
- The predefined reference type equality operators never cause boxing operations to occur for their operands. It would be meaningless to perform such boxing operations, since references to the newly allocated boxed instances would necessarily differ from all other references.

For an operation of the form `x == y` or `x != y`, if any applicable `operator ==` or `operator !=` exists, the operator overload resolution (Section 7.2.4) rules will select that operator instead of the predefined reference type equality operator. However, it is always possible to select the predefined reference type equality operator by explicitly casting one or both of the operands to type `object`. The example

```
using System;
class Test
{
   static void Main() {
      string s = "Test";
      string t = string.Copy(s);
      Console.WriteLine(s == t);
      Console.WriteLine((object)s == t);
      Console.WriteLine(s == (object)t);
      Console.WriteLine((object)s == (object)t);
   }
}
```

produces the output

```
True
False
False
False
```

The `s` and `t` variables refer to two distinct `string` instances containing the same characters. The first comparison outputs `True` because the predefined string equality operator (Section 7.9.7) is selected when both operands are of type `string`. The remaining comparisons all output `False` because the predefined reference type equality operator is selected when one or both of the operands are of type `object`.

Note that the above technique is not meaningful for value types. The example

```
class Test
{
```

```
    static void Main() {
       int i = 123;
       int j = 123;
       System.Console.WriteLine((object)i == (object)j);
    }
 }
```

outputs `False` because the casts create references to two separate instances of boxed `int` values.

7.9.7 String equality operators

The predefined string equality operators are:

```
bool operator ==(string x, string y);
bool operator !=(string x, string y);
```

Two `string` values are considered equal when one of the following is true:

- Both values are `null`.
- Both values are non-null references to string instances that have identical lengths and identical characters in each character position.

The string equality operators compare string values rather than string references. When two separate string instances contain the exact same sequence of characters, the values of the strings are equal, but the references are different. As described in Section 7.9.6, the reference type equality operators can be used to compare string references instead of string values.

7.9.8 Delegate equality operators

Every delegate type implicitly provides the following predefined comparison operators:

```
bool operator ==(System.Delegate x, System.Delegate y);
bool operator !=(System.Delegate x, System.Delegate y);
```

Two delegate instances are considered equal as follows:

- If either of the delegate instances is `null`, they are equal if and only if both are `null`.
- If either of the delegate instances has an invocation list (Section 15.1) containing one entry, they are equal if and only if the other also has an invocation list containing one entry, and either:
  - both refer to the same static method, or
  - both refer to the same non-static method on the same target object.
- If either of the delegate instances has an invocation list containing two or more entries, those instances are equal if and only if their invocation lists are the same length, and each entry in one's invocation list is equal to the corresponding entry, in order, in the other's invocation list.

Note that delegates of different types can be considered equal by the above definition, as long as they have the same return type and parameter types.

7.9.9 The is operator

The `is` operator is used to dynamically check if the run-time type of an object is compatible with a given type. The result of the operation `e is T`, where `e` is an expression and `T` is a type, is a Boolean value indicating whether `e` can successfully be converted to type `T` by a reference conversion, a boxing conversion, or an unboxing conversion. The operation is evaluated as follows:

- If the compile-time type of `e` is the same as `T`, or if an implicit reference conversion (Section 6.1.4) or boxing conversion (Section 6.1.5) exists from the compile-time type of `e` to `T`:
  - If `e` is of a reference type, the result of the operation is equivalent to evaluating `e != null`.
  - If `e` is of a value type, the result of the operation is `true`.
- Otherwise, if an explicit reference conversion (Section 6.2.3) or unboxing conversion (Section 6.2.4) exists from the compile-time type of `e` to `T`, a dynamic type check is performed:
  - If the value of `e` is `null`, the result is `false`.
  - Otherwise, let `R` be the run-time type of the instance referenced by `e`. If `R` and `T` are the same type, if `R` is a reference type and an implicit reference conversion from `R` to `T` exists, or if `R` is a value type and `T` is an interface type that is implemented by `R`, the result is `true`.
  - Otherwise, the result is `false`.
- Otherwise, no reference or boxing conversion of `e` to type `T` is possible, and the result of the operation is false.

Note The `is` operator only considers reference conversions, boxing conversions, and unboxing conversions. Other conversions, such as user defined conversions, are not considered by the `is` operator.

7.9.10 The as operator

The `as` operator is used to explicitly convert a value to a given reference type using a reference conversion or a boxing conversion. Unlike a cast expression (Section 7.6.6), the `as` operator never throws an exception. Instead, if the indicated conversion is not possible, the resulting value is `null`.

In an operation of the form `e as T`, `e` must be an expression and `T` must be a reference type. The type of the result is `T`, and the result is always classified as a value. The operation is evaluated as follows:

- If the compile-time type of `e` is the same as `T`, the result is simply the value of `e`.
- Otherwise, if an implicit reference conversion (Section 6.1.4) or boxing conversion (Section 6.1.5) exists from the compile-time type of e to `T`, this conversion is performed and becomes the result of the operation.
- Otherwise, if an explicit reference conversion (Section 6.2.3) exists from the compile-time type of e to T, a dynamic type check is performed:
    - If the value of e is `null`, the result is the value `null` with the compile-time type `T`.
    - Otherwise, let `R` be the run-time type of the instance referenced by `e`. If `R` and `T` are the same type, if `R` is a reference type and an implicit reference conversion from `R` to `T` exists, or if `R` is a value type and `T` is an interface type that is implemented by `R`, the result is the reference given by `e` with the compile-time type `T`.
    - Otherwise, the result is the value `null` with the compile-time type `T`.
- Otherwise, the indicated conversion is never possible, and a compile-time error occurs.

Note that the `as` operator only performs reference conversions and boxing conversions. Other conversions, such as user defined conversions, are not possible with the `as` operator and should instead be performed using cast expressions.

7.10 Logical operators

The `&`, `^`, and `|` operators are called the logical operators.

and-expression:
  equality-expression
  and-expression & *equality-expression*
exclusive-or-expression:
  and-expression
  exclusive-or-expression ^ *and-expression*
inclusive-or-expression:
  exclusive-or-expression
  inclusive-or-expression | *exclusive-or-expression*

For an operation of the form `x` *op* `y`, where *op* is one of the logical operators, overload resolution (Section 7.2.4) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined logical operators are described in the following sections.

7.10.1 Integer logical operators

The predefined integer logical operators are:

```
int operator &(int x, int y);
uint operator &(uint x, uint y);
long operator &(long x, long y);
ulong operator &(ulong x, ulong y);
int operator |(int x, int y);
uint operator |(uint x, uint y);
long operator |(long x, long y);
ulong operator |(ulong x, ulong y);
int operator ^(int x, int y);
uint operator ^(uint x, uint y);
long operator ^(long x, long y);
ulong operator ^(ulong x, ulong y);
```

The `&` operator computes the bitwise logical `AND` of the two operands, the `|` operator computes the bitwise logical `OR` of the two operands, and the `^` operator computes the bitwise logical exclusive `OR` of the two operands. No overflows are possible from these operations.

7.10.2 Enumeration logical operators

Every enumeration type `E` implicitly provides the following predefined logical operators:

```
E operator &(E x, E y);
E operator |(E x, E y);
E operator ^(E x, E y);
```

The result of evaluating `x` *op* `y`, where `x` and `y` are expressions of an enumeration type `E` with an underlying type `U`, and *op* is one of the logical operators, is exactly the same as evaluating (E) `((U)x` *op* `(U)y)`. In other words, the enumeration type logical operators simply perform the logical operation on the underlying type of the two operands.

7.10.3 Boolean logical operators

The predefined Boolean logical operators are:

```
bool operator &(bool x, bool y);
bool operator |(bool x, bool y);
bool operator ^(bool x, bool y);
```

The result of `x & y` is `true` if both `x` and `y` are `true`. Otherwise, the result is `false`.

The result of `x | y` is `true` if either `x` or `y` is `true`. Otherwise, the result is `false`.

The result of `x ^ y` is `true` if `x` is `true` and `y` is `false`, or `x` is `false` and `y` is `true`. Otherwise, the result is `false`. When the operands are of type `bool`, the `^` operator computes the same result as the `!=` operator.

7.11 Conditional logical operators

The `&&` and `||` operators are called the conditional logical operators. They are also called the "short-circuiting" logical operators.

conditional-and-expression:
  inclusive-or-expression
  conditional-and-expression && *inclusive-or-expression*
conditional-or-expression:
  conditional-and-expression
  conditional-or-expression || *conditional-and-expression*

The `&&` and `||` operators are conditional versions of the `&` and `|` operators:

- The operation `x && y` corresponds to the operation `x & y`, except that `y` is evaluated only if `x` is `true`.
- The operation `x || y` corresponds to the operation `x | y`, except that `y` is evaluated only if `x` is `false`.

An operation of the form `x && y` or `x || y` is processed by applying overload resolution (Section 7.2.4) as if the operation was written `x & y` or `x | y`. Then,

- If overload resolution fails to find a single best operator, or if overload resolution selects one of the predefined integer logical operators, a compile-time error occurs.
- Otherwise, if the selected operator is one of the predefined Boolean logical operators (Section 7.10.2), the operation is processed as described in Section 7.11.1.
- Otherwise, the selected operator is a user-defined operator, and the operation is processed as described in Section 7.11.2.

It is not possible to directly overload the conditional logical operators. However, because the conditional logical operators are evaluated in terms of the regular logical operators, overloads of the regular logical operators are, with certain restrictions, also considered overloads of the conditional logical operators. This is described further in Section 7.11.2.

7.11.1 Boolean conditional logical operators

When the operands of `&&` or `||` are of type `bool`, or when the operands are of types that do not define an applicable `operator &` or `operator |`, but do define implicit conversions to `bool`, the operation is processed as follows:

- The operation `x && y` is evaluated as `x ? y : false`. In other words, `x` is first evaluated and converted to type `bool`. Then, if `x` is `true`, `y` is evaluated and converted to type `bool`, and this becomes the result of the operation. Otherwise, the result of the operation is `false`.
- The operation `x || y` is evaluated as `x ? true : y`. In other words, `x` is first evaluated and converted to type `bool`. Then, if `x` is `true`, the result of the operation is `true`. Otherwise, `y` is evaluated and converted to type `bool`, and this becomes the result of the operation.

7.11.2 User-defined conditional logical operators

When the operands of `&&` or `||` are of types that declare an applicable user-defined `operator &` or `operator |`, both of the following must be true, where `T` is the type in which the selected operator is declared:

- The return type and the type of each parameter of the selected operator must be `T`. In other words, the operator must compute the logical `AND` or the logical `OR` of two operands of type `T`, and must return a result of type `T`.
- `T` must contain declarations of `operator true` and `operator false`.

A compile-time error occurs if either of these requirements is not satisfied. Otherwise, the `&&` or `||` operation is evaluated by combining the user-defined `operator true` or `operator false` with the selected user-defined operator:

- The operation `x && y` is evaluated as `T.false(x) ? x : T.&(x, y)`, where `T.false(x)` is an invocation of the `operator false` declared in `T`, and `T.&(x, y)` is an invocation of the selected `operator &`. In other words, `x` is first evaluated and `operator false` is invoked on the result to determine if `x` is definitely false. Then, if `x` is definitely false, the result of the operation is the value previously computed for `x`. Otherwise, `y` is evaluated, and the selected `operator &` is invoked on the value previously computed for `x` and the value computed for `y` to produce the result of the operation.
- The operation `x || y` is evaluated as `T.true(x) ? x : T.|(x, y)`, where `T.true(x)` is an invocation of the `operator true` declared in `T`, and `T.|(x, y)` is an invocation of the selected `operator |`. In other words, `x` is first evaluated and `operator true` is invoked on the result to determine if `x` is definitely true. Then, if `x` is definitely true, the result of the operation is the value previously computed for `x`. Otherwise, `y` is evaluated, and the selected `operator |` is invoked on the value previously computed for `x` and the value computed for `y` to produce the result of the operation.

In either of these operations, the expression given by `x` is only evaluated once, and the expression given by `y` is either not evaluated or evaluated exactly once.

For an example of a type that implements `operator true` and `operator false`, see Section 11.4.2.

7.12 Conditional operator

The `?:` operator is called the conditional operator. It is at times also called the ternary operator.

conditional-expression:
  conditional-or-expression
  conditional-or-expression ? *expression* : *expression*

A conditional expression of the form `b ? x : y` first evaluates the condition `b`. Then, if `b` is `true`, `x` is evaluated and becomes the result of the operation. Otherwise, `y` is evaluated and becomes the result of the operation. A conditional expression never evaluates both `x` and `y`.

The conditional operator is right-associative, meaning that operations are grouped from right to left. For example, an expression of the form `a ? b : c ? d : e` is evaluated as `a ? b : (c ? d : e)`.

The first operand of the `?:` operator must be an expression of a type that can be implicitly converted to `bool`, or an expression of a type that implements `operator true`. If neither requirement is satisfied, a compile-time error occurs.

The second and third operands of the `?:` operator control the type of the conditional expression. Let `X` and `Y` be the types of the second and third operands. Then,

- If `X` and `Y` are the same type, then this is the type of the conditional expression.
- Otherwise, if an implicit conversion (Section 6.1) exists from `X` to `Y`, but not from `Y` to `X`, then `Y` is the type of the conditional expression.
- Otherwise, if an implicit conversion (Section 6.1) exists from `Y` to `X`, but not from `X` to `Y`, then `X` is the type of the conditional expression.
- Otherwise, no expression type can be determined, and a compile-time error occurs.

The run-time processing of a conditional expression of the form `b ? x : y` consists of the following steps:

- First, `b` is evaluated, and the `bool` value of `b` is determined:
  - If an implicit conversion from the type of `b` to `bool` exists, then this implicit conversion is performed to produce a `bool` value.
  - Otherwise, the `operator true` defined by the type of `b` is invoked to produce a `bool` value.
- If the `bool` value produced by the step above is `true`, then `x` is evaluated and converted to the type of the conditional expression, and this becomes the result of the conditional expression.
- Otherwise, `y` is evaluated and converted to the type of the conditional expression, and this becomes the result of the conditional expression.

7.13 Assignment operators

The assignment operators assign a new value to a variable, a property, an event, or an indexer element.

assignment:
  unary-expression *assignment-operator* *expression*
assignment-operator: one of
  = += -= *= /= %= &= |= ^= <<= >>=

The left operand of an assignment must be an expression classified as a variable, a property access, an indexer access, or an event access.

The `=` operator is called the simple assignment operator. It assigns the value of the right operand to the variable, property, or indexer element given by the left operand. The left operand of the simple assignment operator may not be an event access (except as described in Section 10.7.1. The simple assignment operator is described in Section 7.13.1.

The assignment operators other than the `=` operator are called the compound assignment operators. These operators perform the indicated operation on the two operands, and then assign the resulting value to the variable, property, or indexer element given by the left operand. The compound assignment operators are described in Section 7.13.2.

The `+=` and `-=` operators with an event access expression as the left operand are called the event assignment operators. No other assignment operator is valid with an event access as the left operand. The event assignment operators are described in Section 7.13.3.

The assignment operators are right-associative, meaning that operations are grouped from right to left. For example, an expression of the form `a = b = c` is evaluated as `a = (b = c)`.

7.13.1 Simple assignment

The `=` operator is called the simple assignment operator. In a simple assignment, the right operand must be an expression of a type that is implicitly convertible to the type of the left operand. The operation assigns the value of the right operand to the variable, property, or indexer element given by the left operand.

The result of a simple assignment expression is the value assigned to the left operand. The result has the same type as the left operand and is always classified as a value.

If the left operand is a property or indexer access, the property or indexer must have a `set` accessor. If this is not the case, a compile-time error occurs.

The run-time processing of a simple assignment of the form `x = y` consists of the following steps:

- If x is classified as a variable:
  - `x` is evaluated to produce the variable.
  - `y` is evaluated and, if required, converted to the type of `x` through an implicit conversion (Section 6.1).
  - If the variable given by `x` is an array element of a *reference-type*, a run-time check is performed to ensure that the value computed for `y` is compatible with the array instance of which `x` is an element. The check succeeds if `y` is `null`, or if an implicit reference conversion (Section 6.1.4) exists from the actual type of the instance referenced by `y` to the actual element type of the array instance containing `x`. Otherwise, a `System.ArrayTypeMismatchException` is thrown.
  - The value resulting from the evaluation and conversion of `y` is stored into the location given by the evaluation of `x`.
- If x is classified as a property or indexer access:
  - The instance expression (if `x` is not `static`) and the argument list (if `x` is an indexer access) associated with `x` are evaluated, and the results are used in the subsequent `set` accessor invocation.
  - `y` is evaluated and, if required, converted to the type of `x` through an implicit conversion (Section 6.1).
  - The `set` accessor of `x` is invoked with the value computed for `y` as its `value` argument.

The array co-variance rules (Section 12.5) permit a value of an array type `A[]` to be a reference to an instance of an array type `B[]`, provided an implicit reference conversion exists from `B` to `A`. Because of these rules, assignment to an array element of a *reference-type* requires a run-time check to ensure that the value being assigned is compatible with the array instance. In the example

```
string[] sa = new string[10];
object[] oa = sa;
oa[0] = null;               // Ok
oa[1] = "Hello";            // Ok
oa[2] = new ArrayList();   // ArrayTypeMismatchException
```

the last assignment causes a `System.ArrayTypeMismatchException` to be thrown because an instance of `ArrayList` cannot be stored in an element of a `string[]`.

When a property or indexer declared in a struct-type is the target of an assignment, the instance expression associated with the property or indexer access must be classified as a variable. If the instance expression is classified as a value, a compile-time error occurs. Because of Section 7.5.4, the same rule also applies to fields.

Given the declarations:

```
struct Point
{
   int x, y;
   public Point(int x, int y) {
      this.x = x;
      this.y = y;
   }
   public int X {
      get { return x; }
      set { x = value; }
   }
   public int Y {
      get { return y; }
```

```
        set { y = value; }
    }
}
struct Rectangle
{
    Point a, b;
    public Rectangle(Point a, Point b) {
        this.a = a;
        this.b = b;
    }
    public Point A {
        get { return a; }
        set { a = value; }
    }
    public Point B {
        get { return b; }
        set { b = value; }
    }
}
```

in the example

```
Point p = new Point();
p.X = 100;
p.Y = 100;
Rectangle r = new Rectangle();
r.A = new Point(10, 10);
r.B = p;
```

the assignments to `p.X`, `p.Y`, `r.A`, and `r.B` are permitted because `p` and `r` are variables. However, in the example

```
Rectangle r = new Rectangle();
r.A.X = 10;
r.A.Y = 10;
r.B.X = 100;
r.B.Y = 100;
```

the assignments are all invalid, since `r.A` and `r.B` are not variables.

7.13.2 Compound assignment

An operation of the form `x` *op*`=` `y` is processed by applying binary operator overload resolution (Section 7.2.4) as if the operation was written `x` *op* `y`. Then,

- If the return type of the selected operator is implicitly convertible to the type of `x`, the operation is evaluated as `x = x` *op* `y`, except that `x` is evaluated only once.
- Otherwise, if the selected operator is a predefined operator, if the return type of the selected operator is explicitly convertible to the type of `x`, and if `y` is implicitly convertible to the type of `x`, then the operation is evaluated as `x = (T) (x` *op* `y)`, where `T` is the type of `x`, except that `x` is evaluated only once.
- Otherwise, the compound assignment is invalid, and a compile-time error occurs.

The term "evaluated only once" means that in the evaluation of `x` *op* `y`, the results of any constituent expressions of `x` are temporarily saved and then reused when performing the assignment to `x`. For example, in the assignment `A()[B()] += C()`, where `A` is a method returning `int[]`, and `B` and `C` are methods returning `int`, the methods are invoked only once, in the order `A`, `B`, `C`.

When the left operand of a compound assignment is a property access or indexer access, the property or indexer must have both a `get` accessor and a `set` accessor. If this is not the case, a compile-time error occurs.

The second rule above permits `x` *op*`=` `y` to be evaluated as `x = (T) (x` *op* `y)` in certain contexts. The rule exists such that the predefined operators can be used as compound operators when the left operand is of type `sbyte`, `byte`, `short`, `ushort`, or `char`. Even when both arguments are of one of those types, the predefined operators produce a result of type `int`, as described in Section 7.2.6.2. Thus, without a cast it would not be possible to assign the result to the left operand.

The intuitive effect of the rule for predefined operators is simply that `x` *op*`=` `y` is permitted if both of `x` *op* `y` and `x = y` are permitted. In the example

```
byte b = 0;
char ch = '\0';
int i = 0;
b += 1;            // Ok
b += 1000;         // Error, b = 1000 not permitted
b += i;            // Error, b = i not permitted
b += (byte)i;      // Ok
ch += 1;            // Error, ch = 1 not permitted
ch += (char)1;      // Ok
```

the intuitive reason for each error is that a corresponding simple assignment would also have been an error.

7.13.3 Event assignment

If the left operand of a `+=` or `-=` operator is classified as an event access, then the expression is evaluated as follows:

- The instance expression, if any, of the event access is evaluated.
- The right operand of the `+=` or `-=` operator is evaluated, and, if required, converted to the type of the left operand through an implicit conversion (Section 6.1).
- An event accessor of the event is invoked, with the argument list consisting of the right operand, after evaluation and, if necessary, conversion. If the operator was `+=`, the `add` accessor is invoked. If the operator was `-=`, the `remove` accessor is invoked.

An event assignment expression does not yield a value. Thus, an event assignment expression is valid only in the context of a *statement-expression* (Section 8.6).

7.14 Expression

An *expression* is either a conditional-expression or an assignment.

expression:
  conditional-expression
  assignment

7.15 Constant expressions

A constant-expression is an expression that can be fully evaluated at compile-time.

constant-expression:
  expression

The type of a constant expression can be one of the following: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `string`, any enumeration type, or the null type. The following constructs are permitted in constant expressions:

- Literals (including the `null` literal).
- References to `const` members of class and struct types.
- References to members of enumeration types.
- Parenthesized sub-expressions, which are themselves constant expressions.
- Cast expressions, provided the target type is one of the types listed above.
- The predefined `+`, `-`, `!`, and `~` unary operators.
- The predefined `+`, `-`, `*`, `/`, `%`, `<<`, `>>`, `&`, `|`, `^`, `&&`, `||`, `==`, `!=`, `<`, `>`, `<=`, and `>=` binary operators, provided each operand is of a type listed above.
- The `?:` conditional operator.

Whenever an expression is of one of the types listed above and contains only the constructs listed above, the expression is evaluated at compile-time. This is true even if the expression is a sub-expression of a larger expression that contains non-constant constructs.

The compile-time evaluation of constant expressions uses the same rules as run-time evaluation of non-constant expressions, except that where run-time evaluation would have thrown an exception, compile-time evaluation causes a compile-time error to occur.

Unless a constant expression is explicitly placed in an `unchecked` context, overflows that occur in integral-type arithmetic operations and conversions during the compile-time evaluation of the expression always cause compile-time errors (Section 7.5.12).

Constant expressions occur in the contexts listed below. In these contexts, a compile-time error occurs if an expression cannot be fully evaluated at compile-time.

- Constant declarations (Section 10.3).
- Enumeration member declarations (Section 14.3).
- `case` labels of a `switch` statement (Section 8.7.2).
- `goto case` statements (Section 8.9.3).
- Dimension lengths in an array creation expression (Section 7.5.10.2) that includes an initializer.
- Attributes (Section 17).

An implicit constant expression conversion (Section 6.1.6) permits a constant expression of type `int` to be converted to `sbyte`, `byte`, `short`, `ushort`, `uint`, or `ulong`, provided the value of the constant expression is within the range of the destination type.

7.16 Boolean expressions

A boolean-expression is an expression that yields a result of type `bool`.

boolean-expression:
  expression

The controlling conditional expression of an *if-statement* (Section 8.7.1), while-statement (Section 8.8.1), do-statement (Section 8.8.2), or for-statement (Section 8.8.3) is a boolean-expression. The controlling conditional expression of the `?:` operator (Section 7.12) follows the same rules as a boolean-expression, but for reasons of operator precedence is classified as a conditional-or-expression.

A boolean-expression is required to be of a type that can be implicitly converted to `bool` or of a type that implements `operator true`. If neither requirement is satisfied, a compile-time error occurs.

When a Boolean expression is of a type that cannot be implicitly converted to `bool` but does implement `operator true`, then following evaluation of the expression, the `operator true` implementation provided by that type is invoked to produce a `bool` value.

The `DBBool` struct type in Section 11.4.2 provides an example of a type that implements `operator true` and `operator false`.

8. Statements

C# provides a variety of statements. Most of these statements will be familiar to developers who have programmed in C and C++.

statement:
  labeled-statement
  declaration-statement
  embedded-statement
embedded-statement:
  block
  empty-statement
  expression-statement
  selection-statement
  iteration-statement
  jump-statement
  try-statement
  checked-statement
  unchecked-statement
  lock-statement
  using-statement

The *embedded-statement* nonterminal is used for statements that appear within other statements. The use of *embedded-statement* rather than *statement* excludes the use of declaration statements and labeled statements in these contexts. The example

```
void F(bool b) {
   if (b)
      int i = 44;
}
```

results in a compile-time error because an `if` statement requires an *embedded-statement* rather than a *statement* for its if branch. If this code were permitted, then the variable `i` would be declared, but it could never be used. Note, however, that by placing `i`'s declaration in a block, the example is valid.

8.1 End points and reachability

Every statement has an end point. In intuitive terms, the end point of a statement is the location that immediately follows the statement. The execution rules for composite statements (statements that contain embedded statements) specify the action that is taken when control reaches the end point of an embedded statement. For example, when control reaches the end point of a statement in a block, control is transferred to the next statement in the block.

If a statement can possibly be reached by execution, the statement is said to be reachable. Conversely, if there is no possibility that a statement will be executed, the statement is said to be unreachable.

In the example

```
void F() {
   Console.WriteLine("reachable");
   goto Label;
   Console.WriteLine("unreachable");
   Label:
   Console.WriteLine("reachable");
}
```

the second invocation of `Console.WriteLine` is unreachable because there is no possibility that the statement will be executed.

A warning is reported if the compiler determines that a statement is unreachable. It is specifically not an error for a statement to be unreachable.

To determine whether a particular statement or end point is reachable, the compiler performs flow analysis according to the reachability rules defined for each statement. The flow analysis takes into account the values of constant expressions (Section 7.15) that control the behavior of statements, but the possible values of non-constant expressions are not considered. In other words, for purposes of control flow analysis, a non-constant expression of a given type is considered to have any possible value of that type.

In the example

```
void F() {
   const int i = 1;
   if (i == 2) Console.WriteLine("unreachable");
}
```

the Boolean expression of the `if` statement is a constant expression because both operands of the `==` operator are constants. As the constant expression is evaluated at compile-time, producing the value `false`, the `Console.WriteLine` invocation is considered unreachable. However, if `i` is changed to be a local variable

```
void F() {
   int i = 1;
   if (i == 2) Console.WriteLine("reachable");
}
```

the `Console.WriteLine` invocation is considered reachable, even though, in reality, it will never be executed.

The *block* of a function member is always considered reachable. By successively evaluating the reachability rules of each statement in a block, the reachability of any given statement can be determined.

In the example

```
void F(int x) {
   Console.WriteLine("start");
   if (x < 0) Console.WriteLine("negative");
}
```

the reachability of the second `Console.WriteLine` is determined as follows:

- The first `Console.WriteLine` expression statement is reachable because the block of the `F` method is reachable.
- The end point of the first `Console.WriteLine` expression statement is reachable because that statement is reachable.

- The `if` statement is reachable because the end point of the first `Console.WriteLine` expression statement is reachable.
- The second `Console.WriteLine` expression statement is reachable because the Boolean expression of the `if` statement does not have the constant value `false`.

There are two situations in which it is a compile-time error for the end point of a statement to be reachable:

- Because the `switch` statement does not permit a switch section to "fall through" to the next switch section, it is a compile-time error for the end point of the statement list of a switch section to be reachable. If this error occurs, it is typically an indication that a `break` statement is missing.
- It is a compile-time error for the end point of the block of a function member that computes a value to be reachable. If this error occurs, it is typically an indication that a `return` statement is missing.

8.2 Blocks

A *block* permits multiple statements to be written in contexts where a single statement is allowed.

block:
  { *statement-list*$_{opt}$ }

A *block* consists of an optional *statement-list* (Section 8.2.1), enclosed in braces. If the statement list is omitted, the block is said to be empty.

A block may contain declaration statements (Section 8.5). The scope of a local variable or constant declared in a block is the block.

Within a block, the meaning of a name used in an expression context must always be the same (Section 7.5.2.1).

A block is executed as follows:

- If the block is empty, control is transferred to the end point of the block.
- If the block is not empty, control is transferred to the statement list. When and if control reaches the end point of the statement list, control is transferred to the end point of the block.

The statement list of a block is reachable if the block itself is reachable.

The end point of a block is reachable if the block is empty or if the end point of the statement list is reachable.

8.2.1 Statement lists

A statement list consists of one or more statements written in sequence. Statement lists occur in *blocks* (Section 8.2) and in *switch-blocks* (Section 8.7.2).

statement-list:
  statement
  statement-list statement

A statement list is executed by transferring control to the first statement. When and if control reaches the end point of a statement, control is transferred to the next statement. When and if control reaches the end point of the last statement, control is transferred to the end point of the statement list.

A statement in a statement list is reachable if at least one of the following is true:

- The statement is the first statement and the statement list itself is reachable.
- The end point of the preceding statement is reachable.
- The statement is a labeled statement and the label is referenced by a reachable `goto` statement.

The end point of a statement list is reachable if the end point of the last statement in the list is reachable.

8.3 The empty statement

An *empty-statement* does nothing.

empty-statement:
  ;

An empty statement is used when there are no operations to perform in a context where a statement is required.

Execution of an empty statement simply transfers control to the end point of the statement. Thus, the end point of an empty statement is reachable if the empty statement is reachable.

An empty statement can be used when writing a `while` statement with a null body:

```
bool ProcessMessage() {...}
void ProcessMessages() {
   while (ProcessMessage())
      ;
}
```

Also, an empty statement can be used to declare a label just before the closing "`}`" of a block:

```
void F() {
   ...
   if (done) goto exit;
   ...
   exit: ;
}
```

8.4 Labeled statements

A *labeled-statement* permits a statement to be prefixed by a label. Labeled statements are permitted in blocks, but are not permitted as embedded statements.

labeled-statement:
  identifier : *statement*

A labeled statement declares a label with the name given by the *identifier*. The scope of a label is the whole block in which the label is declared, including any nested blocks. It is a compile-time error for two labels with the same name to have overlapping scopes.

A label can be referenced from `goto` statements (Section 8.9.3) within the scope of the label. This means that `goto` statements can transfer control within blocks and out of blocks, but never into blocks.

Labels have their own declaration space and do not interfere with other identifiers. The example

```
int F(int x) {
   if (x >= 0) goto x;
   x = -x;
   x: return x;
}
```

is valid and uses the name `x` as both a parameter and a label.

Execution of a labeled statement corresponds exactly to execution of the statement following the label.

In addition to the reachability provided by normal flow of control, a labeled statement is reachable if the label is referenced by a reachable `goto` statement. (Exception: If a `goto` statement is inside a `try` that includes a `finally` block, and the labeled statement is outside the `try`, and the end point of the `finally` block is unreachable, then the labeled statement is not reachable from that `goto` statement.)

8.5 Declaration statements

A *declaration-statement* declares a local variable or constant. Declaration statements are permitted in blocks, but are not permitted as embedded statements.

declaration-statement:
  local-variable-declaration ;
  local-constant-declaration ;

8.5.1 Local variable declarations

A *local-variable-declaration* declares one or more local variables.

local-variable-declaration:
  type *local-variable-declarators*
local-variable-declarators:
  local-variable-declarator
  local-variable-declarators , *local-variable-declarator*
local-variable-declarator:
  identifier
  identifier = *local-variable-initializer*
local-variable-initializer:
  expression
  array-initializer

The *type* of a *local-variable-declaration* specifies the type of the variables introduced by the declaration. The type is followed by a list of *local-variable-declarators*, each of which introduces a new variable. A *local-variable-declarator* consists of an *identifier* that names the variable, optionally followed by an "=" token and a *local-variable-initializer* that gives the initial value of the variable.

The value of a local variable is obtained in an expression using a *simple-name* (Section 7.5.2), and the value of a local variable is modified using an *assignment* (Section 7.13). A local variable must be definitely assigned (Section 5.3) at each location where its value is obtained.

The scope of a local variable declared in a *local-variable-declaration* is the block in which the declaration occurs. It is an error to refer to a local variable in a textual position that precedes the *local-variable-declarator* of the local variable. Within the scope of a local variable, it is a compile-time error to declare another local variable or constant with the same name.

A local variable declaration that declares multiple variables is equivalent to multiple declarations of single variables with the same type. Furthermore, a variable initializer in a local variable declaration corresponds exactly to an assignment statement that is inserted immediately after the declaration.

The example

```
void F() {
   int x = 1, y, z = x * 2;
}
```

corresponds exactly to

```
void F() {
   int x; x = 1;
   int y;
   int z; z = x * 2;
}
```

8.5.2 Local constant declarations

A *local-constant-declaration* declares one or more local constants.

local-constant-declaration:
  const *type* *constant-declarators*
constant-declarators:
  constant-declarator
  constant-declarators , *constant-declarator*
constant-declarator:
  identifier = *constant-expression*

The *type* of a *local-constant-declaration* specifies the type of the constants introduced by the declaration. The type is followed by a list of *constant-declarators*, each of which introduces a new constant. A *constant-declarator* consists of an *identifier* that names the constant, followed by an "=" token, followed by a *constant-expression* (Section 7.15) that gives the value of the constant.

The *type* and *constant-expression* of a local constant declaration must follow the same rules as those of a constant member declaration (Section 10.3).

The value of a local constant is obtained in an expression using a *simple-name* (Section 7.5.2).

The scope of a local constant is the block in which the declaration occurs. It is an error to refer to a local constant in a textual position that precedes its *constant-declarator*. Within the scope of a local constant, it is a compile-time error to declare another local variable or constant with the same name.

A local constant declaration that declares multiple constants is equivalent to multiple declarations of single constants with the same type.

8.6 Expression statements

An *expression-statement* evaluates a given expression. The value computed by the expression, if any, is discarded.

expression-statement:
  statement-expression ;
statement-expression:
  invocation-expression
  object-creation-expression
  assignment
  post-increment-expression
  post-decrement-expression
  pre-increment-expression
  pre-decrement-expression

Not all expressions are permitted as *statements*. In particular, expressions such as `x + y` and `x == 1` that merely compute a value (which will be discarded), are not permitted as *statements*.

Execution of an *expression-statement* evaluates the contained *expression* and then transfers control to the end point of the *expression-statement*. The end point of an *expression-statement* is reachable if that *expression-statement* is reachable.

8.7 Selection statements

Selection statements select one of a number of possible statements for execution based on the value of some expression.

selection-statement:
  if-statement
  switch-statement

8.7.1 The if statement

The `if` statement selects a statement for execution based on the value of a Boolean expression.

if-statement:
  if (*boolean-expression*) *embedded-statement*
  if (*boolean-expression*) *embedded-statement* else *embedded-statement*
boolean-expression:
  expression

An `else` part is associated with the lexically nearest preceding `if` that is allowed by the syntax. Thus, an `if` statement of the form

```
if (x) if (y) F(); else G();
```

is equivalent to

```
if (x) {
   if (y) {
      F();
   }
   else {
      G();
   }
}
```

An `if` statement is executed as follows:

- The *boolean-expression* (Section 7.16) is evaluated.
- If the Boolean expression yields `true`, control is transferred to the first embedded statement. When and if control reaches the end point of that statement, control is transferred to the end point of the `if` statement.
- If the Boolean expression yields `false` and if an `else` part is present, control is transferred to the second embedded statement. When and if control reaches the end point of that statement, control is transferred to the end point of the `if` statement.
- If the Boolean expression yields `false` and if an `else` part is not present, control is transferred to the end point of the `if` statement.

The first embedded statement of an `if` statement is reachable if the `if` statement is reachable and the Boolean expression does not have the constant value `false`.

The second embedded statement of an `if` statement, if present, is reachable if the `if` statement is reachable and the Boolean expression does not have the constant value `true`.

The end point of an `if` statement is reachable if the end point of at least one of its embedded statements is reachable. In addition, the end point of an `if` statement with no `else` part is reachable if the `if` statement is reachable and the Boolean expression does not have the constant value `true`.

8.7.2 The switch statement

The switch statement selects for execution a statement list having an associated switch label that corresponds to the value of the switch expression.

switch-statement:
  switch (*expression*) *switch-block*
switch-block:
  { *switch-sections*$_{opt}$ }
switch-sections:
  switch-section
  switch-sections *switch-section*
switch-section:
  switch-labels *statement-list*
switch-labels:
  switch-label
  switch-labels *switch-label*
switch-label:
  case *constant-expression* :
  default :

A *switch-statement* consists of the keyword `switch`, followed by a parenthesized expression (called the switch expression), followed by a *switch-block*. The *switch-block* consists of zero or more *switch-sections*, enclosed in braces. Each *switch-section* consists of one or more *switch-labels* followed by a *statement-list* (Section 8.2.1).

The governing type of a `switch` statement is established by the switch expression. If the type of the switch expression is `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `string`, or an *enum-type*, then that is the governing type of the `switch` statement. Otherwise, exactly one user-defined implicit conversion (Section 6.4) must exist from the type of the switch expression to one of the following possible governing types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `string`. If no such implicit conversion exists, or if more than one such implicit conversion exists, a compile-time error occurs.

The constant expression of each `case` label must denote a value of a type that is implicitly convertible (Section 6.1) to the governing type of the `switch` statement. A compile-time error occurs if two or more `case` labels in the same `switch` statement specify the same constant value.

There can be at most one `default` label in a switch statement.

A `switch` statement is executed as follows:

- The switch expression is evaluated and converted to the governing type.
- If one of the constants specified in a `case` label in the same `switch` statement is equal to the value of the switch expression, control is transferred to the statement list following the matched `case` label.
- If none of the constants specified in `case` labels in the same `switch` statement is equal to the value of the switch expression, and if a `default` label is present, control is transferred to the statement list following the `default` label.
- If none of the constants specified in `case` labels in the same `switch` statement is equal to the value of the switch expression, and if no `default` label is present, control is transferred to the end point of the `switch` statement.

If the end point of the statement list of a switch section is reachable, a compile-time error occurs. This is known as the "no fall through" rule. The example

```
switch (i) {
case 0:
   CaseZero();
   break;
case 1:
   CaseOne();
   break;
default:
   CaseOthers();
   break;
}
```

is valid because no switch section has a reachable end point. Unlike C and C++, execution of a switch section is not permitted to

"fall through" to the next switch section, and the example

```
switch (i) {
case 0:
   CaseZero();
case 1:
   CaseZeroOrOne();
default:
   CaseAny();
}
```

results in a compile-time error. When execution of a switch section is to be followed by execution of another switch section, an explicit `goto case` or `goto default` statement must be used:

```
switch (i) {
case 0:
   CaseZero();
   goto case 1;
case 1:
   CaseZeroOrOne();
   goto default;
default:
   CaseAny();
   break;
}
```

Multiple labels are permitted in a *switch-section*. The example

```
switch (i) {
case 0:
   CaseZero();
   break;
case 1:
   CaseOne();
   break;
case 2:
default:
   CaseTwo();
   break;
}
```

is valid. The example does not violate the "no fall through" rule because the labels `case 2:` and `default:` are part of the same *switch-section*.

The "no fall through" rule prevents a common class of bugs that occur in C and C++ when `break` statements are accidentally omitted. In addition, because of this rule, the switch sections of a `switch` statement can be arbitrarily rearranged without affecting the behavior of the statement. For example, the sections of the `switch` statement above can be reversed without affecting the behavior of the statement:

```
switch (i) {
default:
   CaseAny();
   break;
case 1:
   CaseZeroOrOne();
   goto default;
case 0:
   CaseZero();
   goto case 1;
}
```

The statement list of a switch section typically ends in a `break`, `goto case`, or `goto default` statement, but any construct that renders the end point of the statement list unreachable is permitted. For example, a `while` statement controlled by the Boolean expression `true` is known to never reach its end point. Likewise, a `throw` or `return` statement always transfers control elsewhere

and never reaches its end point. Thus, the following example is valid:

```
switch (i) {
case 0:
   while (true) F();
case 1:
   throw new ArgumentException();
case 2:
   return;
}
```

The governing type of a `switch` statement may be the type `string`. For example:

```
void DoCommand(string command) {
   switch (command.ToLower()) {
   case "run":
      DoRun();
      break;
   case "save":
      DoSave();
      break;
   case "quit":
      DoQuit();
      break;
   default:
      InvalidCommand(command);
      break;
   }
}
```

Like the string equality operators (Section 7.9.7), the `switch` statement is case sensitive and will execute a given switch section only if the switch expression string exactly matches a `case` label constant.

When the governing type of a `switch` statement is `string`, the value `null` is permitted as a case label constant.

The *statement-lists* of a *switch-block* may contain declaration statements (Section 8.5). The scope of a local variable or constant declared in a switch block is the switch block.

Within a switch block, the meaning of a name used in an expression context must always be the same (Section 7.5.2.1).

The statement list of a given switch section is reachable if the `switch` statement is reachable and at least one of the following is true:

- The switch expression is a non-constant value.
- The switch expression is a constant value that matches a `case` label in the switch section.
- The switch expression is a constant value that doesn't match any `case` label, and the switch section contains the `default` label.
- A switch label of the switch section is referenced by a reachable `goto case` or `goto default` statement.

The end point of a `switch` statement is reachable if at least one of the following is true:

- The `switch` statement contains a reachable `break` statement that exits the `switch` statement.
- The `switch` statement is reachable, the switch expression is a non-constant value, and no `default` label is present.
- The `switch` statement is reachable, the switch expression is a constant value that doesn't match any `case` label, and no `default` label is present.

8.8 Iteration statements

Iteration statements repeatedly execute an embedded statement.

iteration-statement:
  while-statement
  do-statement
  for-statement
  foreach-statement

8.8.1 The while statement

The `while` statement conditionally executes an embedded statement zero or more times.

while-statement:
  while (*boolean-expression*) *embedded-statement*

A `while` statement is executed as follows:

- The *boolean-expression* (Section 7.16) is evaluated.
- If the Boolean expression yields `true`, control is transferred to the embedded statement. When and if control reaches the end point of the embedded statement (possibly from execution of a `continue` statement), control is transferred to the beginning of the `while` statement.
- If the Boolean expression yields `false`, control is transferred to the end point of the `while` statement.

Within the embedded statement of a `while` statement, a `break` statement (Section 8.9.1) may be used to transfer control to the end point of the `while` statement (thus ending iteration of the embedded statement), and a `continue` statement (Section 8.9.2) may be used to transfer control to the end point of the embedded statement.

The embedded statement of a `while` statement is reachable if the `while` statement is reachable and the Boolean expression does not have the constant value `false`.

The end point of a `while` statement is reachable if at least one of the following is true:

- The `while` statement contains a reachable `break` statement that exits the `while` statement.
- The `while` statement is reachable and the Boolean expression does not have the constant value `true`.

8.8.2 The do statement

The `do` statement conditionally executes an embedded statement one or more times.

do-statement:
  do *embedded-statement* while (*boolean-expression*) ;

A `do` statement is executed as follows:

- Control is transferred to the embedded statement.
- When and if control reaches the end point of the embedded statement (possibly from execution of a `continue` statement), the *boolean-expression* (Section 7.16) is evaluated. If the Boolean expression yields `true`, control is transferred to the beginning of the `do` statement. Otherwise, control is transferred to the end point of the `do` statement.

Within the embedded statement of a `do` statement, a `break` statement (Section 8.9.1) may be used to transfer control to the end point of the `do` statement (thus ending iteration of the embedded statement), and a `continue` statement (Section 8.9.2) may be used to transfer control to the end point of the embedded statement (thus performing another iteration of the `do` statement).

The embedded statement of a `do` statement is reachable if the `do` statement is reachable.

The end point of a `do` statement is reachable if at least one of the following is true:

- The `do` statement contains a reachable `break` statement that exits the `do` statement.
- The end point of the embedded statement is reachable and the Boolean expression does not have the constant value `true`.

8.8.3 The for statement

The `for` statement evaluates a sequence of initialization expressions and then, while a condition is true, repeatedly executes an embedded statement and evaluates a sequence of iteration expressions.

for-statement:
  for (*for-initializer*$_{opt}$; *for-condition*$_{opt}$; *for-iterator*$_{opt}$) *embedded-statement*
for-initializer:
  local-variable-declaration
  statement-expression-list
for-condition:
  boolean-expression
for-iterator:
  statement-expression-list
statement-expression-list:
  statement-expression
  statement-expression-list , *statement-expression*

The *for-initializer*, if present, consists of either a *local-variable-declaration* (Section 8.5.1) or a list of *statement-expressions* (Section 8.6) separated by commas. The scope of a local variable declared by a *for-initializer* starts at the *local-variable-declarator* for the variable and extends to the end of the embedded statement. The scope includes the *for-condition* and the *for-iterator*.

The *for-condition*, if present, must be a *boolean-expression* (Section 7.16).

The *for-iterator*, if present, consists of a list of *statement-expressions* (Section 8.6) separated by commas.

A for statement is executed as follows:

- If a *for-initializer* is present, the variable initializers or statement expressions are executed in the order they are written. This step is only performed once.
- If a *for-condition* is present, it is evaluated.
- If the *for-condition* is not present or if the evaluation yields `true`, control is transferred to the embedded statement. When and if control reaches the end point of the embedded statement (possibly from execution of a `continue` statement), the expressions of the *for-iterator*, if any, are evaluated in sequence, and then another iteration is performed, starting with evaluation of the *for-condition* in the step above.
- If the *for-condition* is present and the evaluation yields `false`, control is transferred to the end point of the `for` statement.

Within the embedded statement of a `for` statement, a `break` statement (Section 8.9.1) may be used to transfer control to the end point of the `for` statement (thus ending iteration of the embedded statement), and a `continue` statement (Section 8.9.2) may be used to transfer control to the end point of the embedded statement (thus executing the *for-iterator* and performing another iteration of the `for` statement, starting with the *for-condition*).

The embedded statement of a `for` statement is reachable if one of the following is true:

- The `for` statement is reachable and no *for-condition* is present.
- The `for` statement is reachable and a *for-condition* is present and does not have the constant value `false`.

The end point of a `for` statement is reachable if at least one of the following is true:

- The `for` statement contains a reachable `break` statement that exits the `for` statement.
- The `for` statement is reachable and a *for-condition* is present and does not have the constant value `true`.

8.8.4 The foreach statement

The `foreach` statement enumerates the elements of a collection, executing an embedded statement for each element of the collection.

foreach-statement:
foreach (*type* *identifier* in *expression*) *embedded-statement*

The *type* and *identifier* of a `foreach` statement declare the iteration variable of the statement. The iteration variable corresponds to a read-only local variable with a scope that extends over the embedded statement. During execution of a `foreach` statement, the iteration variable represents the collection element for which an iteration is currently being performed. A compile-time error occurs if the embedded statement attempts to modify the iteration variable (by assignment or the `++` and `--` operators) or pass the iteration variable as a `ref` or `out` parameter.

The type of the *expression* of a `foreach` statement must be a collection type (as defined below), and an explicit conversion (Section 6.2) must exist from the element type of the collection to the type of the iteration variable. If *expression* has the value `null`, a `System.NullReferenceException` is thrown.

A type `C` is said to be a collection type if it implements the `System.Collections.IEnumerable` interface or implements the collection pattern by meeting all of the following criteria:

- `C` contains a `public` instance method with the signature `GetEnumerator()` that returns a *struct-type*, *class-type*, or *interface-type*, which is called `E` in the following text.
- `E` contains a `public` instance method with the signature `MoveNext()` and the return type `bool`.
- `E` contains a `public` instance property named `Current` that permits reading the current value. The type of this property is said to be the element type of the collection type.

A type that implements `IEnumerable` is also a collection type, even if it does not satisfy the conditions above. (This is possible if it implements some of the `IEnumerable` members by means of explicit interface member implementation, as described in Section 13.4.1.)

The `System.Array` type (Section 12.1.1) is a collection type, and since all array types derive from `System.Array`, any array type expression is permitted in a `foreach` statement. The order in which `foreach` traverses the elements of an array is as follows: For single-dimensional arrays, elements are traversed in increasing index order, starting with index `0` and ending with index `Length - 1`. For multi-dimensional arrays, elements are traversed such that the indices of the rightmost dimension are increased first, then the next left dimension, and so on to the left.

A `foreach` statement of the form:

```
foreach (ElementType element in collection) statement
```

corresponds to one of two possible expansions:

- If the `collection` expression is of a type that implements the collection pattern (as defined above), the expansion of the `foreach` statement is:

  ```
  E enumerator = (collection).GetEnumerator();
  try {
     while (enumerator.MoveNext()) {
        ElementType element = (ElementType)enumerator.Current;
        statement;
     }
  }
  finally {
     IDisposable disposable = enumerator as System.IDisposable;
     if (disposable != null) disposable.Dispose();
  }
  ```

  Significant optimizations of the above are often easily available. If the type `E` implements `System.IDisposable`, then the expression (`enumerator as System.IDisposable`) will always be non-null and the implementation can safely substitute a simple conversion for a possibly more expensive type test. Conversely, if the type `E` is `sealed` and does not implement

`System.IDisposable`, then the expression (`enumerator as System.IDisposable`) will always evaluate to null. In this case, the implementation can safely optimize away the entire finally clause.

- Otherwise, the `collection` expression is of a type that implements `System.IEnumerable`, and the expansion of the `foreach` statement is:

```
IEnumerator enumerator =
        ((System.Collections.IEnumerable)(collection)).GetEnumerator();
try {
   while (enumerator.MoveNext()) {
      ElementType element = (ElementType)enumerator.Current;
      statement;
   }
}
finally {
   IDisposable disposable = enumerator as System.IDisposable;
   if (disposable != null) disposable.Dispose();
}
```

In either expansion, the `enumerator` variable is a temporary variable that is inaccessible in, and invisible to, the embedded `statement`, and the element variable is read-only in the embedded `statement`.

The following example prints out each value in a two-dimensional array, in element order:

```
using System;
class Test
{
   static void Main() {
      double[,] values = {
         {1.2, 2.3, 3.4, 4.5},
         {5.6, 6.7, 7.8, 8.9}
      };
      foreach (double elementValue in values)
         Console.Write("{0} ", elementValue);
      Console.WriteLine();
   }
}
```

The output produced is as follows:

```
1.2 2.3 3.4 4.5 5.6 6.7 7.8 8.9
```

8.9 Jump statements

Jump statements unconditionally transfer control.

jump-statement:
  break-statement
  continue-statement
  goto-statement
  return-statement
  throw-statement

The location to which a jump statement transfers control is called the target of the jump statement.

When a jump statement occurs within a block, and the target of that jump statement is outside that block, the jump statement is said to exit the block. While a jump statement may transfer control out of a block, it can never transfer control into a block.

Execution of jump statements is complicated by the presence of intervening `try` statements. In the absence of such `try` statements, a jump statement unconditionally transfers control from the jump statement to its target. In the presence of such intervening `try` statements, execution is more complex. If the jump statement exits one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all intervening `try` statements have been executed.

In the example

```
using System;
class Test
{
   static void Main() {
      while (true) {
         try {
            try {
               Console.WriteLine("Before break");
               break;
            }
            finally {
               Console.WriteLine("Innermost finally block");
            }
         }
         finally {
            Console.WriteLine("Outermost finally block");
         }
      }
      Console.WriteLine("After break");
   }
}
```

the finally blocks associated with two try statements are executed before control is transferred to the target of the jump statement.

The output produced is as follows:

```
Before break
Innermost finally block
Outermost finally block
After break
```

8.9.1 The break statement

The `break` statement exits the nearest enclosing `switch`, `while`, `do`, `for`, or `foreach` statement.

break-statement:
  break ;

The target of a `break` statement is the end point of the nearest enclosing `switch`, `while`, `do`, `for`, or `foreach` statement. If a `break` statement is not enclosed by a `switch`, `while`, `do`, `for`, or `foreach` statement, a compile-time error occurs.

When multiple `switch`, `while`, `do`, `for`, or `foreach` statements are nested within each other, a `break` statement applies only to the innermost statement. To transfer control across multiple nesting levels, a `goto` statement (Section 8.9.3) must be used.

A `break` statement cannot exit a `finally` block (Section 8.10). When a `break` statement occurs within a `finally` block, the target of the `break` statement must be within the same `finally` block; otherwise, a compile-time error occurs.

A `break` statement is executed as follows:

- If the `break` statement exits one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all intervening `try` statements have been executed.
- Control is transferred to the target of the `break` statement.

Because a `break` statement unconditionally transfers control elsewhere, the end point of a `break` statement is never reachable.

8.9.2 The continue statement

The `continue` statement starts a new iteration of the nearest enclosing `while`, `do`, `for`, or `foreach` statement.

continue-statement:
  continue ;

The target of a `continue` statement is the end point of the embedded statement of the nearest enclosing `while`, `do`, `for`, or `foreach` statement. If a `continue` statement is not enclosed by a `while`, `do`, `for`, or `foreach` statement, a compile-time error occurs.

When multiple `while`, `do`, `for`, or `foreach` statements are nested within each other, a `continue` statement applies only to the innermost statement. To transfer control across multiple nesting levels, a `goto` statement (Section 8.9.3) must be used.

A `continue` statement cannot exit a `finally` block (Section 8.10). When a `continue` statement occurs within a `finally` block, the target of the `continue` statement must be within the same `finally` block; otherwise, a compile-time error occurs.

A `continue` statement is executed as follows:

- If the `continue` statement exits one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all intervening `try` statements have been executed.
- Control is transferred to the target of the `continue` statement.

Because a `continue` statement unconditionally transfers control elsewhere, the end point of a `continue` statement is never reachable.

8.9.3 The goto statement

The `goto` statement transfers control to a statement that is marked by a label.

goto-statement:
  goto *identifier* ;
  goto case *constant-expression* ;
  goto default ;

The target of a `goto` *identifier* statement is the labeled statement with the given label. If a label with the given name does not exist in the current function member, or if the `goto` statement is not within the scope of the label, a compile-time error occurs. This rule permits the use of a `goto` statement to transfer control *out of* a nested scope, but not *into* a nested scope. In the example

```
using System;
class Test
{
   static void Main(string[] args) {
      string[,] table = {
         {"Red", "Blue", "Green"},
         {"Monday", "Wednesday", "Friday"}
      };
      foreach (string str in args) {
         int row, colm;
         for (row = 0; row <= 1; ++row)
            for (colm = 0; colm <= 2; ++colm)
               if (str == table[row,colm])
                   goto done;
         Console.WriteLine("{0} not found", str);
         continue;
   done:
         Console.WriteLine("Found {0} at [{1}][{2}]", str, row, colm);
      }
   }
}
```

a `goto` statement is used to transfer control out of a nested scope.

The target of a `goto case` statement is the statement list in the immediately enclosing switch statement (Section 8.7.2), which contains a `case` label with the given constant value. If the `goto case` statement is not enclosed by a `switch` statement, if the *constant-expression* is not implicitly convertible (Section 6.1) to the governing type of the nearest enclosing `switch` statement, or if the nearest enclosing `switch` statement does not contain a `case` label with the given constant value, a compile-time error occurs.

The target of a `goto default` statement is the statement list in the immediately enclosing switch statement (Section 8.7.2), which contains a default label. If the `goto default` statement is not enclosed by a `switch` statement, or if the nearest enclosing `switch` statement does not contain a `default` label, a compile-time error occurs.

A `goto` statement cannot exit a `finally` block (Section 8.10). When a `goto` statement occurs within a `finally` block, the target of the `goto` statement must be within the same `finally` block, or otherwise a compile-time error occurs.

A `goto` statement is executed as follows:

- If the `goto` statement exits one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all intervening `try` statements have been executed.
- Control is transferred to the target of the `goto` statement.

Because a `goto` statement unconditionally transfers control elsewhere, the end point of a `goto` statement is never reachable.

8.9.4 The return statement

The `return` statement returns control to the caller of the function member in which the `return` statement appears.

return-statement:
  return *expression*$_{opt}$;

A `return` statement with no expression can be used only in a function member that does not compute a value, that is, a method with the return type `void`, the `set` accessor of a property or indexer, the `add` and `remove` accessors of an event, an instance constructor, a static constructor, or a destructor.

A `return` statement with an expression can only be used in a function member that computes a value, that is, a method with a non-void return type, the `get` accessor of a property or indexer, or a user-defined operator. An implicit conversion (Section 6.1) must exist from the type of the expression to the return type of the containing function member.

It is a compile-time error for a `return` statement to appear in a `finally` block (Section 8.10).

A `return` statement is executed as follows:

- If the `return` statement specifies an expression, the expression is evaluated and the resulting value is converted to the return type of the containing function member by an implicit conversion. The result of the conversion becomes the value returned to the caller.
- If the `return` statement is enclosed by one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all enclosing `try` statements have been executed.
- Control is returned to the caller of the containing function member.

Because a `return` statement unconditionally transfers control elsewhere, the end point of a `return` statement is never reachable.

8.9.5 The throw statement

The `throw` statement throws an exception.

throw-statement:
  throw *expression*$_{opt}$;

A `throw` statement with an expression throws the value produced by evaluating the expression. The expression must denote a value of the class type `System.Exception` or of a class type that derives from `System.Exception`. If evaluation of the expression produces `null`, a `System.NullReferenceException` is thrown instead.

A `throw` statement with no expression can be used only in a `catch` block, in which case that statement re-throws the exception that is currently being handled by that `catch` block.

Because a `throw` statement unconditionally transfers control elsewhere, the end point of a `throw` statement is never reachable.

When an exception is thrown, control is transferred to the first `catch` clause in an enclosing `try` statement that can handle the exception. The process that takes place from the point of the exception being thrown to the point of transferring control to a suitable exception handler is known as exception propagation. Propagation of an exception consists of repeatedly evaluating the following steps until a `catch` clause that matches the exception is found. In this description, the throw point is initially the location at which the exception is thrown.

- In the current function member, each `try` statement that encloses the throw point is examined. For each statement `S`, starting with the innermost `try` statement and ending with the outermost `try` statement, the following steps are evaluated:
- If the `try` block of `S` encloses the throw point and if S has one or more `catch` clauses, the `catch` clauses are examined in order of appearance to locate a suitable handler for the exception. The first `catch` clause that specifies the exception type or a base type of the exception type is considered a match. A general `catch` clause (Section 8.10) is considered a match for any exception type. If a matching `catch` clause is located, the exception propagation is completed by transferring control to the block of that `catch` clause.
- Otherwise, if the `try` block or a `catch` block of `S` encloses the throw point and if `S` has a `finally` block, control is transferred to the `finally` block. If the `finally` block throws another exception, processing of the current exception is terminated. Otherwise, when control reaches the end point of the `finally` block, processing of the current exception is continued.
- If an exception handler was not located in the current function member invocation, the function member invocation is terminated. The steps above are then repeated for the caller of the function member with a throw point corresponding to the statement from which the function member was invoked.
- If the exception processing terminates all function member invocations in the current thread, indicating that the thread has no handler for the exception, then the thread is itself terminated. The impact of such termination is implementation-defined.

8.10 The try statement

The `try` statement provides a mechanism for catching exceptions that occur during execution of a block. Furthermore, the `try` statement provides the ability to specify a block of code that is always executed when control leaves the `try` statement.

try-statement:
  try *block* *catch-clauses*
  try *block* *finally-clause*
  try *block* *catch-clauses* *finally-clause*
catch-clauses:
  specific-catch-clauses *general-catch-clause*$_{opt}$
  specific-catch-clauses$_{opt}$ *general-catch-clause*
specific-catch-clauses:
  specific-catch-clause
  specific-catch-clauses *specific-catch-clause*
specific-catch-clause:
  catch (*class-type* *identifier*$_{opt}$) *block*
general-catch-clause:
  catch *block*
finally-clause:
  finally *block*

There are three possible forms of `try` statements:

- A `try` block followed by one or more `catch` blocks.
- A `try` block followed by a `finally` block.
- A `try` block followed by one or more `catch` blocks followed by a `finally` block.

When a `catch` clause specifies a *class-type*, the type must be `System.Exception` or a type that derives from `System.Exception`.

When a `catch` clause specifies both a *class-type* and an *identifier*, an exception variable of the given name and type is declared. The exception variable corresponds to a local variable with a scope that extends over the `catch` block. During execution of the `catch` block, the exception variable represents the exception currently being handled. For purposes of definite assignment checking, the exception variable is considered definitely assigned in its entire scope.

Unless a `catch` clause includes an exception variable name, it is impossible to access the exception object in the `catch` block.

A `catch` clause that specifies neither an exception type nor an exception variable name is called a general `catch` clause. A `try` statement can only have one general `catch` clause, and if one is present it must be the last `catch` clause.

Some programming languages may support exceptions that are not representable as an object derived from `System.Exception`, although such exceptions could never be generated by C# code. A general catch clause may be used to catch such exceptions. Thus, a general catch clause is semantically different from one that specifies the type `System.Exception`, in that the former may also catch exceptions from other languages.

In order to locate a handler for an exception, `catch` clauses are examined in lexical order. A compile-time error occurs if a `catch` clause specifies a type that is the same as, or is derived from, a type that was specified in an earlier `catch` clause for the same `try`. Without this restriction, it would be possible to write unreachable `catch` clauses.

Within a `catch` block, a `throw` statement (Section 8.9.5) with no expression can be used to re-throw the exception that was caught by the `catch` block. Assignments to an exception variable do not alter the exception that is re-thrown.

In the example

```
using System;
class Test
{
   static void F() {
      try {
         G();
      }
      catch (Exception e) {
         Console.WriteLine("Exception in F: " + e.Message);
         e = new Exception("F");
         throw;            // re-throw
```

```
        }
    }
    static void G() {
        throw new Exception("G");
    }
    static void Main() {
        try {
            F();
        }
        catch (Exception e) {
            Console.WriteLine("Exception in Main: " + e.Message);
        }
    }
}
```

the method `F` catches an exception, writes some diagnostic information to the console, alters the exception variable, and re-throws the exception. The exception that is re-thrown is the original exception, so the output produced is:

```
Exception in F: G
Exception in Main: G
```

If the first catch block had thrown `e` instead of rethrowing the current exception, the output produced is would be as follows:

```
Exception in F: G
Exception in Main: F
```

It is a compile-time error for a `break`, `continue`, or `goto` statement to transfer control out of a `finally` block. When a `break`, `continue`, or `goto` statement occurs in a `finally` block, the target of the statement must be within the same `finally` block, or otherwise a compile-time error occurs.

It is a compile-time error for a `return` statement to occur in a `finally` block.

A `try` statement is executed as follows:

- Control is transferred to the `try` block.
- When and if control reaches the end point of the `try` block:
- If the `try` statement has a `finally` block, the `finally` block is executed.
- Control is transferred to the end point of the `try` statement.
- If an exception is propagated to the `try` statement during execution of the `try` block:
- The `catch` clauses, if any, are examined in order of appearance to locate a suitable handler for the exception. The first `catch` clause that specifies the exception type or a base type of the exception type is considered a match. A general `catch` clause is considered a match for any exception type. If a matching `catch` clause is located:
- If the matching `catch` clause declares an exception variable, the exception object is assigned to the exception variable.
- Control is transferred to the matching `catch` block.
- When and if control reaches the end point of the `catch` block:
- If the `try` statement has a `finally` block, the `finally` block is executed.
- Control is transferred to the end point of the `try` statement.
- If an exception is propagated to the `try` statement during execution of the `catch` block:
- If the `try` statement has a `finally` block, the `finally` block is executed.
- The exception is propagated to the next enclosing `try` statement.
- If the `try` statement has no `catch` clauses or if no `catch` clause matches the exception:
- If the `try` statement has a `finally` block, the `finally` block is executed.
- The exception is propagated to the next enclosing `try` statement.

The statements of a `finally` block are always executed when control leaves a `try` statement. This is true whether the control transfer occurs as a result of normal execution, as a result of executing a `break`, `continue`, `goto`, or `return` statement, or as a result of propagating an exception out of the `try` statement.

If an exception is thrown during execution of a `finally` block, the exception is propagated to the next enclosing `try` statement. If

another exception was in the process of being propagated, that exception is lost. The process of propagating an exception is discussed further in the description of the `throw` statement (Section 8.9.5).

The `try` block of a `try` statement is reachable if the `try` statement is reachable.

A `catch` block of a `try` statement is reachable if the `try` statement is reachable.

The `finally` block of a `try` statement is reachable if the `try` statement is reachable.

The end point of a `try` statement is reachable if both of the following are true:

- The end point of the `try` block is reachable or the end point of at least one `catch` block is reachable.
- If a `finally` block is present, the end point of the `finally` block is reachable.

8.11 The checked and unchecked statements

The `checked` and `unchecked` statements are used to control the overflow checking context for integral-type arithmetic operations and conversions.

checked-statement:
  checked *block*
unchecked-statement:
  unchecked *block*

The `checked` statement causes all expressions in the *block* to be evaluated in a checked context, and the `unchecked` statement causes all expressions in the *block* to be evaluated in an unchecked context.

The `checked` and `unchecked` statements are precisely equivalent to the `checked` and `unchecked` operators (Section 7.5.12), except that they operate on blocks instead of expressions.

8.12 The lock statement

The `lock` statement obtains the mutual-exclusion lock for a given object, executes a statement, and then releases the lock.

lock-statement:
lock (*expression*) *embedded-statement*

The expression of a `lock` statement must denote a value of a *reference-type*. No implicit boxing conversion (Section 6.1.5) is ever performed for the expression of a `lock` statement, and thus it is a compile-time error for the expression to denote a value of a *value-type*.

A `lock` statement of the form

```
lock (x) ...
```

where `x` is an expression of a *reference-type*, is precisely equivalent to

```
System.Threading.Monitor.Enter(x);
try {
   ...
}
finally {
   System.Threading.Monitor.Exit(x);
}
```

except that `x` is only evaluated once.

While a *mutual-exclusion* lock is held, code executing in the same execution thread can also obtain and release the lock. However, code executing in other threads is blocked from obtaining the lock until the lock is released.

The `System.Type` object of a class can conveniently be used as the mutual-exclusion lock for static methods of the class. For example:

```
class Cache
{
   public static void Add(object x) {
      lock (typeof(Cache)) {
         ...
      }
   }
   public static void Remove(object x) {
      lock (typeof(Cache)) {
         ...
      }
   }
}
```

8.13 The using statement

The `using` statement obtains one or more resources, executes a statement, and then disposes of the resource.

using-statement:
  using (*resource-acquisition*) *embedded-statement*
resource-acquisition:
  local-variable-declaration
  expression

A resource is a class or struct that implements `System.IDisposable`, which includes a single parameterless method named `Dispose`. Code that is using a resource can call `Dispose` to indicate that the resource is no longer needed. If `Dispose` is not called, then automatic disposal eventually occurs as a consequence of garbage collection.

If the form of *resource-acquisition* is *local-variable-declaration* then the type of the *local-variable-declaration* must be `System.IDisposable` or a type that can be implicitly converted to `System.IDisposable`. If the form of *resource-acquisition* is *expression* then this expression must be of type `System.IDisposable` or a type that can be implicitly converted to `System.IDisposable`.

Local variables declared in a *resource-acquisition* are read-only, and must include an initializer. A compile-time error occurs if the embedded statement attempts to modify these local variables (by assignment or the ++ and -- operators) or pass them as `ref` or `out` parameters.

A `using` statement is translated into three parts: acquisition, usage, and disposal. Usage of the resource is implicitly enclosed in a `try` statement that includes a `finally` clause. This `finally` clause disposes of the resource. If a `null` resource is acquired, then no call to `Dispose` is made, and no exception is thrown.

A `using` statement of the form

```
using (ResourceType resource = expression) statement
```

corresponds to one of two possible expansions. When `ResourceType` is a value type, the expansion is

```
{
   ResourceType resource = expression;
   try {
      statement;
   }
   finally {
      ((IDisposable)resource).Dispose();
   }
}
```

Otherwise, when `ResourceType` is a reference type, the expansion is

```
{
   ResourceType resource = expression;
   try {
      statement;
   }
   finally {
      if (resource != null) ((IDisposable)resource).Dispose();
   }
}
```

In either expansion, the `resource` variable is read-only in the embedded statement.

A `using` statement of the form

```
using (expression) statement
```

has the same two possible expansions, but in this case `ResourceType` is implicitly the compile-time type of the `expression`, and the `resource` variable is inaccessible in, and invisible to, the embedded statement.

When a *resource-acquisition* takes the form of a *local-variable-declaration*, it is possible to acquire multiple resources of a given type. A `using` statement of the form

```
using (ResourceType r1 = e1, r2 = e2, ..., rN = eN) statement
```

is precisely equivalent to a sequence of nested `using` statements:

```
using (ResourceType r1 = e1)
   using (ResourceType r2 = e2)
      ...
         using (ResourceType rN = eN)
            statement
```

The example below creates a file named `log.txt` and writes two lines of text to the file. The example then opens that same file for reading and copies the contained lines of text to the console.

```
using System;
using System.IO;
class Test
{
   static void Main() {
      using (TextWriter w = File.CreateText("log.txt")) {
         w.WriteLine("This is line one");
         w.WriteLine("This is line two");
      }
      using (TextReader r = File.OpenText("log.txt")) {
         string s;
         while ((s = r.ReadLine()) != null) {
            Console.WriteLine(s);
         }
      }
   }
}
```

Since the `TextWriter` and `TextReader` classes implement the `IDisposable` interface, the example can use `using` statements to ensure that the underlying file is properly closed following the write or read operations.

9. Namespaces

C# programs are organized using namespaces. Namespaces are used both as an "internal" organization system for a program, and as an "external" organization system — a way of presenting program elements that are exposed to other programs.

Using directives (Section 9.3) are provided to facilitate the use of namespaces.

9.1 Compilation units

A *compilation-unit* defines the overall structure of a source file. A compilation unit consists of zero or more *using-directives* followed by zero or more *global-attributes* followed by zero or more *namespace-member-declarations*.

compilation-unit:
  using-directives$_{opt}$ *global-attributes*$_{opt}$ *namespace-member-declarations*$_{opt}$

A C# program consists of one or more compilation units, each contained in a separate source file. When a C# program is compiled, all of the compilation units are processed together. Thus, compilation units can depend on each other, possibly in a circular fashion.

The *using-directives* of a compilation unit affect the *global-attributes* and *namespace-member-declarations* of that compilation unit, but have no effect on other compilation units.

The *global-attributes* (Section 17) of a compilation unit permit the specification of attributes for the target assembly and module. Assemblies and modules act as physical containers for types. An assembly may consist of several physically separate modules.

The *namespace-member-declarations* of each compilation unit of a program contribute members to a single declaration space called the global namespace. For example:

File `A.cs`:

```
class A {}
```

File `B.cs`:

```
class B {}
```

The two compilation units contribute to the single global namespace, in this case declaring two classes with the fully qualified names `A` and `B`. Because the two compilation units contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

9.2 Namespace declarations

A *namespace-declaration* consists of the keyword `namespace`, followed by a namespace name and body, optionally followed by a semicolon.

namespace-declaration:
  namespace *qualified-identifier* *namespace-body* $;_{opt}$
qualified-identifier:
  identifier
  qualified-identifier . *identifier*
namespace-body:
  { $using\text{-}directives_{opt}$ $namespace\text{-}member\text{-}declarations_{opt}$ }

A *namespace-declaration* may occur as a top-level declaration in a *compilation-unit* or as a member declaration within another *namespace-declaration*. When a *namespace-declaration* occurs as a top-level declaration in a *compilation-unit*, the namespace becomes a member of the global namespace. When a *namespace-declaration* occurs within another *namespace-declaration*, the inner namespace becomes a member of the outer namespace. In either case, the name of a namespace must be unique within the containing namespace.

Namespaces are implicitly `public` and the declaration of a namespace cannot include any access modifiers.

Within a *namespace-body*, the optional *using-directives* import the names of other namespaces and types, allowing them to be referenced directly instead of through qualified names. The optional *namespace-member-declarations* contribute members to the declaration space of the namespace. Note that all *using-directives* must appear before any member declarations.

The *qualified-identifier* of a *namespace-declaration* may be a single identifier or a sequence of identifiers separated by "`.`" tokens. The latter form permits a program to define a nested namespace without lexically nesting several namespace declarations. For example,

```
namespace N1.N2
{
   class A {}
   class B {}
}
```

is semantically equivalent to

```
namespace N1
{
   namespace N2
   {
      class A {}
      class B {}
   }
}
```

Namespaces are open-ended, and two namespace declarations with the same fully qualified name contribute to the same declaration space (Section 3.3). In the example

```
namespace N1.N2
{
   class A {}
}
namespace N1.N2
{
   class B {}
}
```

the two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names `N1.N2.A` and `N1.N2.B`. Because the two declarations contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

9.3 Using directives

Using directives facilitate the use of namespaces and types defined in other namespaces. Using directives impact the name resolution process of *namespace-or-type-name*s (Section 3.8) and *simple-name*s (Section 7.5.2), but unlike declarations, using directives do not contribute new members to the underlying declaration spaces of the compilation units or namespaces within which they are used.

using-directives:
  using-directive
  using-directives *using-directive*
using-directive:
  using-alias-directive
  using-namespace-directive

A *using-alias-directive* (Section 9.3.1) introduces an alias for a namespace or type.

A *using-namespace-directive* (Section 9.3.2) imports the type members of a namespace.

The scope of a *using-directive* extends over the *namespace-member-declarations* of its immediately containing compilation unit or namespace body. The scope of a *using-directive* specifically does not include its peer *using-directive*s. Thus, peer *using-directive*s do not affect each other, and the order in which they are written is insignificant.

9.3.1 Using alias directives

A *using-alias-directive* introduces an identifier that serves as an alias for a namespace or type within the immediately enclosing compilation unit or namespace body.

using-alias-directive:
  using *identifier* = *namespace-or-type-name* ;

Within member declarations in a compilation unit or namespace body that contains a *using-alias-directive*, the identifier introduced by the *using-alias-directive* can be used to reference the given namespace or type. For example:

```
namespace N1.N2
{
   class A {}
}
namespace N3
{
   using A = N1.N2.A;
   class B: A {}
}
```

Above, within member declarations in the `N3` namespace, `A` is an alias for `N1.N2.A`, and thus class `N3.B` derives from class `N1.N2.A`. The same effect can be obtained by creating an alias `R` for `N1.N2` and then referencing `R.A`:

```
namespace N3
{
   using R = N1.N2;
   class B: R.A {}
}
```

The *identifier* of a *using-alias-directive* must be unique within the declaration space of the compilation unit or namespace that immediately contains the *using-alias-directive*. For example:

```
namespace N3
{
   class A {}
}
namespace N3
{
   using A = N1.N2.A;      // Error, A already exists
}
```

Above, `N3` already contains a member `A`, so it is a compile-time error for a *using-alias-directive* to use that identifier. Likewise, it is a compile-time error for two or more *using-alias-directives* in the same compilation unit or namespace body to declare aliases by the same name.

A *using-alias-directive* makes an alias available within a particular compilation unit or namespace body, but it does not contribute any new members to the underlying declaration space. In other words, a *using-alias-directive* is not transitive but rather affects only the compilation unit or namespace body in which it occurs. In the example

```
namespace N3
{
   using R = N1.N2;
}
namespace N3
{
   class B: R.A {}         // Error, R unknown
}
```

the scope of the *using-alias-directive* that introduces `R` only extends to member declarations in the namespace body in which it is contained, so `R` is unknown in the second namespace declaration. However, placing the *using-alias-directive* in the containing compilation unit causes the alias to become available within both namespace declarations:

```
using R = N1.N2;
namespace N3
{
   class B: R.A {}
}
namespace N3
{
   class C: R.A {}
}
```

Just like regular members, names introduced by *using-alias-directive*s are hidden by similarly named members in nested scopes. In the example

```
using R = N1.N2;
namespace N3
{
   class R {}
   class B: R.A {}      // Error, R has no member A
}
```

the reference to `R.A` in the declaration of `B` causes a compile-time error because `R` refers to `N3.R`, not `N1.N2`.

The order in which *using-alias-directive*s are written has no significance, and resolution of the *namespace-or-type-name* referenced by a *using-alias-directive* is not affected by the *using-alias-directive* itself or by other *using-directive*s in the immediately containing compilation unit or namespace body. In other words, the *namespace-or-type-name* of a *using-alias-directive* is resolved as if the immediately containing compilation unit or namespace body had no *using-directive*s. In the example

```
namespace N1.N2 {}
namespace N3
{
   using R1 = N1;         // OK
   using R2 = N1.N2;      // OK
   using R3 = R1.N2;      // Error, R1 unknown
}
```

the last *using-alias-directive* results in a compile-time error because it is not affected by the first *using-alias-directive*.

A *using-alias-directive* can create an alias for any namespace or type, including the namespace within which it appears and any namespace or type nested within that namespace.

Accessing a namespace or type through an alias yields exactly the same result as accessing that namespace or type through its declared name. For example, given

```
namespace N1.N2
{
   class A {}
}
namespace N3
{
   using R1 = N1;
   using R2 = N1.N2;
   class B
   {
      N1.N2.A a;         // refers to N1.N2.A
      R1.N2.A b;         // refers to N1.N2.A
      R2.A c;            // refers to N1.N2.A
   }
}
```

the names `N1.N2.A`, `R1.N2.A`, and `R2.A` are equivalent and all refer to the class whose fully qualified name is `N1.N2.A`.

9.3.2 Using namespace directives

A *using-namespace-directive* imports the types contained in a namespace into the immediately enclosing compilation unit or namespace body, enabling the identifier of each type to be used without qualification.

using-namespace-directive:
  using *namespace-name* ;

Within member declarations in a compilation unit or namespace body that contains a *using-namespace-directive*, the types contained in the given namespace can be referenced directly. For example:

```
namespace N1.N2
{
   class A {}
}
namespace N3
{
   using N1.N2;
   class B: A {}
}
```

Above, within member declarations in the `N3` namespace, the type members of `N1.N2` are directly available, and thus class `N3.B` derives from class `N1.N2.A`.

A *using-namespace-directive* imports the types contained in the given namespace, but specifically does not import nested namespaces. In the example

```
namespace N1.N2
{
   class A {}
}
namespace N3
{
   using N1;
   class B: N2.A {}      // Error, N2 unknown
}
```

the *using-namespace-directive* imports the types contained in `N1`, but not the namespaces nested in `N1`. Thus, the reference to `N2.A` in the declaration of `B` results in a compile-time error because no members named `N2` are in scope.

Unlike a *using-alias-directive*, a *using-namespace-directive* may import types whose identifiers are already defined within the enclosing compilation unit or namespace body. In effect, names imported by a *using-namespace-directive* are hidden by similarly named members in the enclosing compilation unit or namespace body. For example:

```
namespace N1.N2
{
   class A {}
   class B {}
}
namespace N3
{
   using N1.N2;
   class A {}
}
```

Here, within member declarations in the `N3` namespace, `A` refers to `N3.A` rather than `N1.N2.A`.

When more than one namespace imported by *using-namespace-directive*s in the same compilation unit or namespace body contain types by the same name, references to that name are considered ambiguous. In the example

```
namespace N1
{
   class A {}
}
```

```
namespace N2
{
   class A {}
}
namespace N3
{
   using N1;
   using N2;
   class B: A {}            // Error, A is ambiguous
}
```

both `N1` and `N2` contain a member `A`, and because `N3` imports both, referencing `A` in `N3` is a compile-time error. In this situation, the conflict can be resolved either through qualification of references to `A`, or by introducing a *using-alias-directive* that picks a particular `A`. For example:

```
namespace N3
{
   using N1;
   using N2;
   using A = N1.A;
   class B: A {}            // A means N1.A
}
```

Like a *using-alias-directive*, a *using-namespace-directive* does not contribute any new members to the underlying declaration space of the compilation unit or namespace, but rather affects only the compilation unit or namespace body in which it appears.

The *namespace-name* referenced by a *using-namespace-directive* is resolved in the same way as the *namespace-or-type-name* referenced by a *using-alias-directive*. Thus, *using-namespace-directive*s in the same compilation unit or namespace body do not affect each other and can be written in any order.

9.4 Namespace members

A *namespace-member-declaration* is either a *namespace-declaration* (Section 9.2) or a *type-declaration* (Section 9.5).

namespace-member-declarations:
  namespace-member-declaration
  namespace-member-declarations namespace-member-declaration
namespace-member-declaration:
  namespace-declaration
  type-declaration

A compilation unit or a namespace body can contain *namespace-member-declarations*, and such declarations contribute new members to the underlying declaration space of the containing compilation unit or namespace body.

9.5 Type declarations

A *type-declaration* is a *class-declaration* (Section 10.1), a *struct-declaration* (Section 11.1), an *interface-declaration* (Section 13.1), an *enum-declaration* (Section 14.1), or a *delegate-declaration* (Section 15.1).

type-declaration:
  class-declaration
  struct-declaration
  interface-declaration
  enum-declaration
  delegate-declaration

A *type-declaration* can occur as a top-level declaration in a compilation unit or as a member declaration within a namespace, class, or struct.

When a type declaration for a type `T` occurs as a top-level declaration in a compilation unit, the fully qualified name of the newly declared type is simply `T`. When a type declaration for a type `T` occurs within a namespace, class, or struct, the fully qualified name of the newly declared type is `N.T`, where `N` is the fully qualified name of the containing namespace, class, or struct.

A type declared within a class or struct is called a nested type (Section 10.2.6).

The permitted access modifiers and the default access for a type declaration depend on the context in which the declaration takes place (Section 3.5.1):

- Types declared in compilation units or namespaces can have `public` or `internal` access. The default is `internal` access.
- Types declared in classes can have `public`, `protected internal`, `protected`, `internal`, or `private` access. The default is `private` access.
- Types declared in structs can have `public`, `internal`, or `private` access. The default is `private` access.

10. Classes

A class is a data structure that may contain data members (constants and fields), function members (methods, properties, events, indexers, operators, instance constructors, destructors and static constructors), and nested types. Class types support inheritance, a mechanism whereby a derived class can extend and specialize a base class.

10.1 Class declarations

A *class-declaration* is a *type-declaration* (Section 9.5) that declares a new class.

class-declaration:
  attributes$_{opt}$ *class-modifiers*$_{opt}$ class *identifier* *class-base*$_{opt}$ *class-body* ;$_{opt}$

A *class-declaration* consists of an optional set of *attributes* (Section 17), followed by an optional set of *class-modifiers* (Section 10.1.1), followed by the keyword `class` and an *identifier* that names the class, followed by an optional *class-base* specification (Section 10.1.2), followed by a *class-body* (Section 10.1.3), optionally followed by a semicolon.

10.1.1 Class modifiers

A *class-declaration* may optionally include a sequence of class modifiers:

class-modifiers:
  class-modifier
  class-modifiers *class-modifier*
class-modifier:
  new
  public
  protected
  internal
  private
  abstract
  sealed

It is a compile-time error for the same modifier to appear multiple times in a class declaration.

The `new` modifier is permitted on nested classes. It specifies that the class hides an inherited member by the same name, as described in Section 10.2.2. It is a compile-time error for the `new` modifier to appear on a class declaration that is not a nested class declaration.

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the class. Depending on the context in which the class declaration occurs, some of these modifiers may not be permitted (Section 3.5.1).

The `abstract` and `sealed` modifiers are discussed in the following sections.

10.1.1.1 Abstract classes

The `abstract` modifier is used to indicate that a class is incomplete and that it is intended to be used only as a base class. An abstract class differs from a non-abstract class in the following ways:

- An abstract class cannot be instantiated directly, and it is a compile-time error to use the `new` operator on an abstract class. While it is possible to have variables and values whose compile-time types are abstract, such variables and values will necessarily either be `null` or contain references to instances of non-abstract classes derived from the abstract types.
- An abstract class is permitted (but not required) to contain abstract members.
- An abstract class cannot be sealed.

When a non-abstract class is derived from an abstract class, the non-abstract class must include actual implementations of all inherited abstract members, thereby overriding those abstract members. In the example

```
abstract class A
{
   public abstract void F();
}
abstract class B: A
{
   public void G() {}
}
class C: B
{
   public override void F() {
      // actual implementation of F
   }
}
```

the abstract class `A` introduces an abstract method `F`. Class `B` introduces an additional method `G`, but since it doesn't provide an implementation of `F`, `B` must also be declared abstract. Class `C` overrides `F` and provides an actual implementation. Since there are no abstract members in `C`, `C` is permitted (but not required) to be non-abstract.

10.1.1.2 Sealed classes

The `sealed` modifier is used to prevent derivation from a class. A compile-time error occurs if a sealed class is specified as the base class of another class.

A sealed class cannot also be an abstract class.

The `sealed` modifier is primarily used to prevent unintended derivation, but it also enables certain run-time optimizations. In particular, because a sealed class is known to never have any derived classes, it is possible to transform virtual function member invocations on sealed class instances into non-virtual invocations.

10.1.2 Class base specification

A class declaration may include a *class-base* specification, which defines the direct base class of the class and the interfaces (**Error! Reference source not found.**) implemented by the class.

class-base:
  : *class-type*
  : *interface-type-list*
  : *class-type* , *interface-type-list*
interface-type-list:
  interface-type
  interface-type-list , *interface-type*

10.1.2.1 Base classes

When a *class-type* is included in the *class-base*, it specifies the direct base class of the class being declared. If a class declaration has no *class-base*, or if the *class-base* lists only interface types, the direct base class is assumed to be `object`. A class inherits members from its direct base class, as described in Section 10.2.1.

In the example

```
class A {}
class B: A {}
```

class `A` is said to be the direct base class of `B`, and `B` is said to be derived from `A`. Since `A` does not explicitly specify a direct base class, its direct base class is implicitly `object`.

The direct base class of a class type must be at least as accessible as the class type itself (Section 3.5.4). For example, it is a compile-time error for a `public` class to derive from a `private` or `internal` class.

The direct base class of a class type must not be any of the following types: `System.Array`, `System.Delegate`, `System.Enum`, or `System.ValueType`.

The base classes of a class are the direct base class and its base classes. In other words, the set of base classes is the transitive closure of the direct base class relationship. Referring to the example above, the base classes of `B` are `A` and `object`.

Except for class `object`, every class has exactly one direct base class. The `object` class has no direct base class and is the ultimate base class of all other classes.

When a class `B` derives from a class `A`, it is a compile-time error for `A` to depend on `B`. A class *directly depends on* its direct base class (if any) and directly depends on the class within which it is immediately nested (if any). Given this definition, the complete set of classes upon which a class depends is the transitive closure of the *directly depends on* relationship.

The example

```
class A: B {}
class B: C {}
class C: A {}
```

is in error because the classes circularly depend on themselves. Likewise, the example

```
class A: B.C {}
class B: A
{
   public class C {}
}
```

results in a compile-time error because `A` depends on `B.C` (its direct base class), which depends on `B` (its immediately enclosing class), which circularly depends on `A`.

Note that a class does not depend on the classes that are nested within it. In the example

```
class A
{
   class B: A {}
}
```

`B` depends on `A` (because `A` is both its direct base class and its immediately enclosing class), but `A` does not depend on `B` (since `B` is neither a base class nor an enclosing class of `A`). Thus, the example is valid.

It is not possible to derive from a `sealed` class. In the example

```
sealed class A {}
class B: A {}         // Error, cannot derive from a sealed class
```

class `B` is in error because it attempts to derive from the `sealed` class `A`.

10.1.2.2 Interface implementations

A *class-base* specification may include a list of interface types, in which case the class is said to implement the given interface types. Interface implementations are discussed further in Section 13.4.

10.1.3 Class body

The *class-body* of a class defines the members of that class.

class-body:
  { *class-member-declarations*$_{opt}$ }

10.2 Class members

The members of a class consist of the members introduced by its *class-member-declaration*s and the members inherited from the direct base class.

class-member-declarations:
  class-member-declaration
  class-member-declarations class-member-declaration
class-member-declaration:
  constant-declaration
  field-declaration
  method-declaration
  property-declaration
  event-declaration
  indexer-declaration
  operator-declaration
  constructor-declaration
  destructor-declaration
  static-constructor-declaration
  type-declaration

The members of a class are divided into the following categories:

- Constants, which represent constant values associated with the class (Section 10.3).
- Fields, which are the variables of the class (Section 10.4).
- Methods, which implement the computations and actions that can be performed by the class (Section 10.5).
- Properties, which define named characteristics associated with reading and writing those characteristics (Section 10.6).
- Events, which define notifications that can be generated by the class (Section 10.7).
- Indexers, which permit instances of the class to be indexed in the same way (syntactically) as arrays (Section 10.8).
- Operators, which define the expression operators that can be applied to instances of the class (Section 10.9).
- Instance constructors, which implement the actions required to initialize instances of the class (Section 10.10)
- Destructors, which implement the actions to be performed before instances of the class are permanently discarded (Section 10.12).
- Static constructors, which implement the actions required to initialize the class itself (Section 10.11).
- Types, which represent the types that are local to the class (Section 9.5).

Members that can contain executable code are collectively known as the *function members* of the class 0. The function members of a class are the methods, properties, events, indexers, operators, instance constructors, destructors, and static constructors of that class.

A *class-declaration* creates a new declaration space (Section 3.3), and the *class-member-declarations* immediately contained by the *class-declaration* introduce new members into this declaration space. The following rules apply to *class-member-declarations*:

- Instance constructors, destructors and static constructors must have the same name as the immediately enclosing class. All other members must have names that differ from the name of the immediately enclosing class.
- The name of a constant, field, property, event, or type must differ from the names of all other members declared in the same class.
- The name of a method must differ from the names of all other non-methods declared in the same class. In addition, the signature (Section 3.6) of a method must differ from the signatures of all other methods declared in the same class.
- The signature of an instance constructor must differ from the signatures of all other instance constructors declared in the same class.
- The signature of an indexer must differ from the signatures of all other indexers declared in the same class.
- The signature of an operator must differ from the signatures of all other operators declared in the same class.

The inherited members of a class (Section 10.2.1) are not part of the declaration space of a class. Thus, a derived class is allowed to declare a member with the same name or signature as an inherited member (which in effect hides the inherited member).

10.2.1 Inheritance

A class inherits the members of its direct base class. Inheritance means that a class implicitly contains all members of its direct base class, except for the instance constructors, destructors and static constructors of the base class. Some important aspects of inheritance are:

- Inheritance is transitive. If `C` is derived from `B`, and `B` is derived from `A`, then `C` inherits the members declared in `B` as well as the members declared in `A`.
- A derived class *extends* its direct base class. A derived class can add new members to those it inherits, but it cannot remove the definition of an inherited member.
- Instance constructors, destructors, and static constructors are not inherited, but all other members are, regardless of their declared accessibility (Section 3.5). However, depending on their declared accessibility, inherited members might not be accessible in a derived class.
- A derived class can hide (Section 3.7.1.2) inherited members by declaring new members with the same name or signature. Note however that hiding an inherited member does not remove that member — it merely makes that member inaccessible directly through the derived class.
- An instance of a class contains a set of all instance fields declared in the class and its base classes, and an implicit conversion (Section 6.1.4) exists from a derived class type to any of its base class types. Thus, a reference to an instance of some derived class can be treated as a reference to an instance of any of its base classes.
- A class can declare virtual methods, properties, and indexers, and derived classes can override the implementation of these function members. This enables classes to exhibit polymorphic behavior wherein the actions performed by a function member invocation varies depending on the run-time type of the instance through which that function member is invoked.

10.2.2 The new modifier

A *class-member-declaration* is permitted to declare a member with the same name or signature as an inherited member. When this occurs, the derived class member is said to hide the base class member. Hiding an inherited member is not considered an error, but it does cause the compiler to issue a warning. To suppress the warning, the declaration of the derived class member can include a `new` modifier to indicate that the derived member is intended to hide the base member. This topic is discussed further in Section 3.7.1.2.

If a `new` modifier is included in a declaration that does not hide an inherited member, a warning to that effect is issued. This warning is suppressed by removing the `new` modifier.

10.2.3 Access modifiers

A *class-member-declaration* can have any one of the five possible kinds of declared accessibility (Section 3.5.1): `public`, `protected internal`, `protected`, `internal`, or `private`. Except for the `protected internal` combination, it is a compile-time error to specify more than one access modifier. When a *class-member-declaration* does not include any access modifiers, `private` is assumed.

10.2.4 Constituent types

Types that are used in the declaration of a member are called the constituent types of that member. Possible constituent types are the type of a constant, field, property, event, or indexer, the return type of a method or operator, and the parameter types of a method, indexer, operator, or instance constructor. The constituent types of a member must be at least as accessible as that member itself (Section 3.5.4).

10.2.5 Static and instance members

Members of a class are either static members or instance members. Generally speaking, it is useful to think of static members as belonging to classes and instance members as belonging to objects (instances of classes).

When a field, method, property, event, operator, or constructor declaration includes a `static` modifier, it declares a static member. In addition, a constant or type declaration implicitly declares a static member. Static members have the following characteristics:

- When a static member `M` is referenced in a *member-access* (Section 7.5.4) of the form `E.M`, `E` must denote a type containing `M`. It is a compile-time error for `E` to denote an instance.
- A static field identifies exactly one storage location. No matter how many instances of a class are created, there is only ever one copy of a static field.
- A static function member (method, property, event, operator, or constructor) does not operate on a specific instance, and it is a compile-time error to refer to `this` in such a function member.

When a field, method, property, event, indexer, constructor, or destructor declaration does not include a `static` modifier, it declares an instance member. (An instance member is sometimes called a non-static member.) Instance members have the following characteristics:

- When an instance member `M` is referenced in a *member-access* (Section 7.5.4) of the form `E.M`, `E` must denote an instance of a type containing `M`. It is a compile-time error for `E` to denote a type.
- Every instance of a class contains a separate set of all instance fields of the class.
- An instance function member (method, property, indexer, instance constructor, or destructor) operates on a given instance of the class, and this instance can be accessed as `this` (Section 7.5.7).

The following example illustrates the rules for accessing static and instance members:

```
class Test
{
   int x;
   static int y;
   void F() {
      x = 1;         // Ok, same as this.x = 1
      y = 1;         // Ok, same as Test.y = 1
   }
   static void G() {
      x = 1;         // Error, cannot access this.x
      y = 1;         // Ok, same as Test.y = 1
   }
   static void Main() {
      Test t = new Test();
      t.x = 1;         // Ok
      t.y = 1;         // Error, cannot access static member through instance
      Test.x = 1;      // Error, cannot access instance member through type
      Test.y = 1;      // Ok
   }
}
```

The `F` method shows that in an instance function member, a *simple-name* (Section 7.5.2) can be used to access both instance members and static members. The `G` method shows that in a static function member, it is a compile-time error to access an instance member through a *simple-name*. The `Main` method shows that in a *member-access* (Section 7.5.4), instance members must be accessed through instances, and static members must be accessed through types.

10.2.6 Nested types

A type declared within a class or struct is called a nested type. A type that is declared within a compilation unit or namespace is called a non-nested type.

In the example

```
using System;
class A
{
   class B
   {
      static void F() {
         Console.WriteLine("A.B.F");
      }
   }
}
```

class `B` is a nested type because it is declared within class `A`, and class `A` is a non-nested type because it is declared within a compilation unit.

10.2.6.1 Fully qualified name

The fully qualified name (Section 3.8.1) for a nested type is `S.N` where `S` is the fully qualified name of the type in which type `N` is declared.

10.2.6.2 Declared accessibility

Non-nested types can have `public` or `internal` declared accessibility and have `internal` declared accessibility by default. Nested types can have these forms of declared accessibility too, plus one or more additional forms of declared accessibility, depending on whether the containing type is a class or struct:

- A nested type that is declared in a class can have any of the five forms of declared accessibility (`public`, `protected internal`, `protected`, `internal`, or `private`) and, like other class members, defaults to `private` declared accessibility.
- A nested type that is declared in a struct can have any of three forms of declared accessibility (`public`, `internal`, or `private`) and, like other struct members, defaults to `private` declared accessibility.

The example

```
public class List
{
   // Private data structure
   private class Node
   {
      public object Data;
      public Node Next;
      public Node(object data, Node next) {
         this.Data = data;
         this.Next = next;
      }
   }
   private Node first = null;
   private Node last = null;
   // Public interface
   public void AddToFront(object o) {...}
   public void AddToBack(object o) {...}
   public object RemoveFromFront() {...}
   public object RemoveFromBack() {...}
   public int Count { get {...} }
}
```

declares a private nested class `Node`.

10.2.6.3 Hiding

A nested type may hide (Section 3.7.1) a base member. The `new` modifier is permitted on nested type declarations so that hiding can be expressed explicitly. The example

```
using System;
class Base
{
   public static void M() {
      Console.WriteLine("Base.M");
   }
}
class Derived: Base
{
   new public class M
   {
      public static void F() {
         Console.WriteLine("Derived.M.F");
      }
   }
}
class Test
{
   static void Main() {
      Derived.M.F();
   }
}
```

shows a nested class `M` that hides the method `M` defined in `Base`.

10.2.6.4 this access

A nested type and its containing type do not have a special relationship with regard to *this-access* (Section 7.5.7). Specifically, `this` within a nested type cannot be used to refer to instance members of the containing type. In cases where a nested type needs access to the instance members of its containing type, access can be provided by providing the `this` for the instance of the containing type as a constructor argument for the nested type. The following example

```
using System;
class C
{
   int i = 123;
   public void F() {
      Nested n = new Nested(this);
      n.G();
   }
   public class Nested {
      C this_c;
      public Nested(C c) {
         this_c = c;
      }
      public void G() {
         Console.WriteLine(this_c.i);
      }
   }
}
class Test {
   static void Main() {
      C c = new C();
      c.F();
   }
}
```

shows this technique. An instance of `C` creates an instance of `Nested` and passes its own this to `Nested`'s constructor in order to provide subsequent access to `C`'s instance members.

10.2.6.5 Access to private and protected members of the containing type

A nested type has access to all of the members that are accessible to its containing type, including members of the containing type that have `private` and `protected` declared accessibility. The example

```
using System;
class C
{
   private static void F() {
      Console.WriteLine("C.F");
   }
   public class Nested
   {
      public static void G() {
         F();
      }
   }
}
class Test
{
   static void Main() {
      C.Nested.G();
   }
}
```

shows a class `C` that contains a nested class `Nested`. Within `Nested`, the method `G` calls the static method `F` defined in `C`, and `F` has private declared accessibility.

A nested type also may access protected members defined in a base type of its containing type. In the example

```
using System;
class Base
{
   protected void F() {
      Console.WriteLine("Base.F");
   }
}
class Derived: Base
{
   public class Nested
   {
      public void G() {
         Derived d = new Derived();
         d.F();      // ok
      }
   }
}
class Test
{
   static void Main() {
      Derived.Nested n = new Derived.Nested();
      n.G();
   }
}
```

the nested class `Derived.Nested` accesses the protected method `F` defined in `Derived`'s base class, `Base`, by calling through an instance of `Derived`.

10.2.7 Reserved member names

To facilitate the underlying C# runtime implementation, for each source member declaration that is a property, event, or indexer, the implementation must reserve two method signatures based on the kind of the member declaration, its name, and its type. It is a compile-time error for a program to declare a member whose signature matches one of these reserved signatures, even if the underlying runtime implementation does not make use of these reservations.

The reserved names do not introduce declarations, thus they do not participate in member lookup. However, a declaration's associated reserved method signatures do participate in inheritance (Section 10.2.1), and can be hidden with the new modifier (Section 10.2.2).

The reservation of these names serves three purposes:

- To allow the underlying implementation to use an ordinary identifier as a method name for get or set access to the C# language feature.
- To allow other languages to interoperate using an ordinary identifier as a method name for get or set access to the C# language feature.
- To help ensure that the source accepted by one conforming compiler is accepted by another, by making the specifics of reserved member names consistent across all C# implementations.

The declaration of a destructor (Section 10.12) also causes a signature to be reserved (Section 10.2.7.4).

10.2.7.1 Member names reserved for properties

For a property `P` (Section 10.6) of type `T`, the following signatures are reserved:

```
T get_P();
void set_P(T value);
```

Both signatures are reserved, even if the property is read-only or write-only.

In the example

```
using System;
class A
{
   public int P {
      get { return 123; }
   }
}
class B: A
{
   new public int get_P() {
      return 456;
   }
   new public void set_P(int value) {
   }
}
class Test
{
   static void Main() {
      B b = new B();
      A a = b;
      Console.WriteLine(a.P);
      Console.WriteLine(b.P);
      Console.WriteLine(b.get_P());
   }
}
```

a class `A` defines a read-only property `P`, thus reserving signatures for `get_P` and `set_P` methods. A class `B` derives from `A` and hides both of these reserved signatures. The example produces the output:

```
123
123
456
```

10.2.7.2 Member names reserved for events

For an event `E` (Section 10.7) of delegate type `T`, the following signatures are reserved:

```
void add_E(T handler);
void remove_E(T handler);
```

10.2.7.3 Member names reserved for indexers

For an indexer (Section 10.8) of type `T` with parameter-list `L`, the following signatures are reserved:

```
T get_Item(L);
void set_Item(L, T value);
```

Both signatures are reserved, even if the indexer is read-only or write-only.

10.2.7.4 Member names reserved for destructors

For a class containing a destructor (Section 10.12), the following signature is reserved:

```
void Finalize();
```

10.3 Constants

A constant is a class member that represents a constant value: a value that can be computed at compile-time. A *constant-declaration* introduces one or more constants of a given type.

constant-declaration:
  attributes$_{opt}$ *constant-modifiers*$_{opt}$ const *type* *constant-declarators* ;
constant-modifiers:
  constant-modifier
  constant-modifiers *constant-modifier*
constant-modifier:
  new
  public
  protected
  internal
  private
constant-declarators:
  constant-declarator
  constant-declarators , *constant-declarator*
constant-declarator:
  identifier = *constant-expression*

A *constant-declaration* may include a set of *attributes* (Section 17), a `new` modifier (Section 10.2.2), and a valid combination of the four access modifiers (Section 10.2.3). The attributes and modifiers apply to all of the members declared by the *constant-declaration*. Even though constants are considered static members, a *constant-declaration* neither requires nor allows a `static` modifier. It is an error for the same modifier to appear multiple times in a constant declaration.

The *type* of a *constant-declaration* specifies the type of the members introduced by the declaration. The type is followed by a list of *constant-declarator*s, each of which introduces a new member. A *constant-declarator* consists of an *identifier* that names the member, followed by an "=" token, followed by a *constant-expression* (Section 7.15) that gives the value of the member.

The *type* specified in a constant declaration must be `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `string`, an *enum-type*, or a *reference-type*. Each *constant-expression* must yield a value of the target type or of a type that can be converted to the target type by an implicit conversion (Section 6.1).

The *type* of a constant must be at least as accessible as the constant itself (Section 3.5.4).

The value of a constant is obtained in an expression using a *simple-name* (Section 7.5.2) or a *member-access* (Section 7.5.4).

A constant can itself participate in a *constant-expression*. Thus, a constant may be used in any construct that requires a *constant-expression*. Examples of such constructs include `case` labels, `goto case` statements, `enum` member declarations, attributes, and other constant declarations.

As described in Section 7.15, a *constant-expression* is an expression that can be fully evaluated at compile-time. Since the only way to create a non-null value of a *reference-type* other than `string` is to apply the `new` operator, and since the `new` operator is not permitted in a *constant-expression*, the only possible value for constants of *reference-types* other than `string` is `null`.

When a symbolic name for a constant value is desired, but when the type of that value is not permitted in a constant declaration, or when the value cannot be computed at compile-time by a *constant-expression*, a `readonly` field (Section 10.4.2) may be used instead.

A constant declaration that declares multiple constants is equivalent to multiple declarations of single constants with the same attributes, modifiers, and type. For example

```
class A
{
   public const double X = 1.0, Y = 2.0, Z = 3.0;
}
```

is equivalent to

```
class A
{
   public const double X = 1.0;
   public const double Y = 2.0;
```

```
   public const double Z = 3.0;
}
```

Constants are permitted to depend on other constants within the same program as long as the dependencies are not of a circular nature. The compiler automatically arranges to evaluate the constant declarations in the appropriate order. In the example

```
class A
{
   public const int X = B.Z + 1;
   public const int Y = 10;
}
class B
{
   public const int Z = A.Y + 1;
}
```

the compiler first evaluates `A.Y`, then evaluates `B.Z`, and finally evaluates `A.X`, producing the values `10`, `11`, and `12`. Constant declarations may depend on constants from other programs, but such dependencies are only possible in one direction. Referring to the example above, if `A` and `B` were declared in separate programs, it would be possible for `A.X` to depend on `B.Z`, but `B.Z` could then not simultaneously depend on `A.Y`.

10.4 Fields

A field is a member that represents a variable associated with an object or class. A *field-declaration* introduces one or more fields of a given type.

field-declaration:
  attributes$_{opt}$ *field-modifiers*$_{opt}$ *type* *variable-declarators* ;
field-modifiers:
  field-modifier
  field-modifiers *field-modifier*
field-modifier:
  new
  public
  protected
  internal
  private
  static
  readonly
  volatile
variable-declarators:
  variable-declarator
  variable-declarators , *variable-declarator*
variable-declarator:
  identifier
  identifier = *variable-initializer*
variable-initializer:
  expression
  array-initializer

A *field-declaration* may include a set of *attributes* (Section 17), a `new` modifier (Section 10.2.2), a valid combination of the four access modifiers (Section 10.2.3), and a `static` modifier (Section 10.4.1). In addition, a *field-declaration* may include a `readonly` modifier (Section 10.4.2) or a `volatile` modifier (Section 10.4.3) but not both. The attributes and modifiers apply to all of the members declared by the *field-declaration*. It is an error for the same modifier to appear multiple times in a field declaration.

The *type* of a *field-declaration* specifies the type of the members introduced by the declaration. The type is followed by a list of *variable-declarators*, each of which introduces a new member. A *variable-declarator* consists of an *identifier* that names that member, optionally followed by an "=" token and a *variable-initializer* (Section 10.4.5) that gives the initial value of that member.

The *type* of a field must be at least as accessible as the field itself (Section 3.5.4).

The value of a field is obtained in an expression using a *simple-name* (Section 7.5.2) or a *member-access* (Section 7.5.4). The value of a non-readonly field is modified using an *assignment* (Section 7.13). The value of a non-readonly field can be both obtained and modified using postfix increment and decrement operators (Section 7.5.9) and prefix increment and decrement operators (Section 7.6.5).

A field declaration that declares multiple fields is equivalent to multiple declarations of single fields with the same attributes, modifiers, and type. For example

```
class A
{
   public static int X = 1, Y, Z = 100;
}
```

is equivalent to

```
class A
{
   public static int X = 1;
   public static int Y;
   public static int Z = 100;
}
```

10.4.1 Static and instance fields

When a *field declaration* includes a `static` modifier, the fields introduced by the declaration are static fields. When no `static` modifier is present, the fields introduced by the declaration are *instance fields*. Static fields and instance fields are two of the several kinds of variables (Section 5) supported by C#, and at times they are referred to as static variables and instance variables, respectively.

A static field is not part of a specific instance; instead, it identifies exactly one storage location. No matter how many instances of a class are created, there is only ever one copy of a static field for the associated application domain.

An instance field belongs to an instance. Specifically, every instance of a class contains a separate set of all the instance fields of that class.

When a field is referenced in a *member-access* (Section 7.5.4) of the form `E.M`, if `M` is a static field, `E` must denote a type containing `M`, and if `M` is an instance field, E must denote an instance of a type containing `M`.

The differences between static and instance members are discussed further in Section 10.2.5.

10.4.2 Readonly fields

When a *field-declaration* includes a `readonly` modifier, the fields introduced by the declaration are readonly fields. Direct assignments to readonly fields can only occur as part of that declaration or in an instance constructor or static constructor in the same class. (A readonly field can be assigned to multiple times in these contexts.) Specifically, direct assignments to a `readonly` field are permitted only in the following contexts:

- In the *variable-declarator* that introduces the field (by including a *variable-initializer* in the declaration).
- For an instance field, in the instance constructors of the class that contains the field declaration; for a static field, in the static constructor of the class that contains the field declaration. These are also the only contexts in which it is valid to pass a `readonly` field as an `out` or `ref` parameter.

Attempting to assign to a `readonly` field or pass it as an `out` or `ref` parameter in any other context is a compile-time error.

10.4.2.1 Using static readonly fields for constants

A `static readonly` field is useful when a symbolic name for a constant value is desired, but when the type of the value is not permitted in a `const` declaration, or when the value cannot be computed at compile-time. In the example

```
public class Color
{
   public static readonly Color Black = new Color(0, 0, 0);
   public static readonly Color White = new Color(255, 255, 255);
   public static readonly Color Red = new Color(255, 0, 0);
   public static readonly Color Green = new Color(0, 255, 0);
   public static readonly Color Blue = new Color(0, 0, 255);
   private byte red, green, blue;
   public Color(byte r, byte g, byte b) {
      red = r;
      green = g;
      blue = b;
   }
}
```

the `Black`, `White`, `Red`, `Green`, and `Blue` members cannot be declared as `const` members because their values cannot be computed at compile-time. However, declaring them `static readonly` instead has much the same effect.

10.4.2.2 Versioning of constants and static readonly fields

Constants and readonly fields have different binary versioning semantics. When an expression references a constant, the value of the constant is obtained at compile-time, but when an expression references a readonly field, the value of the field is not obtained until run-time. Consider an application that consists of two separate programs:

```
using System;
namespace Program1
{
   public class Utils
   {
      public static readonly int X = 1;
   }
}
namespace Program2
{
   class Test
   {
      static void Main() {
         Console.WriteLine(Program1.Utils.X);
      }
   }
}
```

The `Program1` and `Program2` namespaces denote two programs that are compiled separately. Because `Program1.Utils.X` is declared as a static readonly field, the value output by the `Console.WriteLine` statement is not known at compile-time, but rather is obtained at run-time. Thus, if the value of `X` is changed and `Program1` is recompiled, the `Console.WriteLine` statement will output the new value even if `Program2` is not recompiled. However, had `X` been a constant, the value of `X` would have been obtained at the time `Program2` was compiled, and would remain unaffected by changes in `Program1` until `Program2` is recompiled.

10.4.3 Volatile fields

When a *field-declaration* includes a `volatile` modifier, the fields introduced by that declaration are volatile fields.

For non-volatile fields, optimization techniques that reorder instructions can lead to unexpected and unpredictable results in multi-threaded programs that access fields without synchronization such as that provided by the *lock-statement* (Section 8.12). These optimizations can be performed by the compiler, by the runtime system, or by hardware. For volatile fields, such reordering optimizations are restricted:

- A read of a volatile field is called a volatile read. A volatile read has "acquire semantics"; that is, it is guaranteed to occur prior to any references to memory that occur after it in the instruction sequence.
- A write of a volatile field is called a volatile write. A volatile write has "release semantics"; that is, it is guaranteed to happen after any memory references prior to the write instruction in the instruction sequence.

These restrictions ensure that all threads will observe volatile writes performed by any other thread in the order in which they were performed. A conforming implementation is not required to provide a single total ordering of volatile writes as seen from all threads of execution. The type of a volatile field must be one of the following:

- A *reference-type*.
- The type `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `char`, `float`, or `bool`.
- An *enum-type* having an enum base type of `byte`, `sbyte`, `short`, `ushort`, `int`, or `uint`.

The example

```
using System;
using System.Threading;
class Test
{
   public static int result;
   public static volatile bool finished;
   static void Thread2() {
      result = 143;
      finished = true;
   }
   static void Main() {
      finished = false;
      // Run Thread2() in a new thread
      new Thread(new ThreadStart(Thread2)).Start();
      // Wait for Thread2 to signal that it has a result by setting
      // finished to true.
      for (;;) {
         if (finished) {
            Console.WriteLine("result = {0}", result);
            return;
         }
      }
   }
}
```

produces the output:

```
result = 143
```

In this example, the method `Main` starts a new thread running the method `Thread2`. This method stores a value into a non-volatile field called `result`, then stores `true` in the volatile field `finished`. The main thread waits for the field `finished` to be set to `true`, then reads the field `result`. Since `finished` has been declared `volatile`, the main thread must read the value `143` from the field `result`. If the field `finished` had not been declared `volatile`, then it would be permissible for the store to `result` to be visible to the main thread *after* the store to `finished`, and hence for the main thread to read the value `0` from the field `result`. Declaring `finished` as a `volatile` field prevents any such inconsistency.

10.4.4 Field initialization

The initial value of a field, whether it be a static field or an instance field, is the default value (Section 5.2) of the field's type. It is not possible to observe the value of a field before this default initialization has occurred, and a field is thus never "uninitialized". The example

```
using System;
class Test
{
   static bool b;
   int i;
   static void Main() {
      Test t = new Test();
      Console.WriteLine("b = {0}, i = {1}", b, t.i);
   }
}
```

produces the output

```
b = False, i = 0
```

because `b` and `i` are both automatically initialized to default values.

10.4.5 Variable initializers

Field declarations may include *variable-initializer*s. For static fields, variable initializers correspond to assignment statements that are executed during class initialization. For instance fields, variable initializers correspond to assignment statements that are executed when an instance of the class is created.

The example

```
using System;
class Test
{
   static double x = Math.Sqrt(2.0);
   int i = 100;
   string s = "Hello";
   static void Main() {
      Test a = new Test();
      Console.WriteLine("x = {0}, i = {1}, s = {2}", x, a.i, a.s);
   }
}
```

produces the output

```
x = 1.4142135623731, i = 100, s = Hello
```

because an assignment to `x` occurs when static field initializers execute and assignments to `i` and `s` occur when the instance field initializers execute.

The default value initialization described in Section 10.4.4 occurs for all fields, including fields that have variable initializers. Thus, when a class is initialized, all static fields in that class are first initialized to their default values, and then the static field initializers are executed in textual order. Likewise, when an instance of a class is created, all instance fields in that instance are first initialized to their default values, and then the instance field initializers are executed in textual order.

It is possible for static fields with variable initializers to be observed in their default value state. However, this is strongly discouraged as a matter of style. The example

```
using System;
class Test
{
   static int a = b + 1;
   static int b = a + 1;
   static void Main() {
      Console.WriteLine("a = {0}, b = {1}", a, b);
   }
}
```

exhibits this behavior. Despite the circular definitions of a and b, the program is valid. It results in the output

```
a = 1, b = 2
```

because the static fields `a` and `b` are initialized to `0` (the default value for `int`) before their initializers are executed. When the initializer for `a` runs, the value of `b` is zero, and so `a` is initialized to `1`. When the initializer for `b` runs, the value of `a` is already `1`, and so `b` is initialized to `2`.

10.4.5.1 Static field initialization

The static field variable initializers of a class correspond to a sequence of assignments that are executed in the textual order in which they appear in the class declaration. If a static constructor (Section 10.11) exists in the class, execution of the static field initializers occurs immediately prior to executing that static constructor. Otherwise, the static field initializers are executed at an implementation-dependent time prior to the first use of a static field of that class. The example

```
using System;
class Test
{
   static void Main() {
      Console.WriteLine("{0} {1}", B.Y, A.X);
   }
   public static int F(string s) {
      Console.WriteLine(s);
      return 1;
   }
}
class A
{
   public static int X = Test.F("Init A");
}
class B
{
   public static int Y = Test.F("Init B");
}
```

might produce either the output:

```
Init A
Init B
1 1
```

or the output:

```
Init B
Init A
1 1
```

because the execution of `X`'s initializer and `Y`'s initializer could occur in either order; they are only constrained to occur before the references to those fields. However, in the example:

```
using System;
class Test
{
   static void Main() {
      Console.WriteLine("{0} {1}", B.Y, A.X);
   }
   public static int F(string s) {
      Console.WriteLine(s);
      return 1;
   }
}
class A
{
   static A() {}
   public static int X = Test.F("Init A");
}
class B
{
   static B() {}
   public static int Y = Test.F("Init B");
}
```

the output must be:

```
Init B
Init A
1 1
```

because the rules for when static constructors execute (as defined in Section 10.11) provide that `B`'s static constructor (and hence `B`'s static field initializers) must run before `A`'s static constructor and field initializers.

10.4.5.2 Instance field initialization

The instance field variable initializers of a class correspond to a sequence of assignments that are executed immediately upon entry to any one of the instance constructors (Section 10.10.1) of that class. The variable initializers are executed in the textual order in which they appear in the class declaration. The class instance creation and initialization process is described further in Section 10.10.

A variable initializer for an instance field cannot reference the instance being created. Thus, it is a compile-time error to reference `this` in a variable initializer, as it is a compile-time error for a variable initializer to reference any instance member through a *simple-name*. In the example

```
class A
{
   int x = 1;
   int y = x + 1;      // Error, reference to instance member of this
}
```

the variable initializer for `y` results in a compile-time error because it references a member of the instance being created.

10.5 Methods

A method is a member that implements a computation or action that can be performed by an object or class. Methods are declared using *method-declarations*:

method-declaration:
  method-header *method-body*
method-header:
  attributes$_{opt}$ *method-modifiers*$_{opt}$ *return-type* *member-name* (*formal-parameter-list*$_{opt}$)
method-modifiers:
  method-modifier
  method-modifiers *method-modifier*
method-modifier:
  new
  public
  protected
  internal
  private
  static
  virtual
  sealed
  override
  abstract
  extern
return-type:
  type
  void
member-name:
  identifier
  interface-type . *identifier*
method-body:
  block
  ;

A *method-declaration* may include a set of *attributes* (Section 17) and a valid combination of the four access modifiers (Section 10.2.3), the `new` (Section 10.2.2), `static` (Section 10.5.2), `virtual` (Section 10.5.3), `override` (Section 10.5.4), `sealed` (Section 10.5.5), `abstract` (Section 10.5.6), and `extern` (Section 10.5.7) modifiers.

A declaration has a valid combination of modifiers if all of the following are true:

- The declaration includes a valid combination of access modifiers (Section 10.2.3).
- The declaration does not include the same modifier multiple times.
- The declaration includes at most one of the following modifiers: `static`, `virtual`, and `override`.
- The declaration includes at most one of the following modifiers: `new` and `override`.
- If the declaration includes the `abstract` modifier, then the declaration does not include any of the following modifiers: `static`, `virtual`, `sealed`, or `extern`.
- If the declaration includes the `private` modifier, then the declaration does not include any of the following modifiers: `virtual`, `override`, or `abstract`.
- If the declaration includes the `sealed` modifier, then the declaration also includes the `override` modifier.

The *return-type* of a method declaration specifies the type of the value computed and returned by the method. The *return-type* is `void` if the method does not return a value.

The *member-name* specifies the name of the method. Unless the method is an explicit interface member implementation (Section 13.4.1), the *member-name* is simply an *identifier*. For an explicit interface member implementation, the *member-name* consists of an *interface-type* followed by a "`.`" and an *identifier*.

The optional *formal-parameter-list* specifies the parameters of the method (Section 10.5.1).

The *return-type* and each of the types referenced in the *formal-parameter-list* of a method must be at least as accessible as the method itself (Section 3.5.4).

For `abstract` and `extern` methods, the *method-body* consists simply of a semicolon. For all other methods, the *method-body* consists of a *block*, which specifies the statements to execute when the method is invoked.

The name and the formal parameter list of a method define the signature (Section 3.6) of the method. Specifically, the signature of a method consists of its name and the number, modifiers, and types of its formal parameters. The return type is not part of a method's signature, nor are the names of the formal parameters.

The name of a method must differ from the names of all other non-methods declared in the same class. In addition, the signature of a method must differ from the signatures of all other methods declared in the same class.

10.5.1 Method parameters

The parameters of a method, if any, are declared by the method's *formal-parameter-list*.

formal-parameter-list:
  fixed-parameters
  fixed-parameters , *parameter-array*
  parameter-array
fixed-parameters:
  fixed-parameter
  fixed-parameters , *fixed-parameter*
fixed-parameter:
  attributes$_{opt}$ *parameter-modifier*$_{opt}$ *type* *identifier*
parameter-modifier:
  ref
  out
parameter-array:
  attributes$_{opt}$ params *array-type* *identifier*

The formal parameter list consists of one or more comma-separated parameters of which only the last may be a *parameter-array*.

A *fixed-parameter* consists of an optional set of *attributes* (Section 17), an optional `ref` or `out` modifier, a *type*, and an *identifier*. Each *fixed-parameter* declares a parameter of the given type with the given name.

A *parameter-array* consists of an optional set of *attributes* (Section 17), a `params` modifier, an *array-type*, and an *identifier*. A parameter array declares a single parameter of the given array type with the given name. The *array-type* of a parameter array must be a single-dimensional array type (Section 12.1). In a method invocation, a parameter array permits either a single argument of the given array type to be specified, or it permits zero or more arguments of the array element type to be specified. Parameter arrays are further described in Section 10.5.1.4.

A method declaration creates a separate declaration space for parameters and local variables. Names are introduced into this declaration space by the formal parameter list of the method and by local variable declarations in the *block* of the method. All names in the declaration space of a method must be unique. Thus, it is a compile-time error for a parameter or local variable to have the same name as another parameter or local variable.

A method invocation (Section 7.5.5.1) creates a copy, specific to that invocation, of the formal parameters and local variables of the method, and the argument list of the invocation assigns values or variable references to the newly created formal parameters. Within the *block* of a method, formal parameters can be referenced by their identifiers in *simple-name* expressions (Section 7.5.2).

There are four kinds of formal parameters:

- Value parameters, which are declared without any modifiers.
- Reference parameters, which are declared with the `ref` modifier.
- Output parameters, which are declared with the `out` modifier.
- Parameter arrays, which are declared with the `params` modifier.

As described in Section 3.6, the `ref` and `out` modifiers are part of a method's signature, but the `params` modifier is not.

10.5.1.1 Value parameters

A parameter declared with no modifiers is a value parameter. A value parameter corresponds to a local variable that gets its initial value from the corresponding argument supplied in the method invocation.

When a formal parameter is a value parameter, the corresponding argument in a method invocation must be an expression of a type that is implicitly convertible (Section 6.1) to the formal parameter type.

A method is permitted to assign new values to a value parameter. Such assignments only affect the local storage location represented by the value parameter — they have no effect on the actual argument given in the method invocation.

10.5.1.2 Reference parameters

A parameter declared with a `ref` modifier is a reference parameter. Unlike a value parameter, a reference parameter does not create a new storage location. Instead, a reference parameter represents the same storage location as the variable given as the argument in the method invocation.

When a formal parameter is a reference parameter, the corresponding argument in a method invocation must consist of the keyword `ref` followed by a *variable-reference* (Section 5.4) of the same type as the formal parameter. A variable must be definitely assigned before it can be passed as a reference parameter.

Within a method, a reference parameter is always considered definitely assigned.

The example

```
using System;
class Test
{
   static void Swap(ref int x, ref int y) {
      int temp = x;
      x = y;
      y = temp;
   }
   static void Main() {
      int i = 1, j = 2;
      Swap(ref i, ref j);
      Console.WriteLine("i = {0}, j = {1}", i, j);
   }
}
```

produces the output

```
i = 2, j = 1
```

For the invocation of `Swap` in `Main`, `x` represents `i` and `y` represents `j`. Thus, the invocation has the effect of swapping the values of `i` and `j`.

In a method that takes reference parameters it is possible for multiple names to represent the same storage location. In the example

```
class A
{
   string s;
   void F(ref string a, ref string b) {
      s = "One";
      a = "Two";
      b = "Three";
   }
   void G() {
      F(ref s, ref s);
   }
}
```

the invocation of `F` in `G` passes a reference to `s` for both `a` and `b`. Thus, for that invocation, the names `s`, `a`, and `b` all refer to the same storage location, and the three assignments all modify the instance field `s`.

10.5.1.3 Output parameters

A parameter declared with an `out` modifier is an output parameter. Similar to a reference parameter, an output parameter does not create a new storage location. Instead, an output parameter represents the same storage location as the variable given as the argument in the method invocation.

When a formal parameter is an output parameter, the corresponding argument in a method invocation must consist of the keyword `out` followed by a *variable-reference* (Section 5.4) of the same type as the formal parameter. A variable need not be definitely assigned before it can be passed as an output parameter, but following an invocation where a variable was passed as an output parameter, the variable is considered definitely assigned.

Within a method, just like a local variable, an output parameter is initially considered unassigned and must be definitely assigned before its value is used.

Every output parameter of a method must be definitely assigned before the method returns.

Output parameters are typically used in methods that produce multiple return values. For example:

```
using System;
class Test
{
   static void SplitPath(string path, out string dir, out string name) {
      int i = path.Length;
      while (i > 0) {
         char ch = path[i - 1];
         if (ch == '\\' || ch == '/' || ch == ':') break;
         i--;
      }
      dir = path.Substring(0, i);
      name = path.Substring(i);
   }
   static void Main() {
      string dir, name;
      SplitPath("c:\\Windows\\System\\hello.txt", out dir, out name);
      Console.WriteLine(dir);
      Console.WriteLine(name);
   }
}
```

The example produces the output:

```
c:\Windows\System\
hello.txt
```

Note that the `dir` and `name` variables can be unassigned before they are passed to `SplitPath`, and that they are considered definitely assigned following the call.

10.5.1.4 Parameter arrays

A parameter declared with a `params` modifier is a parameter array. If a formal parameter list includes a parameter array, it must be the last parameter in the list and it must be of a single-dimensional array type. For example, the types `string[]` and `string[][]` can be used as the type of a parameter array, but the type `string[,]` cannot. It is not possible to combine the `params` modifier with the modifiers `ref` and `out`.

A parameter array permits arguments to be specified in one of two ways in a method invocation:

- The argument given for a parameter array can be a single expression of a type that is implicitly convertible (Section 6.1) to the parameter array type. In this case, the parameter array acts precisely like a value parameter.
- Alternatively, the invocation can specify zero or more arguments for the parameter array, where each argument is an expression of a type that is implicitly convertible (Section 6.1) to the element type of the parameter array. In this case, the invocation creates an instance of the parameter array type with a length corresponding to the number of arguments, initializes the elements of the array instance with the given argument values, and uses the newly created array instance as the actual argument.

Except for allowing a variable number of arguments in an invocation, a parameter array is precisely equivalent to a value parameter (Section 10.5.1.1) of the same type.

The example

```
using System;
class Test
{
   static void F(params int[] args) {
      Console.Write("Array contains {0} elements:", args.Length);
      foreach (int i in args)
         Console.Write(" {0}", i);
      Console.WriteLine();
   }
   static void Main() {
      int[] arr = {1, 2, 3};
      F(arr);
      F(10, 20, 30, 40);
      F();
   }
}
```

produces the output

```
Array contains 3 elements: 1 2 3
Array contains 4 elements: 10 20 30 40
Array contains 0 elements:
```

The first invocation of `F` simply passes the array `a` as a value parameter. The second invocation of `F` automatically creates a four-element `int[]` with the given element values and passes that array instance as a value parameter. Likewise, the third invocation of `F` creates a zero-element `int[]` and passes that instance as a value parameter. The second and third invocations are precisely equivalent to writing:

```
F(new int[] {10, 20, 30, 40});
F(new int[] {});
```

When performing overload resolution, a method with a parameter array may be applicable either in its normal form or in its expanded form (Section 7.4.2.1). The expanded form of a method is available only if the normal form of the method is not applicable and only if a method with the same signature as the expanded form is not already declared in the same type.

The example

```
using System;
class Test
{
```

```
   static void F(params object[] a) {
      Console.WriteLine("F(object[])");
   }
   static void F() {
      Console.WriteLine("F()");
   }
   static void F(object a0, object a1) {
      Console.WriteLine("F(object,object)");
   }
   static void Main() {
      F();
      F(1);
      F(1, 2);
      F(1, 2, 3);
      F(1, 2, 3, 4);
   }
}
```

produces the output

```
F();
F(object[]);
F(object,object);
F(object[]);
F(object[]);
```

In the example, two of the possible expanded forms of the method with a parameter array are already included in the class as regular methods. These expanded forms are therefore not considered when performing overload resolution, and the first and third method invocations thus select the regular methods. When a class declares a method with a parameter array, it is not uncommon to also include some of the expanded forms as regular methods. By doing so it is possible to avoid the allocation of an array instance that occurs when an expanded form of a method with a parameter array is invoked.

When the type of a parameter array is `object[]`, a potential ambiguity arises between the normal form of the method and the expended form for a single `object` parameter. The reason for the ambiguity is that an `object[]` is itself implicitly convertible to type `object`. The ambiguity presents no problem, however, since it can be resolved by inserting a cast if needed.

The example

```
using System;
class Test
{
   static void F(params object[] args) {
      foreach (object o in args) {
         Console.Write(o.GetType().FullName);
         Console.Write(" ");
      }
      Console.WriteLine();
   }
   static void Main() {
      object[] a = {1, "Hello", 123.456};
      object o = a;
      F(a);
      F((object)a);
      F(o);
      F((object[])o);
   }
}
```

produces the output

```
System.Int32 System.String System.Double
System.Object[]
System.Object[]
System.Int32 System.String System.Double
```

In the first and last invocations of `F`, the normal form of `F` is applicable because an implicit conversion exists from the argument type to the parameter type (both are of type `object[]`). Thus, overload resolution selects the normal form of `F`, and the argument is passed as a regular value parameter. In the second and third invocations, the normal form of `F` is not applicable because no implicit conversion exists from the argument type to the parameter type (type `object` cannot be implicitly converted to type `object[]`). However, the expanded form of `F` is applicable, so it is selected by overload resolution. As a result, a one-element `object[]` is created by the invocation, and the single element of the array is initialized with the given argument value (which itself is a reference to an `object[]`).

10.5.2 Static and instance methods

When a method declaration includes a `static` modifier, that method is said to be a static method. When no `static` modifier is present, the method is said to be an instance method.

A static method does not operate on a specific instance, and it is a compile-time error to refer to `this` in a static method.

An instance method operates on a given instance of a class, and that instance can be accessed as `this` (Section 7.5.7).

When a method is referenced in a *member-access* (Section 7.5.4) of the form `E.M`, if `M` is a static method, `E` must denote a type containing `M`, and if `M` is an instance method, `E` must denote an instance of a type containing `M`.

The differences between static and instance members are discussed further in Section 10.2.5.

10.5.3 Virtual methods

When an instance method declaration includes a `virtual` modifier, that method is said to be a virtual method. When no `virtual` modifier is present, the method is said to be a non-virtual method.

The implementation of a non-virtual method is invariant: The implementation is the same whether the method is invoked on an instance of the class in which it is declared or an instance of a derived class. In contrast, the implementation of a virtual method can be superseded by derived classes. The process of superseding the implementation of an inherited virtual method is known as overriding that method (Section 10.5.4).

In a virtual method invocation, the run-time type of the instance for which that invocation takes place determines the actual method implementation to invoke. In a non-virtual method invocation, the compile-time type of the instance is the determining factor. In precise terms, when a method named `N` is invoked with an argument list `A` on an instance with a compile-time type `C` and a run-time type `R` (where `R` is either `C` or a class derived from `C`), the invocation is processed as follows:

- First, overload resolution is applied to `C`, `N`, and `A`, to select a specific method `M` from the set of methods declared in and inherited by `C`. This is described in Section 7.5.5.1.
- Then, if `M` is a non-virtual method, `M` is invoked.
- Otherwise, `M` is a virtual method, and the most derived implementation of `M` with respect to `R` is invoked.

For every virtual method declared in or inherited by a class, there exists a most derived implementation of the method with respect to that class. The most derived implementation of a virtual method `M` with respect to a class `R` is determined as follows:

- If `R` contains the introducing `virtual` declaration of `M`, then this is the most derived implementation of `M`.
- Otherwise, if `R` contains an `override` of `M`, then this is the most derived implementation of `M`.
- Otherwise, the most derived implementation of `M` with respect to `R` is the same as the most derived implementation of `M` with respect to the direct base class of `R`.

The following example illustrates the differences between virtual and non-virtual methods:

```
using System;
class A
{
   public void F() { Console.WriteLine("A.F"); }
   public virtual void G() { Console.WriteLine("A.G"); }
}
class B: A
{
   new public void F() { Console.WriteLine("B.F"); }
   public override void G() { Console.WriteLine("B.G"); }
}
class Test
{
   static void Main() {
      B b = new B();
      A a = b;
      a.F();
      b.F();
      a.G();
      b.G();
   }
}
```

In the example, `A` introduces a non-virtual method `F` and a virtual method `G`. The class `B` introduces a *new* non-virtual method `F`, thus *hiding* the inherited `F`, and also *overrides* the inherited method `G`. The example produces the output:

```
A.F
B.F
B.G
B.G
```

Notice that the statement `a.G()` invokes `B.G`, not `A.G`. This is because the run-time type of the instance (which is `B`), not the

compile-time type of the instance (which is `A`), determines the actual method implementation to invoke.

Because methods are allowed to hide inherited methods, it is possible for a class to contain several virtual methods with the same signature. This does not present an ambiguity problem, since all but the most derived method are hidden. In the example

```
using System;
class A
{
   public virtual void F() { Console.WriteLine("A.F"); }
}
class B: A
{
   public override void F() { Console.WriteLine("B.F"); }
}
class C: B
{
   new public virtual void F() { Console.WriteLine("C.F"); }
}
class D: C
{
   public override void F() { Console.WriteLine("D.F"); }
}
class Test
{
   static void Main() {
      D d = new D();
      A a = d;
      B b = d;
      C c = d;
      a.F();
      b.F();
      c.F();
      d.F();
   }
}
```

the `C` and `D` classes contain two virtual methods with the same signature: The one introduced by `A` and the one introduced by `C`. The method introduced by `C` hides the method inherited from `A`. Thus, the override declaration in `D` overrides the method introduced by `C`, and it is not possible for `D` to override the method introduced by `A`. The example produces the output:

```
B.F
B.F
D.F
D.F
```

Note that it is possible to invoke the hidden virtual method by accessing an instance of `D` through a less derived type in which the method is not hidden.

10.5.4 Override methods

When an instance method declaration includes an `override` modifier, the method is said to be an override method. An override method overrides an inherited virtual method with the same signature. Whereas a virtual method declaration *introduces* a new method, an override method declaration *specializes* an existing inherited virtual method by providing a new implementation of that method.

The method overridden by an `override` declaration is known as the overridden base method. For an override method `M` declared in a class `C`, the overridden base method is determined by examining each base class of `C`, starting with the direct base class of `C` and continuing with each successive direct base class, until an accessible method with the same signature as `M` is located. For the purposes of locating the overridden base method, a method is considered accessible if it is `public`, if it is `protected`, if it is `protected internal`, or if it is `internal` and declared in the same program as `C`.

A compile-time error occurs unless all of the following are true for an override declaration:

- An overridden base method can be located as described above.
- The overridden base method is a virtual, abstract, or override method. In other words, the overridden base method cannot be static or non-virtual.
- The overridden base method is not a sealed method.
- The override declaration and the overridden base method have the same return type.
- The override declaration and the overridden base method have the same declared accessibility. In other words, an override declaration cannot change the accessibility of the virtual method.

An override declaration can access the overridden base method using a *base-access* (Section 7.5.8). In the example

```
class A
{
   int x;
   public virtual void PrintFields() {
      Console.WriteLine("x = {0}", x);
   }
}
class B: A
{
   int y;
   public override void PrintFields() {
      base.PrintFields();
      Console.WriteLine("y = {0}", y);
   }
}
```

the `base.PrintFields()` invocation in `B` invokes the `PrintFields` method declared in `A`. A *base-access* disables the virtual invocation mechanism and simply treats the base method as a non-virtual method. Had the invocation in `B` been written `((A)this).PrintFields()`, it would recursively invoke the `PrintFields` method declared in `B`, not the one declared in `A`, since `PrintFields` is virtual and the run-time type of `((A)this)` is `B`.

Only by including an `override` modifier can a method override another method. In all other cases, a method with the same signature as an inherited method simply hides the inherited method. In the example

```
class A
{
   public virtual void F() {}
}
class B: A
{
   public virtual void F() {}      // Warning, hiding inherited F()
}
```

the `F` method in `B` does not include an `override` modifier and therefore does not override the `F` method in `A`. Rather, the `F` method in `B` hides the method in `A`, and a warning is reported because the declaration does not include a `new` modifier.

In the example

```
class A
{
   public virtual void F() {}
}
class B: A
{
   new private void F() {}         // Hides A.F within B
}
class C: B
{
   public override void F() {}   // Ok, overrides A.F
}
```

the `F` method in `B` hides the virtual `F` method inherited from `A`. Since the new `F` in `B` has private access, its scope only includes the class body of `B` and does not extend to `C`. Therefore, the declaration of `F` in `C` is permitted to override the `F` inherited from `A`.

10.5.5 Sealed methods

When an instance method declaration includes a `sealed` modifier, that method is said to be a sealed method. If an instance method declaration includes the `sealed` modifier, it must also include the `override` modifier. Use of the `sealed` modifier prevents a derived class from further overriding the method.

The example

```
using System;
class A
{
   public virtual void F() {
      Console.WriteLine("A.F");
   }
   public virtual void G() {
      Console.WriteLine("A.G");
   }
}
class B: A
{
   sealed override public void F() {
      Console.WriteLine("B.F");
   }
   override public void G() {
      Console.WriteLine("B.G");
   }
}
class C: B
{
   override public void G() {
      Console.WriteLine("C.G");
   }
}
```

the class `B` provides two override methods: an `F` method that has the `sealed` modifier and a `G` method that does not. `B`'s use of the sealed `modifier` prevents `C` from further overriding `F`.

10.5.6 Abstract methods

When an instance method declaration includes an `abstract` modifier, that method is said to be an abstract method. Although an abstract method is implicitly also a virtual method, it cannot have the modifier `virtual`.

An abstract method declaration introduces a new virtual method but does not provide an implementation of that method. Instead, non-abstract derived classes are required to provide their own implementation by overriding that method. Because an abstract method provides no actual implementation, the *method-body* of an abstract method simply consists of a semicolon.

Abstract method declarations are only permitted in abstract classes (Section 10.1.1.1).

In the example

```
public abstract class Shape
{
   public abstract void Paint(Graphics g, Rectangle r);
}
public class Ellipse: Shape
{
   public override void Paint(Graphics g, Rectangle r) {
      g.DrawEllipse(r);
   }
}
public class Box: Shape
{
   public override void Paint(Graphics g, Rectangle r) {
      g.DrawRect(r);
   }
}
```

the `Shape` class defines the abstract notion of a geometrical shape object that can paint itself. The `Paint` method is abstract because there is no meaningful default implementation. The `Ellipse` and `Box` classes are concrete `Shape` implementations. Because these classes are non-abstract, they are required to override the `Paint` method and provide an actual implementation.

It is a compile-time error for a *base-access* (Section 7.5.8) to reference an abstract method. In the example

```
abstract class A
{
   public abstract void F();
}
class B: A
{
   public override void F() {
      base.F();                  // Error, base.F is abstract
   }
}
```

a compile-time error is reported for the `base.F()` invocation because it references an abstract method.

An abstract method declaration is permitted to override a virtual method. This allows an abstract class to force re-implementation of the method in derived classes, and makes the original implementation of the method unavailable. In the example

```
using System;
class A
{
   public virtual void F() {
      Console.WriteLine("A.F");
   }
}
abstract class B: A
{
   public abstract override void F();
}
class C: B
{
```

```
    public override void F() {
       Console.WriteLine("C.F");
    }
 }
```

class `A` declares a virtual method, class `B` overrides this method with an abstract method, and class `C` overrides the abstract method to provide its own implementation.

10.5.7 External methods

When a method declaration includes an `extern` modifier, that method is said to be an external method. External methods are implemented externally, typically using a language other than C#. Because an external method declaration provides no actual implementation, the *method-body* of an external method simply consists of a semicolon.

The `extern` modifier is typically used in conjunction with a `DllImport` attribute (Section 10.5.1), allowing external methods to be implemented by DLLs (Dynamic Link Libraries). The execution environment may support other mechanisms whereby implementations of external methods can be provided.

When an external method includes a `DllImport` attribute, the method declaration must also include a `static` modifier. This example demonstrates the use of the `extern` modifier and the `DllImport` attribute:

```
using System.Text;
using System.Security.Permissions;
using System.Runtime.InteropServices;
class Path
{
   [DllImport("kernel32", SetLastError=true)]
   static extern bool CreateDirectory(string name, SecurityAttribute sa);
   [DllImport("kernel32", SetLastError=true)]
   static extern bool RemoveDirectory(string name);
   [DllImport("kernel32", SetLastError=true)]
   static extern int GetCurrentDirectory(int bufSize, StringBuilder buf);
   [DllImport("kernel32", SetLastError=true)]
   static extern bool SetCurrentDirectory(string name);
}
```

10.5.8 Method body

The *method-body* of a method declaration consists of either a *block* or a semicolon.

Abstract and external method declarations do not provide a method implementation, so their method bodies simply consist of a semicolon. For any other method, the method body is a block (Section 8.2) that contains the statements to execute when that method is invoked.

When the return type of a method is `void`, `return` statements (Section 8.9.4) in that method's body are not permitted to specify an expression. If execution of the method body of a void method completes normally (that is, control flows off the end of the method body), that method simply returns to its caller.

When the return type of a method is not `void`, each `return` statement in that method's body must specify an expression of a type that is implicitly convertible to the return type. The endpoint of the method body of a value-returning method must not be reachable. In other words, in a value-returning method, control is not permitted to flow off the end of the method body.

In the example

```
class A
{
   public int F() {}         // Error, return value required
   public int G() {
      return 1;
   }
   public int H(bool b) {
      if (b) {
         return 1;
      }
      else {
         return 0;
      }
   }
}
```

the value-returning `F` method results in a compile-time error because control can flow off the end of the method body. The `G` and `H` methods are correct because all possible execution paths end in a return statement that specifies a return value.

10.5.9 Method overloading

The method overload resolution rules are described in Section 7.4.2.

10.6 Properties

A property is a member that provides access to a characteristic of an object or a class. Examples of properties include the length of a string, the size of a font, the caption of a window, the name of a customer, and so on. Properties are a natural extension of fields — both are named members with associated types, and the syntax for accessing fields and properties is the same. However, unlike fields, properties do not denote storage locations. Instead, properties have accessors that specify the statements to be executed when their values are read or written. Properties thus provide a mechanism for associating actions with the reading and writing of an object's attributes; furthermore, they permit such attributes to be computed.

Properties are declared using *property-declarations*:

property-declaration:
  attributes$_{opt}$ *property-modifiers*$_{opt}$ *type* *member-name* { *accessor-declarations* }
property-modifiers:
  property-modifier
  property-modifiers *property-modifier*
property-modifier:
  new
  public
  protected
  internal
  private
  static
  virtual
  sealed
  override
  abstract
  extern
member-name:
  identifier
  interface-type . *identifier*

A *property-declaration* may include a set of *attributes* (Section 17) and a valid combination of the four access modifiers (Section 10.2.3), the `new` (Section 10.2.2), `static` (Section 10.5.2), `virtual` (Section 10.5.3), `override` (Section 10.5.4), `sealed` (Section 10.5.5), `abstract` (Section 10.5.6), and `extern` (Section 10.5.7) modifiers.

Property declarations are subject to the same rules as method declarations (Section 10.5) with regard to valid combinations of modifiers.

The *type* of a property declaration specifies the type of the property introduced by the declaration, and the *member-name* specifies the name of the property. Unless the property is an explicit interface member implementation, the *member-name* is simply an *identifier*. For an explicit interface member implementation (Section 13.4.1), the *member-name* consists of an *interface-type* followed by a "`.`" and an *identifier*.

The *type* of a property must be at least as accessible as the property itself (Section 3.5.4).

The *accessor-declarations*, which must be enclosed in "`{`" and "`}`" tokens, declare the accessors (Section 10.6.2) of the property. The accessors specify the executable statements associated with reading and writing the property.

Even though the syntax for accessing a property is the same as that for a field, a property is not classified as a variable. Thus, it is not possible to pass a property as a `ref` or `out` argument.

When a property declaration includes an `extern` modifier, the property is said to be an external property. Because an external property declaration provides no actual implementation, each of its *accessor-declarations* consists of a semicolon.

10.6.1 Static and instance properties

When a property declaration includes a `static` modifier, the property is said to be a static property. When no `static` modifier is present, the property is said to be an instance property.

A static property is not associated with a specific instance, and it is a compile-time error to refer to `this` in the accessors of a static property.

An instance property is associated with a given instance of a class, and that instance can be accessed as `this` (Section 7.5.7) in the accessors of that property.

When a property is referenced in a *member-access* (Section 7.5.4) of the form `E.M`, if `M` is a static property, `E` must denote a type containing `M`, and if `M` is an instance property, `E` must denote an instance of a type containing `M`.

The differences between static and instance members are discussed further in Section 10.2.5.

10.6.2 Accessors

The *accessor-declarations* of a property specify the executable statements associated with reading and writing that property.

accessor-declarations:
  get-accessor-declaration *set-accessor-declaration*$_{opt}$
  set-accessor-declaration *get-accessor-declaration*$_{opt}$
get-accessor-declaration:
  attributes$_{opt}$ get *accessor-body*
set-accessor-declaration:
  attributes$_{opt}$ set *accessor-body*
accessor-body:
  block
  ;

The accessor declarations consist of a *get-accessor-declaration*, a *set-accessor-declaration*, or both. Each accessor declaration consists of the token `get` or `set` followed by an *accessor-body*. For `abstract` and `extern` properties, the *accessor-body* for each accessor specified is simply a semicolon. For the accessors of any non-abstract, non-extern property, the *accessor-body* is a *block* that specifies the statements to be executed when the corresponding accessor is invoked.

A `get` accessor corresponds to a parameterless method with a return value of the property type. Except as the target of an assignment, when a property is referenced in an expression, the `get` accessor of the property is invoked to compute the value of the property (Section 7.1.1). The body of a `get` accessor must conform to the rules for value-returning methods described in Section 10.5.8. In particular, all `return` statements in the body of a `get` accessor must specify an expression that is implicitly convertible to the property type. Furthermore, the endpoint of a `get` accessor must not be reachable.

A `set` accessor corresponds to a method with a single value parameter of the property type and a `void` return type. The implicit parameter of a `set` accessor is always named `value`. When a property is referenced as the target of an assignment (Section 7.13), or as the operand of `++` or `--` (Section 7.5.9, Section 7.6.5), the `set` accessor is invoked with an argument (whose value is that of the right-hand side of the assignment or the operand of the `++` or `--` operator) that provides the new value (Section 7.13.1). The body of a `set` accessor must conform to the rules for `void` methods described in Section 10.5.8. In particular, `return` statements in the `set` accessor body are not permitted to specify an expression. Since a `set` accessor implicitly has a parameter named `value`, it is a compile-time error for a local variable or constant declaration in a `set` accessor to have that name.

Based on the presence or absence of the `get` and `set` accessors, a property is classified as follows:

- A property that includes both a `get` accessor and a `set` accessor is said to be a read-write property.
- A property that has only a `get` accessor is said to be a read-only property. It is a compile-time error for a read-only property to be the target of an assignment.
- A property that has only a `set` accessor is said to be a write-only property. Except as the target of an assignment, it is a compile-time error to reference a write-only property in an expression.

In the example

```
public class Button: Control
{
   private string caption;
   public string Caption {
      get {
         return caption;
      }
      set {
         if (caption != value) {
            caption = value;
            Repaint();
         }
      }
   }
   public override void Paint(Graphics g, Rectangle r) {
      // Painting code goes here
   }
}
```

the `Button` control declares a public `Caption` property. The `get` accessor of the `Caption` property returns the string stored in the private `caption` field. The `set` accessor checks if the new value is different from the current value, and if so, it stores the new value and repaints the control. Properties often follow the pattern shown above: The `get` accessor simply returns a value stored in a private field, and the `set` accessor modifies that private field and then performs any additional actions required to fully update the state of the object.

Given the `Button` class above, the following is an example of use of the `Caption` property:

```
Button okButton = new Button();
okButton.Caption = "OK";         // Invokes set accessor
string s = okButton.Caption;      // Invokes get accessor
```

Here, the `set` accessor is invoked by assigning a value to the property, and the `get` accessor is invoked by referencing the property in an expression.

The `get` and `set` accessors of a property are not distinct members, and it is not possible to declare the accessors of a property separately. As such, it is not possible for the two accessors of a read-write property to have different accessibility. The example

```
class A
{
   private string name;
   public string Name {            // Error, duplicate member name
      get { return name; }
   }
   public string Name {            // Error, duplicate member name
      set { name = value; }
   }
}
```

does not declare a single read-write property. Rather, it declares two properties with the same name, one read-only and one write-only. Since two members declared in the same class cannot have the same name, the example causes a compile-time error to occur.

When a derived class declares a property by the same name as an inherited property, the derived property hides the inherited property with respect to both reading and writing. In the example

```
class A
{
   public int P {
      set {...}
   }
}
class B: A
{
   new public int P {
      get {...}
   }
}
```

the `P` property in `B` hides the `P` property in `A` with respect to both reading and writing. Thus, in the statements

```
B b = new B();
b.P = 1;         // Error, B.P is read-only
((A)b).P = 1;   // Ok, reference to A.P
```

the assignment to `b.P` causes a compile-time error to be reported, since the read-only `P` property in `B` hides the write-only `P` property in `A`. Note, however, that a cast can be used to access the hidden `P` property.

Unlike public fields, properties provide a separation between an object's internal state and its public interface. Consider the example:

```
class Label
{
   private int x, y;
```

```
   private string caption;
   public Label(int x, int y, string caption) {
      this.x = x;
      this.y = y;
      this.caption = caption;
   }
   public int X {
      get { return x; }
   }
   public int Y {
      get { return y; }
   }
   public Point Location {
      get { return new Point(x, y); }
   }
   public string Caption {
      get { return caption; }
   }
}
```

Here, the `Label` class uses two `int` fields, `x` and `y`, to store its location. The location is publicly exposed both as an `X` and a `Y` property and as a `Location` property of type `Point`. If, in a future version of `Label`, it becomes more convenient to store the location as a `Point` internally, the change can be made without affecting the public interface of the class:

```
class Label
{
   private Point location;
   private string caption;
   public Label(int x, int y, string caption) {
      this.location = new Point(x, y);
      this.caption = caption;
   }
   public int X {
      get { return location.x; }
   }
   public int Y {
      get { return location.y; }
   }
   public Point Location {
      get { return location; }
   }
   public string Caption {
      get { return caption; }
   }
}
```

Had `x` and `y` instead been `public readonly` fields, it would have been impossible to make such a change to the `Label` class.

Exposing state through properties is not necessarily any less efficient than exposing fields directly. In particular, when a property is non-virtual and contains only a small amount of code, the execution environment may replace calls to accessors with the actual code of the accessors. This process is known as inlining, and it makes property access as efficient as field access, yet preserves the increased flexibility of properties.

Since invoking a `get` accessor is conceptually equivalent to reading the value of a field, it is considered bad programming style for `get` accessors to have observable side effects. In the example

```
class Counter
{
   private int next;
   public int Next {
      get { return next++; }
   }
}
```

the value of the `Next` property depends on the number of times the property has previously been accessed. Thus, accessing the

property produces an observable side effect, and the property should be implemented as a method instead.

The "no side-effects" convention for `get` accessors doesn't mean that `get` accessors should always be written to simply return values stored in fields. Indeed, `get` accessors often compute the value of a property by accessing multiple fields or invoking methods. However, a properly designed `get` accessor performs no actions that cause observable changes in the state of the object.

Properties can be used to delay initialization of a resource until the moment it is first referenced. For example:

```
using System.IO;
public class Console
{
   private static TextReader reader;
   private static TextWriter writer;
   private static TextWriter error;
   public static TextReader In {
      get {
         if (reader == null) {
            reader = new StreamReader(Console.OpenStandardInput());
         }
         return reader;
      }
   }
   public static TextWriter Out {
      get {
         if (writer == null) {
            writer = new StreamWriter(Console.OpenStandardOutput());
         }
         return writer;
      }
   }
   public static TextWriter Error {
      get {
         if (error == null) {
            error = new StreamWriter(Console.OpenStandardError());
         }
         return error;
      }
   }
}
```

The `Console` class contains three properties, `In`, `Out`, and `Error`, that represent the standard input, output, and error devices, respectively. By exposing these members as properties, the `Console` class can delay their initialization until they are actually used. For example, upon first referencing the `Out` property, as in

```
Console.Out.WriteLine("hello, world");
```

the underlying `TextWriter` for the output device is created. But if the application makes no reference to the `In` and `Error` properties, then no objects are created for those devices.

10.6.3 Virtual, sealed, override, and abstract accessors

A `virtual` property declaration specifies that the accessors of the property are virtual. The `virtual` modifier applies to both accessors of a read-write property — it is not possible for only one accessor of a read-write property to be virtual.

An `abstract` property declaration specifies that the accessors of the property are virtual, but does not provide an actual implementation of the accessors. Instead, non-abstract derived classes are required to provide their own implementation for the accessors by overriding the property. Because an accessor for an abstract property declaration provides no actual implementation, its *accessor-body* simply consists of a semicolon.

A property declaration that includes both the `abstract` and `override` modifiers specifies that the property is abstract and overrides a base property. The accessors of such a property are also abstract.

Abstract property declarations are only permitted in abstract classes (Section 10.1.1.1).The accessors of an inherited virtual property can be overridden in a derived class by including a property declaration that specifies an `override` directive. This is known as an overriding property declaration. An overriding property declaration does not declare a new property. Instead, it simply specializes the implementations of the accessors of an existing virtual property.

An overriding property declaration must specify the exact same accessibility modifiers, type, and name as the inherited property. If the inherited property has only a single accessor (i.e., if the inherited property is read-only or write-only), the overriding property must include only that accessor. If the inherited property includes both accessors (i.e., if the inherited property is read-write), the overriding property can include either a single accessor or both accessors.

An overriding property declaration may include the `sealed` modifier. Use of this modifier prevents a derived class from further overriding the property. The accessors of a sealed property are also sealed.

Except for differences in declaration and invocation syntax, virtual, sealed, override, and abstract accessors behave exactly like virtual, sealed, override and abstract methods. Specifically, the rules described in Section 10.5.3, Section 10.5.4, Section 10.5.5, and Section 10.5.6 apply as if accessors were methods of a corresponding form:

- A `get` accessor corresponds to a parameterless method with a return value of the property type and the same modifiers as the containing property.
- A `set` accessor corresponds to a method with a single value parameter of the property type, a `void` return type, and the same modifiers as the containing property.

In the example

```
abstract class A
{
   int y;
   public virtual int X {
      get { return 0; }
   }
   public virtual int Y {
      get { return y; }
      set { y = value; }
   }
   public abstract int Z { get; set; }
}
```

`X` is a virtual read-only property, `Y` is a virtual read-write property, and `Z` is an abstract read-write property. Because `Z` is abstract, the containing class `A` must also be declared abstract.

A class that derives from `A` is show below:

```
class B: A
{
   int z;
   public override int X {
      get { return base.X + 1; }
   }
   public override int Y {
      set { base.Y = value < 0? 0: value; }
   }
   public override int Z {
```

```
        get { return z; }
        set { z = value; }
    }
}
```

Here, the declarations of `X`, `Y`, and `Z` are overriding property declarations. Each property declaration exactly matches the accessibility modifiers, type, and name of the corresponding inherited property. The `get` accessor of `X` and the `set` accessor of `Y` use the `base` keyword to access the inherited accessors. The declaration of `Z` overrides both abstract accessors — thus, there are no outstanding abstract function members in `B`, and `B` is permitted to be a non-abstract class.

10.7 Events

An event is a member that enables an object or class to provide notifications. Clients can attach executable code for events by supplying event handlers.

Events are declared using *event-declarations*:

event-declaration:
  attributes$_{opt}$ *event-modifiers*$_{opt}$ event *type* *variable-declarators* ;
  attributes$_{opt}$ *event-modifiers*$_{opt}$ event *type* *member-name* { *event-accessor-declarations* }
event-modifiers:
  event-modifier
  event-modifiers *event-modifier*
event-modifier:
  new
  public
  protected
  internal
  private
  static
  virtual
  sealed
  override
  abstract
  extern
event-accessor-declarations:
  add-accessor-declaration *remove-accessor-declaration*
  remove-accessor-declaration *add-accessor-declaration*
add-accessor-declaration:
  attributes$_{opt}$ add *block*
remove-accessor-declaration:
  attributes$_{opt}$ remove *block*

An *event-declaration* may include a set of *attributes* (Section 17) and a valid combination of the four access modifiers (Section 10.2.3), the `new` (Section 10.2.2), `static` (Section 10.5.2), `virtual` (Section 10.5.3), `override` (Section 10.5.4), `sealed` (Section 10.5.5), `abstract` (Section 10.5.6), and `extern` (Section 10.5.7) modifiers.

Event declarations are subject to the same rules as method declarations (Section 10.5) with regard to valid combinations of modifiers.

The *type* of an event declaration must be a *delegate-type* (Section 4.2), and that *delegate-type* must be at least as accessible as the event itself (Section 3.5.4).

An event declaration may include *event-accessor-declaration*s. However, if it does not, for non-extern, non-abstract events, the compiler supplies them automatically (Section 3.7.1); for extern events, the accessors are provided externally.

An event declaration that omits *event-accessor-declaration*s defines one or more events — one for each of the *variable-declarator*s. The attributes and modifiers apply to all of the members declared by such an *event-declaration*.

It is a compile-time error for an *event-declaration* to include both the `abstract` modifier and brace-delimited *event-accessor-declaration*s.

When an event declaration includes an `extern` modifier, the event is said to be an external event. Because an external event declaration provides no actual implementation, it is an error for it to include both the `extern` modifier and *event-accessor-declaration*s.

An event can be used as the left-hand operand of the `+=` and `-=` operators (Section 7.13.3). These operators are used, respectively, to attach event handlers to or to remove event handlers from an event, and the access modifiers of the event control the contexts in which such operations are permitted.

Since `+=` and `-=` are the only operations that are permitted on an event outside the type that declares the event, external code can add and remove handlers for an event, but cannot in any other way obtain or modify the underlying list of event handlers.

In an operation of the form `x += y` or `x -= y`, when `x` is an event and the reference takes place outside the type that contains the declaration of `x`, the result of the operation has type `void` (as opposed to having the type of `x`, with the value of `x` after the

assignment). This rule prohibits external code from indirectly examining the underlying delegate of an event.

The following example shows how event handlers are attached to instances of the `Button` class:

```
public delegate void EventHandler(object sender, EventArgs e);
public class Button: Control
{
   public event EventHandler Click;
}
public class LoginDialog: Form
{
   Button OkButton;
   Button CancelButton;
   public LoginDialog() {
      OkButton = new Button(...);
      OkButton.Click += new EventHandler(OkButtonClick);
      CancelButton = new Button(...);
      CancelButton.Click += new EventHandler(CancelButtonClick);
   }
   void OkButtonClick(object sender, EventArgs e) {
      // Handle OkButton.Click event
   }
   void CancelButtonClick(object sender, EventArgs e) {
      // Handle CancelButton.Click event
   }
}
```

Here, the `LoginDialog` instance constructor creates two `Button` instances and attaches event handlers to the `Click` events.

10.7.1 Field-like events

Within the program text of the class or struct that contains the declaration of an event, certain events can be used like fields. To be used in this way, an event must not be `abstract` or `extern`, and must not explicitly include *event-accessor-declarations*. Such an event can be used in any context that permits a field. The field contains a delegate (Section 15) that refers to the list of event handlers that have been added to the event. If no event handlers have been added, the field contains `null`.

In the example

```
public delegate void EventHandler(object sender, EventArgs e);
public class Button: Control
{
   public event EventHandler Click;
   protected void OnClick(EventArgs e) {
      if (Click != null) Click(this, e);
   }
   public void Reset() {
      Click = null;
   }
}
```

`Click` is used as a field within the `Button` class. As the example demonstrates, the field can be examined, modified, and used in delegate invocation expressions. The `OnClick` method in the `Button` class "raises" the `Click` event. The notion of raising an event is precisely equivalent to invoking the delegate represented by the event — thus, there are no special language constructs for raising events. Note that the delegate invocation is preceded by a check that ensures the delegate is non-null.

Outside the declaration of the `Button` class, the `Click` member can only be used on the left side of the += and -= operators, as in

```
b.Click += new EventHandler(...);
```

which appends a delegate to the invocation list of the `Click` event, and

```
b.Click -= new EventHandler(...);
```

which removes a delegate from the invocation list of the `Click` event.

When compiling a field-like event, the compiler automatically creates storage to hold the delegate, and creates accessors for the event that add or remove event handlers to the delegate field. In order to be thread-safe, the addition or removal operations are done while holding the lock (Section 8.12) on the containing object for an instance event, or the type object (Section 7.5.11) for a static event.

Thus, an instance event declaration of the form:

```
class X {
   public event D Ev;
}
```

could be compiled to something equivalent to:

```
class X {
   private D __Ev;  // field to hold the delegate
   public event D Ev {
      add {
         lock(this) { __Ev = __Ev + value; }
      }
      remove {
         lock(this) { __Ev = __Ev - value; }
      }
   }
}
```

Within the class `X`, references to `Ev` are compiled to reference the hidden field `__Ev` instead. The name "`__Ev`" is arbitrary; the

hidden field could have any name or no name at all.

Similarly, a static event declaration of the form:

```
class X {
   public static event D Ev;
```

could be compiled to something equivalent to:

```
class X {
   private static D __Ev;  // field to hold the delegate
   public static event D Ev {
      add {
         lock(typeof(X)) { __Ev = __Ev + value; }
      }
      remove {
         lock(typeof(X)) { __Ev = __Ev - value; }
      }
   }
}
```

10.7.2 Event accessors

Event declarations typically omit *event-accessor-declarations*, as in the `Button` example above. One situation for doing so involves the case in which the storage cost of one field per event is not acceptable. In such cases, a class can include *event-accessor-declarations* and use a private mechanism for storing the list of event handlers.

The *event-accessor-declarations* of an event specify the executable statements associated with adding and removing event handlers.

The accessor declarations consist of an *add-accessor-declaration* and a *remove-accessor-declaration*. Each accessor declaration consists of the token `add` or `remove` followed by a *block*. The *block* associated with an *add-accessor-declaration* specifies the statements to execute when an event handler is added, and the *block* associated with a *remove-accessor-declaration* specifies the statements to execute when an event handler is removed.

Each *add-accessor-declaration* and *remove-accessor-declaration* corresponds to a method with a single value parameter of the event type and a `void` return type. The implicit parameter of an event accessor is named `value`. When an event is used in an event assignment, the appropriate event accessor is used. Specifically, if the assignment operator is `+=` then the add accessor is used, and if the assignment operator is `-=` then the remove accessor is used. In either case, the right-hand operand of the assignment operator is used as the argument to the event accessor. The block of an *add-accessor-declaration* or a *remove-accessor-declaration* must conform to the rules for `void` methods described in Section 10.5.8. In particular, `return` statements in such a block are not permitted to specify an expression.

Since an event accessor implicitly has a parameter named `value`, it is a compile-time error for a local variable or constant declared in an event accessor to have that name.

In the example

```
class Control: Component
{
   // Unique keys for events
   static readonly object mouseDownEventKey = new object();
   static readonly object mouseUpEventKey = new object();
   // Return event handler associated with key
   protected Delegate GetEventHandler(object key) {...}
   // Add event handler associated with key
   protected void AddEventHandler(object key, Delegate handler) {...}
   // Remove event handler associated with key
   protected void RemoveEventHandler(object key, Delegate handler) {...}
   // MouseDown event
   public event MouseEventHandler MouseDown {
      add { AddEventHandler(mouseDownEventKey, value); }
      remove { RemoveEventHandler(mouseDownEventKey, value); }
   }
   // MouseUp event
   public event MouseEventHandler MouseUp {
      add { AddEventHandler(mouseUpEventKey, value); }
      remove { RemoveEventHandler(mouseUpEventKey, value); }
   }
   // Invoke the MouseUp event
   protected void OnMouseUp(MouseEventArgs args) {
      MouseEventHandler handler;
      handler = (MouseEventHandler)GetEventHandler(mouseUpEventKey);
      if (handler != null)
         handler(this, args);
   }
}
```

the `Control` class implements an internal storage mechanism for events. The `AddEventHandler` method associates a delegate value with a key, the `GetEventHandler` method returns the delegate currently associated with a key, and the `RemoveEventHandler` method removes a delegate as an event handler for the specified event. Presumably, the underlying storage mechanism is designed such that there is no cost for associating a `null` delegate value with a key, and thus unhandled events consume no storage.

10.7.3 Static and instance events

When an event declaration includes a `static` modifier, the event is said to be a static event. When no `static` modifier is present, the event is said to be an instance event.

A static event is not associated with a specific instance, and it is a compile-time error to refer to `this` in the accessors of a static event.

An instance event is associated with a given instance of a class, and this instance can be accessed as `this` (Section 7.5.7) in the accessors of that event.

When an event is referenced in a *member-access* (Section 7.5.4) of the form `E.M`, if `M` is a static event, `E` must denote a type containing `M`, and if `M` is an instance event, `E` must denote an instance of a type containing `M`.

The differences between static and instance members are discussed further in Section 10.2.5.

10.7.4 Virtual, sealed, override, and abstract accessors

A `virtual` event declaration specifies that the accessors of that event are virtual. The `virtual` modifier applies to both accessors of an event.

An `abstract` event declaration specifies that the accessors of the event are virtual, but does not provide an actual implementation of the accessors. Instead, non-abstract derived classes are required to provide their own implementation for the accessors by overriding the event. Because an accessor for an abstract event declaration provides no actual implementation, its *accessor-body* simply consists of a semicolon.

An event declaration that includes both the `abstract` and `override` modifiers specifies that the event is abstract and overrides a base event. The accessors of such an event are also abstract.

Abstract event declarations are only permitted in abstract classes (Section 10.1.1.1).

The accessors of an inherited virtual event can be overridden in a derived class by including an event declaration that specifies an `override` modifier. This is known as an overriding event declaration. An overriding event declaration does not declare a new event. Instead, it simply specializes the implementations of the accessors of an existing virtual event.

An overriding event declaration must specify the exact same accessibility modifiers, type, and name as the overridden event.

An overriding event declaration may include the `sealed` modifier. Use of this modifier prevents a derived class from further overriding the event. The accessors of a sealed event are also sealed.

It is a compile-time error for an overriding event declaration to include a `new` modifier.

Except for differences in declaration and invocation syntax, virtual, sealed, override, and abstract accessors behave exactly like virtual, sealed, override and abstract methods. Specifically, the rules described in Section 10.5.3, Section 10.5.4, Section 10.5.5, and Section 10.5.6 apply as if accessors were methods of a corresponding form. Each accessor corresponds to a method with a single value parameter of the event type, a `void` return type, and the same modifiers as the containing event.

10.8 Indexers

An indexer is a member that enables an object to be indexed in the same way as an array. Indexers are declared using *indexer-declarations*:

indexer-declaration:
  attributes$_{opt}$ *indexer-modifiers*$_{opt}$ *indexer-declarator* { *accessor-declarations* }
indexer-modifiers:
  indexer-modifier
  indexer-modifiers *indexer-modifier*
indexer-modifier:
  new
  public
  protected
  internal
  private
  virtual
  sealed
  override
  abstract
  extern
indexer-declarator:
  type this [*formal-parameter-list*]
  type *interface-type* . this [*formal-parameter-list*]

An *indexer-declaration* may include a set of *attributes* (Section 17) and a valid combination of the four access modifiers (Section 10.2.3), the `new` (Section 10.2.2), `virtual` (Section 10.5.3), `override` (Section 10.5.4), `sealed` (Section 10.5.5), `abstract` (Section 10.5.6), and `extern` (Section 10.5.7) modifiers.

Indexer declarations are subject to the same rules as method declarations (Section 10.5) with regard to valid combinations of modifiers, with the one exception being that the static modifier is not permitted on an indexer declaration.

The modifiers `virtual`, `override`, and `abstract` are mutually exclusive except in one case. The `abstract` and `override` modifiers may be used together so that an abstract indexer can override a virtual one.

The *type* of an indexer declaration specifies the element type of the indexer introduced by the declaration. Unless the indexer is an explicit interface member implementation, the *type* is followed by the keyword `this`. For an explicit interface member implementation, the *type* is followed by an *interface-type*, a "`.`", and the keyword `this`. Unlike other members, indexers do not have user-defined names.

The *formal-parameter-list* specifies the parameters of the indexer. The formal parameter list of an indexer corresponds to that of a method (Section 10.5.1), except that at least one parameter must be specified, and that the `ref` and `out` parameter modifiers are not permitted.

The *type* of an indexer and each of the types referenced in the *formal-parameter-list* must be at least as accessible as the indexer itself (Section 3.5.4).

The *accessor-declarations* (Section 10.6.2), which must be enclosed in "`{`" and "`}`" tokens, declare the accessors of the indexer. The accessors specify the executable statements associated with reading and writing indexer elements.

Even though the syntax for accessing an indexer element is the same as that for an array element, an indexer element is not classified as a variable. Thus, it is not possible to pass an indexer element as a `ref` or `out` argument.

The formal parameter list of an indexer defines the signature (Section 3.6) of the indexer. Specifically, the signature of an indexer consists of the number and types of its formal parameters. The element type and names of the formal parameters are not part of an indexer's signature.

The signature of an indexer must differ from the signatures of all other indexers declared in the same class.

Indexers and properties are very similar in concept, but differ in the following ways:

- A property is identified by its name, whereas an indexer is identified by its signature.
- A property is accessed through a *simple-name* (Section 7.5.2) or a *member-access* (Section 7.5.4), whereas an indexer element is accessed through an *element-access* (Section 7.5.6.2).
- A property can be a `static` member, whereas an indexer is always an instance member.

- A `get` accessor of a property corresponds to a method with no parameters, whereas a `get` accessor of an indexer corresponds to a method with the same formal parameter list as the indexer.
- A `set` accessor of a property corresponds to a method with a single parameter named `value`, whereas a `set` accessor of an indexer corresponds to a method with the same formal parameter list as the indexer, plus an additional parameter named `value`.
- It is a compile-time error for an indexer accessor to declare a local variable with the same name as an indexer parameter.
- In an overriding property declaration, the inherited property is accessed using the syntax `base.P`, where `P` is the property name. In an overriding indexer declaration, the inherited indexer is accessed using the syntax `base[E]`, where `E` is a comma separated list of expressions.

Aside from these differences, all rules defined in Section 10.6.2 and Section 10.6.3 apply to indexer accessors as well as to property accessors.

When an indexer declaration includes an `extern` modifier, the indexer is said to be an external indexer. Because an external indexer declaration provides no actual implementation, each of its *accessor-declarations* consists of a semicolon.

The example below declares a `BitArray` class that implements an indexer for accessing the individual bits in the bit array.

```
using System;
class BitArray
{
   int[] bits;
   int length;
   public BitArray(int length) {
      if (length < 0) throw new ArgumentException();
      bits = new int[((length - 1) >> 5) + 1];
      this.length = length;
   }
   public int Length {
      get { return length; }
   }
   public bool this[int index] {
      get {
         if (index < 0 || index >= length) {
            throw new IndexOutOfRangeException();
         }
         return (bits[index >> 5] & 1 << index) != 0;
      }
      set {
         if (index < 0 || index >= length) {
            throw new IndexOutOfRangeException();
         }
         if (value) {
            bits[index >> 5] |= 1 << index;
         }
         else {
            bits[index >> 5] &= ~(1 << index);
         }
      }
   }
}
```

An instance of the `BitArray` class consumes substantially less memory than a corresponding `bool[]` (since each value of the former occupies only one bit instead of the latter's one byte), but it permits the same operations as a `bool[]`.

The following `CountPrimes` class uses a `BitArray` and the classical "sieve" algorithm to compute the number of primes between 1 and a given maximum:

```
class CountPrimes
{
   static int Count(int max) {
      BitArray flags = new BitArray(max + 1);
      int count = 1;
      for (int i = 2; i <= max; i++) {
         if (!flags[i]) {
```

```
            for (int j = i * 2; j <= max; j += i) flags[j] = true;
            count++;
         }
      }
      return count;
   }
   static void Main(string[] args) {
      int max = int.Parse(args[0]);
      int count = Count(max);
      Console.WriteLine("Found {0} primes between 1 and {1}", count, max);
   }
}
```

Note that the syntax for accessing elements of the `BitArray` is precisely the same as for a `bool[]`.

The following example shows a 26 by 10 grid class that has an indexer with two parameters. The first parameter is required to be an upper- or lowercase letter in the range A–Z, and the second is required to be an integer in the range 0–9.

```
using System;
class Grid
{
   const int NumRows = 26;
   const int NumCols = 10;
   int[,] cells = new int[NumRows, NumCols];
   public int this[char c, int col] {
      get {
         c = Char.ToUpper(c);
         if (c < 'A' || c > 'Z') {
            throw new ArgumentException();
         }
         if (col < 0 || col >= NumCols) {
            throw new IndexOutOfRangeException();
         }
         return cells[c - 'A', col];
      }
      set {
         c = Char.ToUpper(c);
         if (c < 'A' || c > 'Z') {
            throw new ArgumentException();
         }
         if (col < 0 || col >= NumCols) {
            throw new IndexOutOfRangeException();
         }
         cells[c - 'A', col] = value;
      }
   }
}
```

10.8.1 Indexer overloading

The indexer overload resolution rules are described in Section 7.4.2.

10.9 Operators

An operator is a member that defines the meaning of an expression operator that can be applied to instances of the class. Operators are declared using *operator-declarations*:

operator-declaration:
  attributes$_{opt}$ *operator-modifiers* *operator-declarator* *operator-body*
operator-modifiers:
  operator-modifier
  operator-modifiers *operator-modifier*
operator-modifier:
  public
  static
  extern
operator-declarator:
  unary-operator-declarator
  binary-operator-declarator
  conversion-operator-declarator
unary-operator-declarator:
  type operator *overloadable-unary-operator* (*type* *identifier*)
overloadable-unary-operator: one of
  + - ! ~ ++ -- true false
binary-operator-declarator:
  type operator *overloadable-binary-operator* (*type* *identifier* , *type* *identifier*)
overloadable-binary-operator: one of
  + - * / % & | ^ << >> == != > < >= <=
conversion-operator-declarator:
  implicit operator *type* (*type* *identifier*)
  explicit operator *type* (*type* *identifier*)
operator-body:
  block
  ;

There are three categories of overloadable operators: Unary operators (Section 10.9.1), binary operators (Section 10.9.2), and conversion operators (Section 10.9.3).

When an operator declaration includes an `extern` modifier, the operator is said to be an external operator. Because an external operator provides no actual implementation, its *operator-body* consists of a semi-colon. For all other operators, the *operator-body* consists of a *block*, which specifies the statements to execute when the operator is invoked. The *block* of an operator must conform to the rules for value-returning methods described in Section 10.5.8.

The following rules apply to all operator declarations:

- An operator declaration must include both a `public` and a `static` modifier.
- The parameter(s) of an operator must be value parameters. It is a compile-time error for an operator declaration to specify `ref` or `out` parameters.
- The signature of an operator (Section 10.9.1, Section 10.9.2, Section 10.9.3) must differ from the signatures of all other operators declared in the same class.
- All types referenced in an operator declaration must be at least as accessible as the operator itself (Section 3.5.4).
- It is an error for the same modifier to appear multiple times in an operator declaration.

Each operator category imposes additional restrictions, as described in the following sections.

Like other members, operators declared in a base class are inherited by derived classes. Because operator declarations always require the class or struct in which the operator is declared to participate in the signature of the operator, it is not possible for an operator declared in a derived class to hide an operator declared in a base class. Thus, the `new` modifier is never required, and therefore never permitted, in an operator declaration.

Additional information on unary and binary operators can be found in Section 7.2.

Additional information on conversion operators can be found in Section 6.4.

10.9.1 Unary operators

The following rules apply to unary operator declarations, where `T` denotes the class or struct type that contains the operator declaration:

- A unary `+`, `-`, `!`, or `~` operator must take a single parameter of type `T` and can return any type.
- A unary `++` or `--` operator must take a single parameter of type `T` and must return type `T`.
- A unary `true` or `false` operator must take a single parameter of type `T` and must return type `bool`.

The signature of a unary operator consists of the operator token (`+`, `-`, `!`, `~`, `++`, `--`, `true`, or `false`) and the type of the single formal parameter. The return type is not part of a unary operator's signature, nor is the name of the formal parameter.

The `true` and `false` unary operators require pair-wise declaration. A compile-time error occurs if a class declares one of these operators without also declaring the other. The `true` and `false` operators are described further in Section 7.16.

The following example shows an implementation and subsequent usage of operator `++` for an integer vector class:

```
public class IntVector
{
   public IntVector(int length) {...}
   public int Length {...}               // read-only property
   public int this[int index] {...}      // read-write indexer
   public static IntVector operator ++(IntVector iv) {
      IntVector temp = new IntVector(iv.Length);
      for (int i = 0; i < iv.Length; i++)
         temp[i] = iv[i] + 1;
      return temp;
   }
}
class Test
{
   static void Main() {
      IntVector iv1 = new IntVector(4);   // vector of 4 x 0
      IntVector iv2;
      iv2 = iv1++;   // iv2 contains 4 x 0, iv1 contains 4 x 1
      iv2 = ++iv1;   // iv2 contains 4 x 2, iv1 contains 4 x 2
   }
}
```

Note how the operator method returns the value produced by adding 1 to the operand, just like the postfix increment and decrement operators (Section 7.5.9), and the prefix increment and decrement operators (Section 7.6.5). Unlike in C++, this method need not modify the value of its operand directly. In fact, modifying the operand value would violate the standard semantics of the postfix increment operator.

10.9.2 Binary operators

A binary operator must take two parameters, at least one of which must have the class or struct type in which the operator is declared. Parameters of the shift operators (Section 7.8) are further constrained. A binary operator can return any type.

The signature of a binary operator consists of the operator token (`+`, `-`, `*`, `/`, `%`, `&`, `|`, `^`, `<<`, `>>`, `==`, `!=`, `>`, `<`, `>=`, or `<=`) and the types of the two formal parameters. The return type and the names of the formal parameters are not part of a binary operator's signature.

Certain binary operators require pair-wise declaration. For every declaration of either operator of a pair, there must be a matching declaration of the other operator of the pair. Two operator declarations match when they have the same return type and the same type for each parameter. The following operators require pair-wise declaration:

- `operator ==` and `operator !=`
- `operator >` and `operator <`
- `operator >=` and `operator <=`

10.9.3 Conversion operators

A conversion operator declaration introduces a user-defined conversion (Section 6.4), which augments the pre-defined implicit and explicit conversions.

A conversion operator declaration that includes the `implicit` keyword introduces a user-defined implicit conversion. Implicit conversions can occur in a variety of situations, including function member invocations, cast expressions, and assignments. This is described further in Section 6.1.

A conversion operator declaration that includes the `explicit` keyword introduces a user-defined explicit conversion. Explicit conversions can occur in cast expressions, and are described further in Section 6.2.

A conversion operator converts from a source type, indicated by the parameter type of the conversion operator, to a target type, indicated by the return type of the conversion operator. A class or struct is permitted to declare a conversion from a source type `S` to a target type `T` provided all of the following are true:

- `S` and `T` are different types.
- Either `S` or `T` is the class or struct type in which the operator declaration takes place.
- Neither `S` nor `T` is `object` or an *interface-type*.
- `T` is not a base class of `S`, and `S` is not a base class of `T`.

From the second rule it follows that a conversion operator must convert either to or from the class or struct type in which the operator is declared. For example, it is possible for a class or struct type `C` to define a conversion from `C` to `int` and from `int` to `C`, but not from `int` to `bool`.

It is not possible to redefine a pre-defined conversion. Thus, conversion operators are not allowed to convert from or to `object` because implicit and explicit conversions already exist between `object` and all other types. Likewise, neither the source nor the target types of a conversion can be a base type of the other, since a conversion would then already exist.

User-defined conversions are not allowed to convert from or to *interface-types*. In particular, this restriction ensures that no user-defined transformations occur when converting to an *interface-type*, and that a conversion to an *interface-type* succeeds only if the object being converted actually implements the specified *interface-type*.

The signature of a conversion operator consists of the source type and the target type. (Note that this is the only form of member for which the return type participates in the signature.) The `implicit` or `explicit` classification of a conversion operator is not part of the operator's signature. Thus, a class or struct cannot declare both an `implicit` and an `explicit` conversion operator with the same source and target types.

In general, user-defined implicit conversions should be designed to never throw exceptions and never lose information. If a user-defined conversion can give rise to exceptions (for example, because the source argument is out of range) or loss of information (such as discarding high-order bits), then that conversion should be defined as an explicit conversion.

In the example

```
using System;
public struct Digit
{
   byte value;
   public Digit(byte value) {
      if (value < 0 || value > 9) throw new ArgumentException();
      this.value = value;
   }
   public static implicit operator byte(Digit d) {
      return d.value;
   }
   public static explicit operator Digit(byte b) {
      return new Digit(b);
   }
}
```

the conversion from `Digit` to `byte` is implicit because it never throws exceptions or loses information, but the conversion from `byte` to `Digit` is explicit since `Digit` can only represent a subset of the possible values of a `byte`.

10.10 Instance constructors

An instance constructor is a member that implements the actions required to initialize an instance of a class. Instance constructors are declared using *constructor-declarations*:

constructor-declaration:
  attributes$_{opt}$ *constructor-modifiers*$_{opt}$ *constructor-declarator* *constructor-body*
constructor-modifiers:
  constructor-modifier
  constructor-modifiers *constructor-modifier*
constructor-modifier:
  public
  protected
  internal
  private
  extern
constructor-declarator:
  identifier (*formal-parameter-list*$_{opt}$) *constructor-initializer*$_{opt}$
constructor-initializer:
  : base (*argument-list*$_{opt}$)
  : this (*argument-list*$_{opt}$)
constructor-body:
  block
  ;

A *constructor-declaration* may include a set of *attributes* (Section 17), a valid combination of the four access modifiers (Section 10.2.3), and an `extern` (Section 10.5.7) modifier. A constructor declaration is not permitted to include the same modifier multiple times.

The *identifier* of a *constructor-declarator* must name the class in which the instance constructor is declared. If any other name is specified, a compile-time error occurs.

The optional *formal-parameter-list* of an instance constructor is subject to the same rules as the *formal-parameter-list* of a method (Section 10.5). The formal parameter list defines the signature (Section 3.6) of an instance constructor and governs the process whereby overload resolution (Section 7.4.2) selects a particular instance constructor in an invocation.

Each of the types referenced in the *formal-parameter-list* of an instance constructor must be at least as accessible as the constructor itself (Section 3.5.4).

The optional *constructor-initializer* specifies another instance constructor to invoke before executing the statements given in the *constructor-body* of this instance constructor. This is described further in Section 10.10.1.

When a constructor declaration includes an `extern` modifier, the constructor is said to be an external constructor. Because an external constructor declaration provides no actual implementation, its *constructor-body* consists of a semicolon. For all other constructors, the *constructor-body* consists of a *block* that specifies the statements to initialize a new instance of the class. This corresponds exactly to the *block* of an instance method with a `void` return type (Section 10.5.8).

Instance constructors are not inherited. Thus, a class has no instance constructors other than those actually declared in the class. If a class contains no instance constructor declarations, a default instance constructor is automatically provided (Section 10.10.4).

Instance constructors are invoked by *object-creation-expressions* (Section 7.5.10.1) and through *constructor-initializers*.

10.10.1 Constructor initializers

All instance constructors (except those for class `object`) implicitly include an invocation of another instance constructor immediately before the *constructor-body*. The constructor to implicitly invoke is determined by the *constructor-initializer*:

- An instance constructor initializer of the form `base(`*argument-listopt*`)` causes an instance constructor from the direct base class to be invoked. That constructor is selected using *argument-list* and the overload resolution rules of Section 7.4.2. The set of candidate instance constructors consists of all accessible instance constructors contained in the direct base class (including any default constructor, as defined in Section 10.10.4). If this set is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs.
- An instance constructor initializer of the form `this(`*argument-listopt*`)` causes an instance constructor from the class itself to be invoked. The constructor is selected using *argument-list* and the overload resolution rules of Section 7.4.2. The set of candidate instance constructors consists of all accessible instance constructors declared in the class itself. If this set is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs. If an instance constructor declaration includes a constructor initializer that invokes the constructor itself, a compile-time error occurs.

If an instance constructor has no constructor initializer, a constructor initializer of the form `base()` is implicitly provided. Thus, an instance constructor declaration of the form

```
C(...) {...}
```

is exactly equivalent to

```
C(...): base() {...}
```

The scope of the parameters given by the *formal-parameter-list* of an instance constructor declaration includes the constructor initializer of that declaration. Thus, a constructor initializer is permitted to access the parameters of the constructor. For example:

```
class A
{
   public A(int x, int y) {}
}
class B: A
{
   public B(int x, int y): base(x + y, x - y) {}
}
```

An instance constructor initializer cannot access the instance being created. Therefore it is a compile-time error to reference `this` in an argument expression of the constructor initializer, as is it a compile-time error for an argument expression to reference any instance member through a *simple-name*.

10.10.2 Instance variable initializers

When an instance constructor has no constructor initializer, or it has a constructor initializer of the form `base(...)`, that constructor implicitly performs the initializations specified by the *variable-initializer*s of the instance fields declared in its class. This corresponds to a sequence of assignments that are executed immediately upon entry to the constructor and before the implicit invocation of the direct base class constructor. The variable initializers are executed in the textual order in which they appear in the class declaration.

10.10.3 Constructor execution

Variable initializers are transformed into assignment statements, and these assignment statements are executed before the invocation of the base class instance constructor. This ordering ensures that all instance fields are initialized by their variable initializers before any statements that have access to that instance are executed.

Given the example

```
using System;
class A
{
   public A() {
      PrintFields();
   }
   public virtual void PrintFields() {}
}
class B: A
{
   int x = 1;
   int y;
   public B() {
      y = -1;
   }
   public override void PrintFields() {
      Console.WriteLine("x = {0}, y = {1}", x, y);
   }
}
```

when `new B()` is used to create an instance of `B`, the following output is produced:

```
x = 1, y = 0
```

The value of `x` is 1 because the variable initializer is executed before the base class instance constructor is invoked. However, the value of `y` is 0 (the default value of an `int`) because the assignment to `y` is not executed until after the base class constructor returns.

It is useful to think of instance variable initializers and constructor initializers as statements that are automatically inserted before the *constructor-body*. The example

```
using System;
using System.Collections;
class A
{
   int x = 1, y = -1, count;
   public A() {
      count = 0;
   }
   public A(int n) {
      count = n;
   }
}
class B: A
{
   double sqrt2 = Math.Sqrt(2.0);
   ArrayList items = new ArrayList(100);
   int max;
   public B(): this(100) {
      items.Add("default");
   }
   public B(int n): base(n - 1) {
      max = n;
   }
}
```

contains several variable initializers; it also contains constructor initializers of both forms (`base` and `this`). The example corresponds to the code shown below, where each comment indicates an automatically inserted statement (the syntax used for the automatically inserted constructor invocations is not valid, but merely serves to illustrate the mechanism).

```
using System.Collections;
class A
{
   int x, y, count;
   public A() {
      x = 1;                        // Variable initializer
      y = -1;                        // Variable initializer
      object();                     // Invoke object() constructor
      count = 0;
   }
   public A(int n) {
      x = 1;                        // Variable initializer
      y = -1;                        // Variable initializer
      object();                     // Invoke object() constructor
      count = n;
   }
}
class B: A
{
   double sqrt2;
   ArrayList items;
   int max;
   public B(): this(100) {
      B(100);                        // Invoke B(int) constructor
      items.Add("default");
   }
   public B(int n): base(n - 1) {
      sqrt2 = Math.Sqrt(2.0);         // Variable initializer
      items = new ArrayList(100);   // Variable initializer
      A(n - 1);                     // Invoke A(int) constructor
      max = n;
   }
}
```

10.10.4 Default constructors

If a class contains no instance constructor declarations, a default instance constructor is automatically provided. That default constructor simply invokes the parameterless constructor of the direct base class. If the direct base class does not have an accessible parameterless instance constructor, a compile-time error occurs. If the class is abstract then the declared accessibility for the default constructor is protected. Otherwise, the declared accessibility for the default constructor is public. Thus, the default constructor is always of the form

```
protected C(): base() {}
```

or

```
public C(): base() {}
```

where `C` is the name of the class.

In the example

```
class Message
{
   object sender;
   string text;
}
```

a default constructor is provided because the class contains no instance constructor declarations. Thus, the example is precisely equivalent to

```
class Message
{
   object sender;
   string text;
   public Message(): base() {}
}
```

10.10.5 Private constructors

When a class `T` declares only private instance constructors, it is not possible for classes outside the program text of `T` to derive from `T` or to directly create instances of `T`. Thus, if a class contains only static members and isn't intended to be instantiated, adding an empty private instance constructor will prevent instantiation. For example:

```
public class Trig
{
   private Trig() {}      // Prevent instantiation
   public const double PI = 3.14159265358979323846;
   public static double Sin(double x) {...}
   public static double Cos(double x) {...}
   public static double Tan(double x) {...}
}
```

The `Trig` class groups related methods and constants, but is not intended to be instantiated. Therefore it declares a single empty private instance constructor. At least one instance constructor must be declared to suppress the automatic generation of a default constructor.

10.10.6 Optional instance constructor parameters

The `this(...)` form of constructor initializer is commonly used in conjunction with overloading to implement optional instance constructor parameters. In the example

```
class Text
{
   public Text(): this(0, 0, null) {}
   public Text(int x, int y): this(x, y, null) {}
   public Text(int x, int y, string s) {
      // Actual constructor implementation
   }
}
```

the first two instance constructors merely provide the default values for the missing arguments. Both use a `this(...)` constructor initializer to invoke the third instance constructor, which actually does the work of initializing the new instance. The effect is that of optional constructor parameters:

```
Text t1 = new Text();               // Same as Text(0, 0, null)
Text t2 = new Text(5, 10);            // Same as Text(5, 10, null)
Text t3 = new Text(5, 20, "Hello");
```

10.11 Static constructors

A static constructor is a member that implements the actions required to initialize a class. Static constructors are declared using *static-constructor-declarations*:

static-constructor-declaration:
  attributes$_{opt}$ *static-constructor-modifiers* *identifier* ( ) *static-constructor-body*
static-constructor-modifiers:
  extern$_{opt}$ static
  static extern$_{opt}$
static-constructor-body:
  block
  ;

A *static-constructor-declaration* may include a set of *attributes* (Section 17) and an `extern` (Section 10.5.7) modifier.

The *identifier* of a *static-constructor-declaration* must name the class in which the static constructor is declared. If any other name is specified, a compile-time error occurs.

When a static constructor declaration includes an `extern` modifier, the static constructor is said to be an external static constructor. Because an external static constructor declaration provides no actual implementation, its *static-constructor-body* consists of a semicolon. For all other static constructor declarations, the *static-constructor-body* consists of a *block* that specifies the statements to execute in order to initialize the class. This corresponds exactly to the *method-body* of a static method with a `void` return type (Section 10.5.8).

Static constructors are not inherited, and cannot be called directly.

The static constructor for a class executes at most once in a given application domain. The execution of a static constructor is triggered by the first of the following events to occur within an application domain:

- An instance of the class is created.
- Any of the static members of the class are referenced.

If a class contains the `Main` method (Section 3.1) in which execution begins, the static constructor for that class executes before the `Main` method is called. If a class contains any static fields with initializers, those initializers are executed in textual order immediately prior to executing the static constructor.

The example

```
using System;
class Test
{
   static void Main() {
      A.F();
      B.F();
   }
}
class A
{
   static A() {
      Console.WriteLine("Init A");
   }
   public static void F() {
      Console.WriteLine("A.F");
   }
}
class B
{
   static B() {
      Console.WriteLine("Init B");
   }
   public static void F() {
      Console.WriteLine("B.F");
   }
}
```

must produce the output:

```
Init A
A.F
Init B
B.F
```

because the execution of `A`'s static constructor is triggered by the call to `A.F`, and the execution of `B`'s static constructor is triggered by the call to `B.F`.

It is possible to construct circular dependencies that allow static fields with variable initializers to be observed in their default value state.

The example

```
using System;
class A
{
   public static int X;
   static A() {
      X = B.Y + 1;
   }
}
class B
{
   public static int Y = A.X + 1;
   static B() {}
   static void Main() {
      Console.WriteLine("X = {0}, Y = {1}", A.X, B.Y);
   }
}
```

produces the output

```
X = 1, Y = 2
```

To execute the `Main` method, the system first runs the initializer for `B.Y`, prior to class `B`'s static constructor. `Y`'s initializer causes `A`'s static constructor to be run because the value of `A.X` is referenced. The static constructor of `A` in turn proceeds to compute the value of `X`, and in doing so fetches the default value of `Y`, which is zero. `A.X` is thus initialized to 1. The process of running `A`'s static field initializers and static constructor then completes, returning to the calculation of the initial value of `Y`, the result of which becomes 2.

10.12 Destructors

A destructor is a member that implements the actions required to destruct an instance of a class. A destructor is declared using a *destructor-declaration*:

destructor-declaration:
  attributes$_{opt}$ extern$_{opt}$ ~ *identifier* ( ) *destructor-body*
destructor-body:
  block
  ;

A *destructor-declaration* may include a set of *attributes* (Section 17).

The *identifier* of a *destructor-declarator* must name the class in which the destructor is declared. If any other name is specified, a compile-time error occurs.

When a destructor declaration includes an `extern` modifier, the destructor is said to be an external destructor. Because an external destructor declaration provides no actual implementation, its *destructor-body* consists of a semicolon. For all other destructors, the *destructor-body* consists of a *block* that specifies the statements to execute in order to destruct an instance of the class. A *destructor-body* corresponds exactly to the *method-body* of an instance method with a `void` return type (Section 10.5.8).

Destructors are not inherited. Thus, a class has no destructors other than the one that may be declared in that class.

Since a destructor is required to have no parameters, it cannot be overloaded, so a class can have, at most, one destructor.

Destructors are invoked automatically, and cannot be invoked explicitly. An instance becomes eligible for destruction when it is no longer possible for any code to use that instance. Execution of the destructor for the instance may occur at any time after the instance becomes eligible for destruction. When an instance is destructed, the destructors in that instance's inheritance chain are called, in order, from most derived to least derived. A destructor may be executed on any thread. For further discussion of the rules that govern when and how a destructor is executed, see Section 3.9.

The output of the example

```
using System;
class A
{
   ~A() {
      Console.WriteLine("A's destructor");
   }
}
class B: A
{
   ~B() {
      Console.WriteLine("B's destructor");
   }
}
class Test
{
    static void Main() {
      B b = new B();
      b = null;
      GC.Collect();
      GC.WaitForPendingFinalizers();
   }
}
```

is

```
B's destructor
A's destructor
```

since destructors in an inheritance chain are called in order, from most derived to least derived.

Destructors are implemented by overriding the virtual method `Finalize` on `System.Object`. C# programs are not permitted to override this method or call it (or overrides of it) directly. For instance, the program

```
class A
{
   override protected void Finalize() {}   // error
   public void F() {
      this.Finalize();                     // error
   }
}
```

contains two errors.

The compiler behaves as if this method, and overrides of it, do not exist at all. Thus, this program:

```
class A
{
   void Finalize() {}                     // permitted
}
```

is valid, and the method shown hides `System.Object`'s `Finalize` method.

For a discussion of the behavior when an exception is thrown from a destructor, see Section 16.3.

11. Structs

Structs are similar to classes in that they represent data structures that can contain data members and function members. However, unlike classes, structs are value types and do not require heap allocation. A variable of a struct type directly contains the data of the struct, whereas a variable of a class type contains a reference to the data, the latter known as an object.

Structs are particularly useful for small data structures that have value semantics. Complex numbers, points in a coordinate system, or key-value pairs in a dictionary are all good examples of structs. Key to these data structures is that they have few data members, that they do not require use of inheritance or referential identity, and that they can be conveniently implemented using value semantics where assignment copies the value instead of the reference.

As described in Section 4.1.3, the simple types provided by C#, such as `int`, `double`, and `bool`, are in fact all struct types. Just as these predefined types are structs, it is also possible to use structs and operator overloading to implement new "primitive" types in the C# language. Two examples of such types are given at the end of this chapter (Section 11.4).

11.1 Struct declarations

A *struct-declaration* is a *type-declaration* (Section 9.5) that declares a new struct:

struct-declaration:
  attributes$_{opt}$ *struct-modifiers*$_{opt}$ struct *identifier* *struct-interfaces*$_{opt}$ *struct-body* ;$_{opt}$

A *struct-declaration* consists of an optional set of *attributes* (Section 17), followed by an optional set of *struct-modifiers* (Section 11.1.1), followed by the keyword `struct` and an *identifier* that names the struct, followed by an optional *struct-interfaces* specification (Section 11.1.2), followed by a *struct-body* (Section 11.1.3), optionally followed by a semicolon.

11.1.1 Struct modifiers

A *struct-declaration* may optionally include a sequence of struct modifiers:

struct-modifiers:
  struct-modifier
  struct-modifiers *struct-modifier*
struct-modifier:
  new
  public
  protected
  internal
  private

It is a compile-time error for the same modifier to appear multiple times in a struct declaration.

The modifiers of a struct declaration have the same meaning as those of a class declaration (Section 10.1.1).

11.1.2 Struct interfaces

A struct declaration may include a *struct-interfaces* specification, in which case the struct is said to implement the given interface types.

struct-interfaces:
  ; *interface-type-list*

Interface implementations are discussed further in Section 13.4.

11.1.3 Struct body

The *struct-body* of a struct defines the members of the struct.

struct-body:
  { *struct-member-declarations*$_{opt}$ }

11.2 Struct members

The members of a struct consist of the members introduced by its *struct-member-declaration*s and the members inherited from the type `System.ValueType`.

struct-member-declarations:
  struct-member-declaration
  struct-member-declarations struct-member-declaration
struct-member-declaration:
  constant-declaration
  field-declaration
  method-declaration
  property-declaration
  event-declaration
  indexer-declaration
  operator-declaration
  constructor-declaration
  static-constructor-declaration
  type-declaration

Except for the differences noted in Section 11.3, the descriptions of class members provided in Section 10.2 through Section 10.11 apply to struct members as well.

11.3 Class and struct differences

Structs differ from classes in several important ways:

- Structs are value types (Section 11.3.1).
- All struct types implicitly inherit from the class `System.ValueType` (Section 11.3.2).
- Assignment to a variable of a struct type creates a *copy* of the value being assigned (Section 11.3.3).
- The default value of a struct is the value produced by setting all value type fields to their default value and all reference type fields to `null` (Section 11.3.4).
- Boxing and unboxing operations are used to convert between a struct type and `object` (Section 11.3.5).
- The meaning of `this` is different for structs (Section 11.3.6).
- Instance field declarations for a struct are not permitted to include variable initializers (Section 11.3.7).
- A struct is not permitted to declare a parameterless instance constructor (Section 11.3.8).
- A struct is not permitted to declare a destructor (Section 11.3.9).

11.3.1 Value semantics

Structs are value types (Section 4.1) and are said to have value semantics. Classes, on the other hand, are reference types (Section 4.2) and are said to have reference semantics.

A variable of a struct type directly contains the data of the struct, whereas a variable of a class type contains a reference to the data, the latter known as an object.

With classes, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With structs, the variables each have their own copy of the data (except in the case of ref and out parameter variables), and it is not possible for operations on one to affect the other. Furthermore, because structs are not reference types, it is not possible for values of a struct type to be `null`.

Given the declaration

```
struct Point
{
   public int x, y;
   public Point(int x, int y) {
      this.x = x;
      this.y = y;
   }
}
```

the code fragment

```
Point a = new Point(10, 10);
Point b = a;
a.x = 100;
System.Console.WriteLine(b.x);
```

outputs the value `10`. The assignment of `a` to `b` creates a copy of the value, and `b` is thus unaffected by the assignment to `a.x`. Had `Point` instead been declared as a class, the output would be `100` because `a` and `b` would reference the same object.

11.3.2 Inheritance

All struct types implicitly inherit from the class `System.ValueType`, which, in turn, inherits from class `object`. A struct declaration may specify a list of implemented interfaces, but it is not possible for a struct declaration to specify a base class.

Struct types are never abstract and are always implicitly sealed. The `abstract` and `sealed` modifiers are therefore not permitted in a struct declaration.

Since inheritance is not supported for structs, the declared accessibility of a struct member cannot be `protected` or `protected internal`.

Function members in a struct cannot be `abstract` or `virtual`, and the `override` modifier is allowed only to override methods inherited from `System.ValueType`.

11.3.3 Assignment

Assignment to a variable of a struct type creates a *copy* of the value being assigned. This differs from assignment to a variable of a class type, which copies the reference but not the object identified by the reference.

Similar to an assignment, when a struct is passed as a value parameter or returned as the result of a function member, a copy of the struct is created. A struct may be passed by reference to a function member using a `ref` or `out` parameter.

When a property or indexer of a struct is the target of an assignment, the instance expression associated with the property or indexer access must be classified as a variable. If the instance expression is classified as a value, a compile-time error occurs. This is described in further detail in Section 7.13.1.

11.3.4 Default values

As described in Section 5.2, several kinds of variables are automatically initialized to their default value when they are created. For variables of class types and other reference types, this default value is `null`. However, since structs are value types that cannot be `null`, the default value of a struct is the value produced by setting all value type fields to their default value and all reference type fields to `null`.

Referring to the `Point` struct declared above, the example

```
Point[] a = new Point[100];
```

initializes each `Point` in the array to the value produced by setting the `x` and `y` fields to zero.

The default value of a struct corresponds to the value returned by the default constructor of the struct (Section 4.1.1). Unlike a class, a struct is not permitted to declare a parameterless instance constructor. Instead, every struct implicitly has a parameterless instance constructor, which always returns the value that results from setting all value type fields to their default value and all reference type fields to `null`.

Structs should be designed to consider the default initialization state a valid state. In the example

```
using System;
struct KeyValuePair
{
   string key;
   string value;
   public KeyValuePair(string key, string value) {
      if (key == null || value == null) throw new ArgumentException();
      this.key = key;
      this.value = value;
   }
}
```

the user-defined instance constructor protects against null values only where it is explicitly called. In cases where a `KeyValuePair` variable is subject to default value initialization, the `key` and `value` fields will be null, and the struct must be prepared to handle this state.

11.3.5 Boxing and unboxing

A value of a class type can be converted to type `object` or to an interface type that is implemented by the class simply by treating the reference as another type at compile-time. Likewise, a value of type `object` or a value of an interface type can be converted back to a class type without changing the reference (but of course a run-time type check is required in this case).

Since structs are not reference types, these operations are implemented differently for struct types. When a value of a struct type is converted to type `object` or to an interface type that is implemented by the struct, a boxing operation takes place. Likewise, when a value of type `object` or a value of an interface type is converted back to a struct type, an unboxing operation takes place. A key difference from the same operations on class types is that boxing and unboxing *copies* the struct value either into or out of the boxed instance. Thus, following a boxing or unboxing operation, changes made to the unboxed struct are not reflected in the boxed struct.

For further details on boxing and unboxing, see Section 4.3.

11.3.6 Meaning of this

Within an instance constructor or instance function member of a class, `this` is classified as a value. Thus, while `this` can be used to refer to the instance for which the function member was invoked, it is not possible to assign to `this` in a function member of a class.

Within an instance constructor of a struct, `this` corresponds to an `out` parameter of the struct type, and within an instance function member of a struct, `this` corresponds to a `ref` parameter of the struct type. In both cases, `this` is classified as a variable, and it is possible to modify the entire struct for which the function member was invoked by assigning to `this` or by passing this as a `ref` or `out` parameter.

11.3.7 Field initializers

As described in Section 11.3.4, the default value of a struct consists of the value that results from setting all value type fields to their default value and all reference type fields to `null`. For this reason, a struct does not permit instance field declarations to include variable initializers. This restriction applies only to instance fields. Static fields of a struct are permitted to include variable initializers.

The example

```
struct Point
{
   public int x = 1;  // Error, initializer not permitted
   public int y = 1;  // Error, initializer not permitted
}
```

is in error because the instance field declarations include variable initializers.

11.3.8 Constructors

Unlike a class, a struct is not permitted to declare a parameterless instance constructor. Instead, every struct implicitly has a parameterless instance constructor that always returns the value that results from setting all value type fields to their default value and all reference type fields to null (Section 4.1.1). A struct can declare instance constructors having parameters. For example

```
struct Point
{
   int x, y;
   public Point(int x, int y) {
      this.x = x;
      this.y = y;
   }
}
```

Given the above declaration, the statements

```
Point p1 = new Point();
Point p2 = new Point(0, 0);
```

both create a `Point` with `x` and `y` initialized to zero.

A struct instance constructor is not permitted to include a constructor initializer of the form `base(...)`.

If the struct instance constructor doesn't specify a constructor initializer, the `this` variable corresponds to an `out` parameter of the struct type, and similar to an `out` parameter, this must be definitely assigned (Section 5.3) at every location where the constructor returns. If the struct instance constructor specifies a constructor initializer, the `this` variable corresponds to a `ref` parameter of the struct type, and similar to a `ref` parameter, `this` is considered definitely assigned on entry to the constructor body. Consider the instance constructor implementation below:

```
struct Point
{
   int x, y;
   public int X {
      set { x = value; }
   }
   public int Y {
      set { y = value; }
   }
   public Point(int x, int y) {
      X = x;      // error, this is not yet definitely assigned
      Y = y;      // error, this is not yet definitely assigned
   }
}
```

No instance member function (including the set accessors for the properties `X` and `Y`) can be called until all fields of the struct being constructed have been definitely assigned. Note, however, that if `Point` were a class instead of a struct, the instance constructor implementation would be permitted.

11.3.9 Destructors

A struct is not permitted to declare a destructor.

11.4 Struct examples

The following shows two significant examples of using `struct` types to create types that can be used similarly to the built-in types of the language, but with modified semantics.

11.4.1 Database integer type

The `DBInt` struct below implements an integer type that can represent the complete set of values of the `int` type, plus an additional state that indicates an unknown value. A type with these characteristics is commonly used in databases.

```
using System;
public struct DBInt
{
   // The Null member represents an unknown DBInt value.
   public static readonly DBInt Null = new DBInt();
   // When the defined field is true, this DBInt represents a known value
   // which is stored in the value field. When the defined field is false,
   // this DBInt represents an unknown value, and the value field is 0.
   int value;
   bool defined;
   // Private instance constructor. Creates a DBInt with a known value.
   DBInt(int value) {
      this.value = value;
      this.defined = true;
   }
   // The IsNull property is true if this DBInt represents an unknown value.
   public bool IsNull { get { return !defined; } }
   // The Value property is the known value of this DBInt, or 0 if this
   // DBInt represents an unknown value.
   public int Value { get { return value; } }
   // Implicit conversion from int to DBInt.
   public static implicit operator DBInt(int x) {
      return new DBInt(x);
   }
   // Explicit conversion from DBInt to int. Throws an exception if the
   // given DBInt represents an unknown value.
   public static explicit operator int(DBInt x) {
      if (!x.defined) throw new InvalidOperationException();
      return x.value;
   }
   public static DBInt operator +(DBInt x) {
      return x;
   }
   public static DBInt operator -(DBInt x) {
      return x.defined ? -x.value : Null;
   }
   public static DBInt operator +(DBInt x, DBInt y) {
      return x.defined && y.defined? x.value + y.value: Null;
   }
   public static DBInt operator -(DBInt x, DBInt y) {
      return x.defined && y.defined? x.value - y.value: Null;
   }
   public static DBInt operator *(DBInt x, DBInt y) {
      return x.defined && y.defined? x.value * y.value: Null;
   }
   public static DBInt operator /(DBInt x, DBInt y) {
      return x.defined && y.defined? x.value / y.value: Null;
   }
   public static DBInt operator %(DBInt x, DBInt y) {
      return x.defined && y.defined? x.value % y.value: Null;
   }
   public static DBBool operator ==(DBInt x, DBInt y) {
      return x.defined && y.defined? x.value == y.value: DBBool.Null;
   }
   public static DBBool operator !=(DBInt x, DBInt y) {
      return x.defined && y.defined? x.value != y.value: DBBool.Null;
   }
   public static DBBool operator >(DBInt x, DBInt y) {
      return x.defined && y.defined? x.value > y.value: DBBool.Null;
   }
   public static DBBool operator <(DBInt x, DBInt y) {
```

```
        return x.defined && y.defined? x.value < y.value: DBBool.Null;
    }
    public static DBBool operator >=(DBInt x, DBInt y) {
        return x.defined && y.defined? x.value >= y.value: DBBool.Null;
    }
    public static DBBool operator <=(DBInt x, DBInt y) {
        return x.defined && y.defined? x.value <= y.value: DBBool.Null;
    }
    public override bool Equals(object obj) {
        if (!(obj is DBInt)) return false;
        DBInt x = (DBInt)obj;
        return value == x.value && defined == x.defined;
    }
    public override int GetHashCode() {
        return value;
    }
    public override string ToString() {
        return defined? value.ToString(): "DBInt.Null";
    }
}
```

11.4.2 Database boolean type

The `DBBool` struct below implements a three-valued logical type. The possible values of this type are `DBBool.True`, `DBBool.False`, and `DBBool.Null`, where the `Null` member indicates an unknown value. Such three-valued logical types are commonly used in databases.

```
using System;
public struct DBBool
{
   // The three possible DBBool values.
   public static readonly DBBool Null = new DBBool(0);
   public static readonly DBBool False = new DBBool(-1);
   public static readonly DBBool True = new DBBool(1);
   // Private field that stores –1, 0, 1 for False, Null, True.
   sbyte value;
   // Private instance constructor. The value parameter must be –1, 0, or 1.
   DBBool(int value) {
      this.value = (sbyte)value;
   }
   // Properties to examine the value of a DBBool. Return true if this
   // DBBool has the given value, false otherwise.
   public bool IsNull { get { return value == 0; } }
   public bool IsFalse { get { return value < 0; } }
   public bool IsTrue { get { return value > 0; } }
   // Implicit conversion from bool to DBBool. Maps true to DBBool.True and
   // false to DBBool.False.
   public static implicit operator DBBool(bool x) {
      return x? True: False;
   }
   // Explicit conversion from DBBool to bool. Throws an exception if the
   // given DBBool is Null, otherwise returns true or false.
   public static explicit operator bool(DBBool x) {
      if (x.value == 0) throw new InvalidOperationException();
      return x.value > 0;
   }
   // Equality operator. Returns Null if either operand is Null, otherwise
   // returns True or False.
   public static DBBool operator ==(DBBool x, DBBool y) {
      if (x.value == 0 || y.value == 0) return Null;
      return x.value == y.value? True: False;
   }
   // Inequality operator. Returns Null if either operand is Null, otherwise
   // returns True or False.
   public static DBBool operator !=(DBBool x, DBBool y) {
      if (x.value == 0 || y.value == 0) return Null;
      return x.value != y.value? True: False;
   }
   // Logical negation operator. Returns True if the operand is False, Null
   // if the operand is Null, or False if the operand is True.
   public static DBBool operator !(DBBool x) {
      return new DBBool(-x.value);
   }
   // Logical AND operator. Returns False if either operand is False,
   // otherwise Null if either operand is Null, otherwise True.
   public static DBBool operator &(DBBool x, DBBool y) {
      return new DBBool(x.value < y.value? x.value: y.value);
   }
   // Logical OR operator. Returns True if either operand is True, otherwise
   // Null if either operand is Null, otherwise False.
   public static DBBool operator |(DBBool x, DBBool y) {
      return new DBBool(x.value > y.value? x.value: y.value);
   }
   // Definitely true operator. Returns true if the operand is True, false
   // otherwise.
   public static bool operator true(DBBool x) {
      return x.value > 0;
```

```
    }
    // Definitely false operator. Returns true if the operand is False, false
    // otherwise.
    public static bool operator false(DBBool x) {
       return x.value < 0;
    }
    public override bool Equals(object obj) {
       if (!(obj is DBBool)) return false;
       return value == ((DBBool)obj).value;
    }
    public override int GetHashCode() {
       return value;
    }
    public override string ToString() {
       if (value > 0) return "DBBool.True";
       if (value < 0) return "DBBool.False";
       return "DBBool.Null";
    }
 }
```

12. Arrays

An array is a data structure that contains a number of variables, which are accessed through computed indices. The variables contained in an array, also called the elements of the array, are all of the same type, and this type is called the element type of the array.

An array has a rank that determines the number of indices associated with each array element. The rank of an array is also referred to as the dimensions of the array. An array with a rank of one is called a single-dimensional array. An array with a rank greater than one is called a multi-dimensional array. Specific sized multidimensional arrays are often referred to as two-dimensional arrays, three-dimensional arrays, and so on.

Each dimension of an array has an associated length that is an integral number greater than or equal to zero. The dimension lengths are not part of the type of the array, but rather are established when an instance of the array type is created at run-time. The length of a dimension determines the valid range of indices for that dimension: For a dimension of length `N`, indices can range from `0` to `N - 1` inclusive. The total number of elements in an array is the product of the lengths of each dimension in the array. If one or more of the dimensions of an array have a length of zero, the array is said to be empty.

The element type of an array can be any type, including an array type.

12.1 Array types

An array type is written as a *non-array-type* followed by one or more *rank-specifiers*:

array-type:
  non-array-type *rank-specifiers*
non-array-type:
  type
rank-specifiers:
  rank-specifier
  rank-specifiers *rank-specifier*
rank-specifier:
  [*dim-separators*$_{opt}$]
dim-separators:
  ,
  dim-separators ,

A *non-array-type* is any type that is not itself an *array-type*.

The rank of an array type is given by the leftmost *rank-specifier* in the *array-type*: A *rank-specifier* indicates that the array is an array with a rank of one plus the number of "`,`" tokens in the *rank-specifier*.

The element type of an array type is the type that results from deleting the leftmost *rank-specifier*:

- An array type of the form `T[R]` is an array with rank `R` and a non-array element type `T`.
- An array type of the form `T[R][R1]...[RN]` is an array with rank `R` and an element type `T[R1]...[RN]`.

In effect, the *rank-specifiers* are read from left to right before the final non-array element type. The type `int[][,,][,]` is a single-dimensional array of three-dimensional arrays of two-dimensional arrays of `int`.

At run-time, a value of an array type can be `null` or a reference to an instance of that array type.

12.1.1 The System.Array type

The type `System.Array` is the abstract base type of all array types. An implicit reference conversion (Section 6.1.4) exists from any array type to `System.Array`, and an explicit reference conversion (Section 6.2.3) exists from `System.Array` to any array type. Note that `System.Array` is not itself an *array-type*. Rather, it is a *class-type* from which all *array-type*s are derived.

At run-time, a value of type `System.Array` can be `null` or a reference to an instance of any array type.

12.2 Array creation

Array instances are created by *array-creation-expression*s (Section 7.5.10.2) or by field or local variable declarations that include an *array-initializer* (Section 12.6).

When an array instance is created, the rank and length of each dimension are established and then remain constant for the entire lifetime of the instance. In other words, it is not possible to change the rank of an existing array instance, nor is it possible to resize its dimensions.

An array instance is always of an array type. The `System.Array` type is an abstract type that cannot be instantiated.

Elements of arrays created by *array-creation-expression*s are always initialized to their default value (Section 5.2).

12.3 Array element access

Array elements are accessed using *element-access* expressions (Section 7.5.6.1) of the form `A[I1, I2, ..., IN]`, where `A` is an expression of an array type and each `IX` is an expression of type `int`, `uint`, `long`, `ulong`, or of a type that can be implicitly converted to one or more of these types. The result of an array element access is a variable, namely the array element selected by the indices.

The elements of an array can be enumerated using a `foreach` statement (Section 8.8.4).

12.4 Array members

Every array type inherits the members declared by the `System.Array` type.

12.5 Array covariance

For any two *reference-types* `A` and `B`, if an implicit reference conversion (Section 6.1.4) or explicit reference conversion (Section 6.2.3) exists from `A` to `B`, then the same reference conversion also exists from the array type `A[R]` to the array type `B[R]`, where `R` is any given *rank-specifier* (but the same for both array types). This relationship is known as array covariance. Array covariance in particular means that a value of an array type `A[R]` may actually be a reference to an instance of an array type `B[R]`, provided an implicit reference conversion exists from `B` to `A`.

Because of array covariance, assignments to elements of reference type arrays include a run-time check that ensures that the value being assigned to the array element is actually of a permitted type (Section 7.13.1). For example:

```
class Test
{
   static void Fill(object[] array, int index, int count, object value) {
      for (int i = index; i < index + count; i++) array[i] = value;
   }
   static void Main() {
      string[] strings = new string[100];
      Fill(strings, 0, 100, "Undefined");
      Fill(strings, 0, 10, null);
      Fill(strings, 90, 10, 0);
   }
}
```

The assignment to `array[i]` in the `Fill` method implicitly includes a run-time check that ensures that the object referenced by `value` is either `null` or an instance of a type that is compatible with the actual element type of `array`. In `Main`, the first two invocations of `Fill` succeed, but the third invocation causes a `System.ArrayTypeMismatchException` to be thrown upon executing the first assignment to `array[i]`. The exception occurs because a boxed `int` cannot be stored in a `string` array.

Array covariance specifically does not extend to arrays of *value-types*. For example, no conversion exists that permits an `int[]` to be treated as an `object[]`.

12.6 Array initializers

Array initializers may be specified in field declarations (Section 10.4), local variable declarations (Section 8.5.1), and array creation expressions (Section 7.5.10.2):

array-initializer:
  { *variable-initializer-list*$_{opt}$ }
  { *variable-initializer-list* , }
variable-initializer-list:
  variable-initializer
  variable-initializer-list , *variable-initializer*
variable-initializer:
  expression
  array-initializer

An array initializer consists of a sequence of variable initializers, enclosed by "`{`"and "`}`" tokens and separated by "`,`" tokens. Each variable initializer is an expression or, in the case of a multi-dimensional array, a nested array initializer.

The context in which an array initializer is used determines the type of the array being initialized. In an array creation expression, the array type immediately precedes the initializer. In a field or variable declaration, the array type is the type of the field or variable being declared. When an array initializer is used in a field or variable declaration, such as:

```
int[] a = {0, 2, 4, 6, 8};
```

it is simply shorthand for an equivalent array creation expression:

```
int[] a = new int[] {0, 2, 4, 6, 8};
```

For a single-dimensional array, the array initializer must consist of a sequence of expressions that are assignment compatible with the element type of the array. The expressions initialize array elements in increasing order, starting with the element at index zero. The number of expressions in the array initializer determines the length of the array instance being created. For example, the array initializer above creates an `int[]` instance of length 5 and then initializes the instance with the following values:

```
a[0] = 0; a[1] = 2; a[2] = 4; a[3] = 6; a[4] = 8;
```

For a multi-dimensional array, the array initializer must have as many levels of nesting as there are dimensions in the array. The outermost nesting level corresponds to the leftmost dimension and the innermost nesting level corresponds to the rightmost dimension. The length of each dimension of the array is determined by the number of elements at the corresponding nesting level in the array initializer. For each nested array initializer, the number of elements must be the same as the other array initializers at the same level. The example:

```
int[,] b = {{0, 1}, {2, 3}, {4, 5}, {6, 7}, {8, 9}};
```

creates a two-dimensional array with a length of five for the leftmost dimension and a length of two for the rightmost dimension:

```
int[,] b = new int[5, 2];
```

and then initializes the array instance with the following values:

```
b[0, 0] = 0; b[0, 1] = 1;
b[1, 0] = 2; b[1, 1] = 3;
b[2, 0] = 4; b[2, 1] = 5;
b[3, 0] = 6; b[3, 1] = 7;
b[4, 0] = 8; b[4, 1] = 9;
```

When an array creation expression includes both explicit dimension lengths and an array initializer, the lengths must be constant expressions and the number of elements at each nesting level must match the corresponding dimension length. Here are some examples:

```
int i = 3;
int[] x = new int[3] {0, 1, 2};      // OK
int[] y = new int[i] {0, 1, 2};      // Error, i not a constant
int[] z = new int[3] {0, 1, 2, 3};   // Error, length/initializer mismatch
```

Here, the initializer for `y` results in a compile-time error because the dimension length expression is not a constant, and the initializer for `z` results in a compile-time error because the length and the number of elements in the initializer do not agree.

13. Interfaces

An interface defines a contract. A class or struct that implements an interface must adhere to its contract. An interface may inherit from multiple base interfaces, and a class or struct may implement multiple interfaces.

Interfaces can contain methods, properties, events, and indexers. The interface itself does not provide implementations for the members that it defines. The interface merely specifies the members that must be supplied by classes or structs that implement the interface.

13.1 Interface declarations

An *interface-declaration* is a *type-declaration* (Section 9.5) that declares a new interface type.

interface-declaration:
  attributes$_{opt}$ *interface-modifiers*$_{opt}$ interface *identifier* *interface-base*$_{opt}$ *interface-body* ;$_{opt}$

An *interface-declaration* consists of an optional set of attributes (Section 17), followed by an optional set of *interface-modifiers* (Section 13.1.1), followed by the keyword `interface` and an *identifier* that names the interface, optionally followed by an optional *interface-base* specification (Section 13.1.2), followed by a *interface-body* (Section 13.1.3), optionally followed by a semicolon.

13.1.1 Interface modifiers

An *interface-declaration* may optionally include a sequence of interface modifiers:

interface-modifiers:
  interface-modifier
  interface-modifiers *interface-modifier*
interface-modifier:
  new
  public
  protected
  internal
  private

It is a compile-time error for the same modifier to appear multiple times in an interface declaration.

The `new` modifier is only permitted on interfaces defined within a class. It specifies that the interface hides an inherited member by the same name, as described in Section 10.2.2.

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the interface. Depending on the context in which the interface declaration occurs, only some of these modifiers may be permitted (Section 3.5.1).

13.1.2 Base interfaces

An interface can inherit from zero or more interfaces, which are called the explicit base interfaces of the interface. When an interface has one or more explicit base interfaces, then in the declaration of that interface, the interface identifier is followed by a colon and a comma separated list of base interface identifiers.

interface-base:
  ; *interface-type-list*

The explicit base interfaces of an interface must be at least as accessible as the interface itself (Section 3.5.4). For example, it is a compile-time error to specify a `private` or `internal` interface in the *interface-base* of a `public` interface.

It is a compile-time error for an interface to directly or indirectly inherit from itself.

The base interfaces of an interface are the explicit base interfaces and their base interfaces. In other words, the set of base interfaces is the complete transitive closure of the explicit base interfaces, their explicit base interfaces, and so on. An interface inherits all members of its base interfaces. In the example

```
interface IControl
{
   void Paint();
}
interface ITextBox: IControl
{
   void SetText(string text);
}
interface IListBox: IControl
{
   void SetItems(string[] items);
}
interface IComboBox: ITextBox, IListBox {}
```

the base interfaces of `IComboBox` are `IControl`, `ITextBox`, and `IListBox`.

In other words, the `IComboBox` interface above inherits members `SetText` and `SetItems` as well as `Paint`.

A class or struct that implements an interface also implicitly implements all of the interface's base interfaces.

13.1.3 Interface body

The *interface-body* of an interface defines the members of the interface.

interface-body:
  { *interface-member-declarations*$_{opt}$ }

13.2 Interface members

The members of an interface are the members inherited from the base interfaces and the members declared by the interface itself.

interface-member-declarations:
  interface-member-declaration
  interface-member-declarations *interface-member-declaration*
interface-member-declaration:
  interface-method-declaration
  interface-property-declaration
  interface-event-declaration
  interface-indexer-declaration

An interface declaration may declare zero or more members. The members of an interface must be methods, properties, events, or indexers. An interface cannot contain constants, fields, operators, instance constructors, destructors, or types, nor can an interface contain static members of any kind.

All interface members implicitly have public access. It is a compile-time error for interface member declarations to include any modifiers. In particular, interfaces members cannot be declared with the modifiers `abstract`, `public`, `protected`, `internal`, `private`, `virtual`, `override`, or `static`.

The example

```
public delegate void StringListEvent(IStringList sender);
public interface IStringList
{
   void Add(string s);
   int Count { get; }
   event StringListEvent Changed;
   string this[int index] { get; set; }
}
```

declares an interface that contains one each of the possible kinds of members: A method, a property, an event, and an indexer.

An *interface-declaration* creates a new declaration space (Section 3.3), and the *interface-member-declarations* immediately contained by the *interface-declaration* introduce new members into this declaration space. The following rules apply to *interface-member-declarations*:

- The name of a method must differ from the names of all properties and events declared in the same interface. In addition, the signature (Section 3.6) of a method must differ from the signatures of all other methods declared in the same interface.
- The name of a property or event must differ from the names of all other members declared in the same interface.
- The signature of an indexer must differ from the signatures of all other indexers declared in the same interface.

The inherited members of an interface are specifically not part of the declaration space of the interface. Thus, an interface is allowed to declare a member with the same name or signature as an inherited member. When this occurs, the derived interface member is said to *hide* the base interface member. Hiding an inherited member is not considered an error, but it does cause the compiler to issue a warning. To suppress the warning, the declaration of the derived interface member must include a `new` modifier to indicate that the derived member is intended to hide the base member. This topic is discussed further in Section 3.7.1.2.

If a `new` modifier is included in a declaration that doesn't hide an inherited member, a warning is issued to that effect. This warning is suppressed by removing the `new` modifier.

13.2.1 Interface methods

Interface methods are declared using *interface-method-declarations*:

interface-method-declaration:
  attributes$_{opt}$ new$_{opt}$ *return-type* *identifier* (*formal-parameter-list*$_{opt}$) ;

The *attributes*, *return-type*, *identifier*, and *formal-parameter-list* of an interface method declaration have the same meaning as those of a method declaration in a class (Section 10.5). An interface method declaration is not permitted to specify a method body, and the declaration therefore always ends with a semicolon.

13.2.2 Interface properties

Interface properties are declared using *interface-property-declarations*:

interface-property-declaration:
  attributes$_{opt}$ new$_{opt}$ *type* *identifier* { *interface-accessors* }
interface-accessors:
  attributes$_{opt}$ get ;
  attributes$_{opt}$ set ;
  attributes$_{opt}$ get ; *attributes*$_{opt}$ set ;
  attributes$_{opt}$ set ; *attributes*$_{opt}$ get ;

The *attributes*, *type*, and *identifier* of an interface property declaration have the same meaning as those of a property declaration in a class (Section 10.6).

The accessors of an interface property declaration correspond to the accessors of a class property declaration (Section 10.6.2), except that the accessor body must always be a semicolon. Thus, the accessors simply indicate whether the property is read-write, read-only, or write-only.

13.2.3 Interface events

Interface events are declared using *interface-event-declarations*:

interface-event-declaration:
  attributes$_{opt}$ new$_{opt}$ event *type* *identifier* ;

The *attributes*, *type*, and *identifier* of an interface event declaration have the same meaning as those of an event declaration in a class (Section 10.7).

13.2.4 Interface indexers

Interface indexers are declared using *interface-indexer-declarations*:

interface-indexer-declaration:
  attributes$_{opt}$ new$_{opt}$ *type* this [*formal-parameter-list*] { *interface-accessors* }

The *attributes*, *type*, and *formal-parameter-list* of an interface indexer declaration have the same meaning as those of an indexer declaration in a class (Section 10.8).

The accessors of an interface indexer declaration correspond to the accessors of a class indexer declaration (Section 10.8), except that the accessor body must always be a semicolon. Thus, the accessors simply indicate whether the indexer is read-write, read-only, or write-only.

13.2.5 Interface member access

Interface members are accessed through member access (Section 7.5.4) and indexer access (Section 7.5.6.2) expressions of the form `I.M` and `I[A]`, where `I` is an interface type, `M` is a method, property, or event of that interface type, and `A` is an indexer argument list.

For interfaces that are strictly single-inheritance (each interface in the inheritance chain has exactly zero or one direct base interface), the effects of the member lookup (Section 7.3), method invocation (Section 7.5.5.1), and indexer access (Section 7.5.6.2) rules are exactly the same as for classes and structs: More derived members hide less derived members with the same name or signature. However, for multiple-inheritance interfaces, ambiguities can occur when two or more unrelated base interfaces declare members with the same name or signature. This section shows several examples of such situations. In all cases, explicit casts can be used to resolve the ambiguities.

In the example

```
interface IList
{
   int Count { get; set; }
}
interface ICounter
{
   void Count(int i);
}
interface IListCounter: IList, ICounter {}
class C
{
   void Test(IListCounter x) {
      x.Count(1);                  // Error
      x.Count = 1;               // Error
      ((IList)x).Count = 1;      // Ok, invokes IList.Count.set
      ((ICounter)x).Count(1);      // Ok, invokes ICounter.Count
   }
}
```

the first two statements cause compile-time errors because the member lookup (Section 7.3) of `Count` in `IListCounter` is ambiguous. As illustrated by the example, the ambiguity is resolved by casting `x` to the appropriate base interface type. Such casts have no run-time costs — they merely consist of viewing the instance as a less derived type at compile-time.

In the example

```
interface IInteger
{
   void Add(int i);
}
interface IDouble
{
   void Add(double d);
}
interface INumber: IInteger, IDouble {}
class C
{
   void Test(INumber n) {
      n.Add(1);               // Error, both Add methods are applicable
      n.Add(1.0);               // Ok, only IDouble.Add is applicable
      ((IInteger)n).Add(1);   // Ok, only IInteger.Add is a candidate
      ((IDouble)n).Add(1);      // Ok, only IDouble.Add is a candidate
   }
}
```

the invocation `n.Add(1)` is ambiguous because a method invocation (Section 7.5.5.1) requires all overloaded candidate methods to be declared in the same type. However, the invocation `n.Add(1.0)` is permitted because only `IDouble.Add` is applicable. When explicit casts are inserted, there is only one candidate method, and thus no ambiguity.

In the example

```
interface IBase
{
   void F(int i);
}
interface ILeft: IBase
{
   new void F(int i);
}
interface IRight: IBase
{
   void G();
}
interface IDerived: ILeft, IRight {}
class A
{
   void Test(IDerived d) {
      d.F(1);               // Invokes ILeft.F
      ((IBase)d).F(1);      // Invokes IBase.F
      ((ILeft)d).F(1);      // Invokes ILeft.F
      ((IRight)d).F(1);      // Invokes IBase.F
   }
}
```

the `IBase.F` member is hidden by the `ILeft.F` member. The invocation `d.F(1)` thus selects `ILeft.F`, even though `IBase.F` appears to not be hidden in the access path that leads through `IRight`.

The intuitive rule for hiding in multiple-inheritance interfaces is simply this: If a member is hidden in any access path, it is hidden in all access paths. Because the access path from `IDerived` to `ILeft` to `IBase` hides `IBase.F`, the member is also hidden in the access path from `IDerived` to `IRight` to `IBase`.

13.3 Fully qualified interface member names

An interface member is sometimes referred to by its fully qualified name. The fully qualified name of an interface member consists of the name of the interface in which the member is declared, followed by a dot, followed by the name of the member. The fully qualified name of a member references the interface in which the member is declared. For example, given the declarations

```
interface IControl
{
   void Paint();
}
interface ITextBox: IControl
{
   void SetText(string text);
}
```

the fully qualified name of `Paint` is `IControl.Paint` and the fully qualified name of `SetText` is `ITextBox.SetText`.

In the example above, it is not possible to refer to `Paint` as `ITextBox.Paint`.

When an interface is part of a namespace, the fully qualified name of an interface member includes the namespace name. For example

```
namespace System
{
   public interface ICloneable
   {
      object Clone();
   }
}
```

Here, the fully qualified name of the `Clone` method is `System.ICloneable.Clone`.

13.4 Interface implementations

Interfaces may be implemented by classes and structs. To indicate that a class or struct implements an interface, the interface identifier is included in the base class list of the class or struct. For example:

```
interface ICloneable
{
   object Clone();
}
interface IComparable
{
   int CompareTo(object other);
}
class ListEntry: ICloneable, IComparable
{
   public object Clone() {...}
   public int CompareTo(object other) {...}
}
```

A class or struct that implements an interface also implicitly implements all of the interface's base interfaces. This is true even if the class or struct doesn't explicitly list all base interfaces in the base class list. For example:

```
interface IControl
{
   void Paint();
}
interface ITextBox: IControl
{
   void SetText(string text);
}
class TextBox: ITextBox
{
   public void Paint() {...}
   public void SetText(string text) {...}
}
```

Here, class `TextBox` implements both `IControl` and `ITextBox`.

13.4.1 Explicit interface member implementations

For purposes of implementing interfaces, a class or struct may declare explicit interface member implementations. An explicit interface member implementation is a method, property, event, or indexer declaration that references a fully qualified interface member name. For example

```
interface ICloneable
{
   object Clone();
}
interface IComparable
{
   int CompareTo(object other);
}
class ListEntry: ICloneable, IComparable
{
   object ICloneable.Clone() {...}
   int IComparable.CompareTo(object other) {...}
}
```

Here, `ICloneable.Clone` and `IComparable.CompareTo` are explicit interface member implementations.

In some cases, the name of an interface member may not be appropriate for the implementing class, in which case the interface member may be implemented using explicit interface member implementation. A class implementing a file abstraction, for example, would likely implement a `Close` member function that has the effect of releasing the file resource, and implement the `Dispose` method of the `IDisposable` interface using explicit interface member implementation:

```
interface IDisposable
{
   void Dispose();
}
class MyFile: IDisposable
{
   void IDisposable.Dispose() {
      Close();
   }
   public void Close() {
      // Do what's necessary to close the file
      System.GC.SuppressFinalize(this);
   }
}
```

It is not possible to access an explicit interface member implementation through its fully qualified name in a method invocation, property access, or indexer access. An explicit interface member implementation can only be accessed through an interface instance, and is in that case referenced simply by its member name.

It is a compile-time error for an explicit interface member implementation to include access modifiers, and it is a compile-time error to include the modifiers `abstract`, `virtual`, `override`, or `static`.

Explicit interface member implementations have different accessibility characteristics than other members. Because explicit interface member implementations are never accessible through their fully qualified name in a method invocation or a property access, they are in a sense private. However, since they can be accessed through an interface instance, they are in a sense also public.

Explicit interface member implementations serve two primary purposes:

- Because explicit interface member implementations are not accessible through class or struct instances, they allow interface implementations to be excluded from the public interface of a class or struct. This is particularly useful when a class or struct implements an internal interface that is of no interest to a consumer of that class or struct.
- Explicit interface member implementations allow disambiguation of interface members with the same signature. Without explicit interface member implementations it would be impossible for a class or struct to have different implementations of interface members with the same signature and return type, as would it be impossible for a class or struct to have any implementation at all of interface members with the same signature but with different return types.

For an explicit interface member implementation to be valid, the class or struct must name an interface in its base class list that contains a member whose fully qualified name, type, and parameter types exactly match those of the explicit interface member implementation. Thus, in the following class

```
class Shape: ICloneable
{
   object ICloneable.Clone() {...}
   int IComparable.CompareTo(object other) {...}   // invalid
}
```

the declaration of `IComparable.CompareTo` results in a compile-time error because `IComparable` is not listed in the base class list of `Shape` and is not a base interface of `ICloneable`. Likewise, in the declarations

```
class Shape: ICloneable
{
   object ICloneable.Clone() {...}
}
class Ellipse: Shape
{
   object ICloneable.Clone() {...}   // invalid
}
```

the declaration of `ICloneable.Clone` in `Ellipse` results in a compile-time error because `ICloneable` is not explicitly listed in the base class list of `Ellipse`.

The fully qualified name of an interface member must reference the interface in which the member was declared. Thus, in the declarations

```
interface IControl
{
   void Paint();
}
interface ITextBox: IControl
{
   void SetText(string text);
}
class TextBox: ITextBox
{
   void IControl.Paint() {...}
   void ITextBox.SetText(string text) {...}
}
```

the explicit interface member implementation of `Paint` must be written as `IControl.Paint`.

13.4.2 Interface mapping

A class or struct must provide implementations of all members of the interfaces that are listed in the base class list of the class or struct. The process of locating implementations of interface members in an implementing class or struct is known as interface mapping.

Interface mapping for a class or struct `C` locates an implementation for each member of each interface specified in the base class list of `C`. The implementation of a particular interface member `I.M`, where `I` is the interface in which the member `M` is declared, is determined by examining each class or struct `S`, starting with `C` and repeating for each successive base class of `C`, until a match is located:

- If `S` contains a declaration of an explicit interface member implementation that matches `I` and `M`, then this member is the implementation of `I.M`.
- Otherwise, if `S` contains a declaration of a non-static public member that matches `M`, then this member is the implementation of `I.M`.

A compile-time error occurs if implementations cannot be located for all members of all interfaces specified in the base class list of `C`. Note that the members of an interface include those members that are inherited from base interfaces.

For purposes of interface mapping, a class member `A` matches an interface member `B` when:

- `A` and `B` are methods, and the name, type, and formal parameter lists of `A` and `B` are identical.
- `A` and `B` are properties, the name and type of `A` and `B` are identical, and `A` has the same accessors as `B` (`A` is permitted to have additional accessors if it is not an explicit interface member implementation).
- `A` and `B` are events, and the name and type of `A` and `B` are identical.
- `A` and `B` are indexers, the type and formal parameter lists of `A` and `B` are identical, and `A` has the same accessors as `B` (`A` is permitted to have additional accessors if it is not an explicit interface member implementation).

Notable implications of the interface mapping algorithm are:

- Explicit interface member implementations take precedence over other members in the same class or struct when determining the class or struct member that implements an interface member.
- Neither non-public nor static members participate in interface mapping.

In the example

```
interface ICloneable
{
   object Clone();
}
class C: ICloneable
{
   object ICloneable.Clone() {...}
   public object Clone() {...}
}
```

the `ICloneable.Clone` member of `C` becomes the implementation of `Clone` in `ICloneable` because explicit interface member implementations take precedence over other members.

If a class or struct implements two or more interfaces containing a member with the same name, type, and parameter types, it is possible to map each of those interface members onto a single class or struct member. For example

```
interface IControl
{
   void Paint();
}
interface IForm
{
   void Paint();
}
class Page: IControl, IForm
{
```

```
   public void Paint() {...}
}
```

Here, the `Paint` methods of both `IControl` and `IForm` are mapped onto the `Paint` method in `Page`. It is of course also possible to have separate explicit interface member implementations for the two methods.

If a class or struct implements an interface that contains hidden members, then some members must necessarily be implemented through explicit interface member implementations. For example

```
interface IBase
{
   int P { get; }
}
interface IDerived: IBase
{
   new int P();
}
```

An implementation of this interface would require at least one explicit interface member implementation, and would take one of the following forms

```
class C: IDerived
{
   int IBase.P { get {...} }
   int IDerived.P() {...}
}
class C: IDerived
{
   public int P { get {...} }
   int IDerived.P() {...}
}
class C: IDerived
{
   int IBase.P { get {...} }
   public int P() {...}
}
```

When a class implements multiple interfaces that have the same base interface, there can be only one implementation of the base interface. In the example

```
interface IControl
{
   void Paint();
}
interface ITextBox: IControl
{
   void SetText(string text);
}
interface IListBox: IControl
{
   void SetItems(string[] items);
}
class ComboBox: IControl, ITextBox, IListBox
{
   void IControl.Paint() {...}
   void ITextBox.SetText(string text) {...}
   void IListBox.SetItems(string[] items) {...}
}
```

it is not possible to have separate implementations for the `IControl` named in the base class list, the `IControl` inherited by `ITextBox`, and the `IControl` inherited by `IListBox`. Indeed, there is no notion of a separate identity for these interfaces. Rather, the implementations of `ITextBox` and `IListBox` share the same implementation of `IControl`, and `ComboBox` is simply considered to implement three interfaces, `IControl`, `ITextBox`, and `IListBox`.

The members of a base class participate in interface mapping. In the example

```
interface Interface1
{
   void F();
}
class Class1
{
   public void F() {}
   public void G() {}
}
class Class2: Class1, Interface1
{
   new public void G() {}
}
```

the method `F` in `Class1` is used in `Class2`'s implementation of `Interface1`.

13.4.3 Interface implementation inheritance

A class inherits all interface implementations provided by its base classes.

Without explicitly re-implementing an interface, a derived class cannot in any way alter the interface mappings it inherits from its base classes. For example, in the declarations

```
interface IControl
{
   void Paint();
}
class Control: IControl
{
   public void Paint() {...}
}
class TextBox: Control
{
   new public void Paint() {...}
}
```

the `Paint` method in `TextBox` hides the `Paint` method in `Control`, but it does not alter the mapping of `Control.Paint` onto `IControl.Paint`, and calls to `Paint` through class instances and interface instances will have the following effects

```
Control c = new Control();
TextBox t = new TextBox();
IControl ic = c;
IControl it = t;
c.Paint();         // invokes Control.Paint();
t.Paint();         // invokes TextBox.Paint();
ic.Paint();         // invokes Control.Paint();
it.Paint();         // invokes Control.Paint();
```

However, when an interface method is mapped onto a virtual method in a class, it is possible for derived classes to override the virtual method and alter the implementation of the interface. For example, rewriting the declarations above to

```
interface IControl
{
   void Paint();
}
class Control: IControl
{
   public virtual void Paint() {...}
}
class TextBox: Control
{
   public override void Paint() {...}
}
```

the following effects will now be observed

```
Control c = new Control();
TextBox t = new TextBox();
IControl ic = c;
IControl it = t;
c.Paint();         // invokes Control.Paint();
t.Paint();         // invokes TextBox.Paint();
ic.Paint();         // invokes Control.Paint();
it.Paint();         // invokes TextBox.Paint();
```

Since explicit interface member implementations cannot be declared virtual, it is not possible to override an explicit interface member implementation. However, it is perfectly valid for an explicit interface member implementation to call another method, and that other method can be declared virtual to allow derived classes to override it. For example

```
interface IControl
{
   void Paint();
}
class Control: IControl
{
   void IControl.Paint() { PaintControl(); }
   protected virtual void PaintControl() {...}
}
class TextBox: Control
{
   protected override void PaintControl() {...}
}
```

Here, classes derived from `Control` can specialize the implementation of `IControl.Paint` by overriding the `PaintControl` method.

13.4.4 Interface re-implementation

A class that inherits an interface implementation is permitted to re-implement the interface by including it in the base class list.

A re-implementation of an interface follows exactly the same interface mapping rules as an initial implementation of an interface. Thus, the inherited interface mapping has no effect whatsoever on the interface mapping established for the re-implementation of the interface. For example, in the declarations

```
interface IControl
{
   void Paint();
}
class Control: IControl
{
   void IControl.Paint() {...}
}
class MyControl: Control, IControl
{
   public void Paint() {}
}
```

the fact that `Control` maps `IControl.Paint` onto `Control.IControl.Paint` doesn't affect the re-implementation in `MyControl`, which maps `IControl.Paint` onto `MyControl.Paint`.

Inherited public member declarations and inherited explicit interface member declarations participate in the interface mapping process for re-implemented interfaces. For example

```
interface IMethods
{
   void F();
   void G();
   void H();
   void I();
}
class Base: IMethods
{
   void IMethods.F() {}
   void IMethods.G() {}
   public void H() {}
   public void I() {}
}
class Derived: Base, IMethods
{
   public void F() {}
   void IMethods.H() {}
}
```

Here, the implementation of `IMethods` in `Derived` maps the interface methods onto `Derived.F`, `Base.IMethods.G`, `Derived.IMethods.H`, and `Base.I`.

When a class implements an interface, it implicitly also implements all of that interface's base interfaces. Likewise, a re-implementation of an interface is also implicitly a re-implementation of all of the interface's base interfaces. For example

```
interface IBase
{
   void F();
}
interface IDerived: IBase
{
   void G();
}
class C: IDerived
{
   void IBase.F() {...}
```

```
    void IDerived.G() {...}
}
class D: C, IDerived
{
    public void F() {...}
    public void G() {...}
}
```

Here, the re-implementation of `IDerived` also re-implements `IBase`, mapping `IBase.F` onto `D.F`.

13.4.5 Abstract classes and interfaces

Like a non-abstract class, an abstract class must provide implementations of all members of the interfaces that are listed in the base class list of the class. However, an abstract class is permitted to map interface methods onto abstract methods. For example

```
interface IMethods
{
   void F();
   void G();
}
abstract class C: IMethods
{
   public abstract void F();
   public abstract void G();
}
```

Here, the implementation of `IMethods` maps `F` and `G` onto abstract methods, which must be overridden in non-abstract classes that derive from `C`.

Note that explicit interface member implementations cannot be abstract, but explicit interface member implementations are of course permitted to call abstract methods. For example

```
interface IMethods
{
   void F();
   void G();
}
abstract class C: IMethods
{
   void IMethods.F() { FF(); }
   void IMethods.G() { GG(); }
   protected abstract void FF();
   protected abstract void GG();
}
```

Here, non-abstract classes that derive from `C` would be required to override `FF` and `GG`, thus providing the actual implementation of `IMethods`.

14. Enums

An enum type is a distinct value type (Section 4.1) that declares a set of named constants.

The example

```
enum Color
{
   Red,
   Green,
   Blue
}
```

declares an enum type named `Color` with members `Red`, `Green`, and `Blue`.

14.1 Enum declarations

An enum declaration declares a new enum type. An enum declaration begins with the keyword `enum`, and defines the name, accessibility, underlying type, and members of the enum.

enum-declaration:
  attributes$_{opt}$ *enum-modifiers*$_{opt}$ enum *identifier* *enum-base*$_{opt}$ *enum-body* ;$_{opt}$
enum-base:
  ; *integral-type*
enum-body:
  { *enum-member-declarations*$_{opt}$ }
  { *enum-member-declarations* , }

Each enum type has a corresponding integral type called the underlying type of the enum type. This underlying type must be able to represent all the enumerator values defined in the enumeration. An enum declaration may explicitly declare an underlying type of `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `long` or `ulong`. Note that `char` cannot be used as an underlying type. An enum declaration that does not explicitly declare an underlying type has an underlying type of `int`.

The example

```
enum Color: long
{
   Red,
   Green,
   Blue
}
```

declares an enum with an underlying type of `long`. A developer might choose to use an underlying type of `long`, as in the example, to enable the use of values that are in the range of `long` but not in the range of `int`, or to preserve this option for the future.

14.2 Enum modifiers

An *enum-declaration* may optionally include a sequence of enum modifiers:

enum-modifiers:
  enum-modifier
  enum-modifiers *enum-modifier*
enum-modifier:
  new
  public
  protected
  internal
  private

It is a compile-time error for the same modifier to appear multiple times in an enum declaration.

The modifiers of an enum declaration have the same meaning as those of a class declaration (Section 10.1.1). Note, however, that the `abstract` and `sealed` modifiers are not permitted in an enum declaration. Enums cannot be abstract and do not permit derivation.

14.3 Enum members

The body of an enum type declaration defines zero or more enum members, which are the named constants of the enum type. No two enum members can have the same name.

enum-member-declarations:
  enum-member-declaration
  enum-member-declarations , *enum-member-declaration*
enum-member-declaration:
  $attributes_{opt}$ *identifier*
  $attributes_{opt}$ *identifier* = *constant-expression*

Each enum member has an associated constant value. The type of this value is the underlying type for the containing enum. The constant value for each enum member must be in the range of the underlying type for the enum. The example

```
enum Color: uint
{
   Red = -1,
   Green = -2,
   Blue = -3
}
```

results in a compile-time error because the constant values `-1`, `-2`, and `-3` are not in the range of the underlying integral type `uint`.

Multiple enum members may share the same associated value. The example

```
enum Color
{
   Red,
   Green,
   Blue,
   Max = Blue
}
```

shows an enum in which two enum members — `Blue` and `Max` — have the same associated value.

The associated value of an enum member is assigned either implicitly or explicitly. If the declaration of the enum member has a *constant-expression* initializer, the value of that constant expression, implicitly converted to the underlying type of the enum, is the associated value of the enum member. If the declaration of the enum member has no initializer, its associated value is set implicitly, as follows:

- If the enum member is the first enum member declared in the enum type, its associated value is zero.
- Otherwise, the associated value of the enum member is obtained by increasing the associated value of the textually preceding enum member by one. This increased value must be within the range of values that can be represented by the underlying type; otherwise, a compile-time error occurs.

The example

```
using System;
enum Color
{
   Red,
   Green = 10,
   Blue
}
class Test
{
   static void Main() {
      Console.WriteLine(StringFromColor(Color.Red));
      Console.WriteLine(StringFromColor(Color.Green));
      Console.WriteLine(StringFromColor(Color.Blue));
   }
   static string StringFromColor(Color c) {
```

```
        switch (c) {
           case Color.Red:
              return String.Format("Red = {0}", (int) c);
           case Color.Green:
              return String.Format("Green = {0}", (int) c);
           case Color.Blue:
              return String.Format("Blue = {0}", (int) c);
           default:
              return "Invalid color";
        }
     }
  }
```

prints out the enum member names and their associated values. The output is:

```
Red = 0
Green = 10
Blue = 11
```

for the following reasons:

- The enum member `Red` is automatically assigned the value zero (since it has no initializer and is the first enum member).
- The enum member `Green` is explicitly given the value `10`.
- The enum member `Blue` is automatically assigned the value one greater than the member that textually precedes it.

The associated value of an enum member may not, directly or indirectly, use the value of its own associated enum member. Other than this circularity restriction, enum member initializers may freely refer to other enum member initializers, regardless of their textual position. Within an enum member initializer, values of other enum members are always treated as having the type of their underlying type, so that casts are not necessary when referring to other enum members.

The example

```
enum Circular
{
   A = B,
   B
}
```

results in a compile-time error because the declarations of `A` and `B` are circular. `A` depends on `B` explicitly, and `B` depends on `A` implicitly.

Enum members are named and scoped in a manner exactly analogous to fields within classes. The scope of an enum member is the body of its containing enum type. Within that scope, enum members can be referred to by their simple name. From all other code, the name of an enum member must be qualified with the name of its enum type. Enum members do not have any declared accessibility — an enum member is accessible if its containing enum type is accessible.

14.4 The System.Enum type

The type `System.Enum` is the abstract base class of all enum types (this is distinct and different from the underlying type of the enum type), and the members inherited from `System.Enum` are available in any enum type. A boxing conversion (Section 4.3.1) exists from any enum type to `System.Enum`, and an unboxing conversion (Section 4.3.2) exists from `System.Enum` to any enum type.

Note that `System.Enum` is not itself an *enum-type*. Rather, it is a *class-type* from which all *enum-type*s are derived. The type `System.Enum` inherits from the type `System.ValueType` (Section 4.1.1), which, in turn, inherits from type `object`. At run-time, a value of type `System.Enum` can be `null` or a reference to a boxed value of any enum type.

14.5 Enum values and operations

Each enum type defines a distinct type; an explicit enumeration conversion (Section 6.2.2) is required to convert between an enum type and an integral type, or between two enum types. The set of values that an enum type can take on is not limited by its enum members. In particular, any value of the underlying type of an enum can be cast to the enum type, and is a distinct valid value of that enum type.

Enum members have the type of their containing enum type (except within other enum member initializers: see Section 14.3). The value of an enum member declared in enum type `E` with associated value `v` is `(E)v`.

The following operators can be used on values of enum types: `==`, `!=`, `<`, `>`, `<=`, `>=` (Section 7.9.5), `+` (Section 7.7.4), `-` (Section 7.7.5), `^`, `&`, `|` (Section 7.10.2), `~` (Section 7.6.4), `++`, `--` (Section 7.5.9 and Section 7.6.5), `sizeof` (Section A.5.4).

15. Delegates

Delegates enable scenarios that other languages — such as C++, Pascal, and Modula — have addressed with function pointers. Unlike C++ function pointers, however, delegates are fully object oriented, and unlike C++ pointers to member functions, delegates encapsulate both an object instance and a method.

A delegate declaration defines a class that is derived from the class `System.Delegate`. A delegate instance encapsulates an invocation list, which is a list one or more methods, each of which is referred to as a callable entity. For instance methods, a callable entity consists of an instance and a method on that instance. For static methods, a callable entity consists of just a method. Invoking a delegate instance with an appropriate set of arguments causes each of the delegate's callable entities to be invoked with the given set of arguments.

An interesting and useful property of a delegate instance is that it does not know or care about the classes of the methods it encapsulates; all that matters is that those methods be compatible (Section 15.1) with the delegate's type. This makes delegates perfectly suited for "anonymous" invocation.

15.1 Delegate declarations

A *delegate-declaration* is a *type-declaration* (Section 9.5) that declares a new delegate type.

delegate-declaration:
  attributes$_{opt}$ *delegate-modifiers*$_{opt}$ delegate *return-type* *identifier* (*formal-parameter-list*$_{opt}$) ;
delegate-modifiers:
  delegate-modifier
  delegate-modifiers *delegate-modifier*
delegate-modifier:
  new
  public
  protected
  internal
  private

It is a compile-time error for the same modifier to appear multiple times in a delegate declaration.

The `new` modifier is only permitted on delegates declared within another type, in which case it specifies that such a delegate hides an inherited member by the same name, as described in Section 10.2.2.

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the delegate type. Depending on the context in which the delegate declaration occurs, some of these modifiers may not be permitted (Section 3.5.1).

The delegate's type name is *identifier*.

The optional *formal-parameter-list* specifies the parameters of the delegate, and *return-type* indicates the return type of the delegate. A method and a delegate type are compatible if both of the following are true:

- They have the same number or parameters, with the same types, in the same order, with the same parameter modifiers.
- Their return types are the same.

Delegate types in C# are name equivalent, not structurally equivalent. Specifically, two different delegate types that have the same parameter lists and return type are considered different delegate types. However, instances of two distinct but structurally equivalent delegate types may compare as equal (Section 7.9.8)).

For example:

```
delegate int D1(int i, double d);
class A
{
   public static int M1(int a, double b) {...}
}
class B
{
   delegate int D2(int c, double d);
   public static int M1(int f, double g) {...}
   public static void M2(int k, double l) {...}
   public static int M3(int g) {...}
   public static void M4(int g) {...}
}
```

The delegate types `D1` and `D2` are both compatible with the methods `A.M1` and `B.M1`, since they have the same return type and parameter list; however, these delegate types are two different types, so they are not interchangeable. The delegate types `D1` and `D2` are incompatible with the methods `B.M2`, `B.M3`, and `B.M4`, since they have different return types or parameter lists.

The only way to declare a delegate type is via a *delegate-declaration*. A delegate type is a class type that is derived from `System.Delegate`. Delegate types are implicitly `sealed`, so it is not permissible to derive any type from a delegate type. It is also not permissible to derive a non-delegate class type from `System.Delegate`. Note that `System.Delegate` is not itself a delegate type; it is a class type from which all delegate types are derived.

C# provides special syntax for delegate instantiation and invocation. Except for instantiation, any operation that can be applied to a class or class instance can also be applied to a delegate class or instance, respectively. In particular, it is possible to access members of the `System.Delegate` type via the usual member access syntax.

The set of methods encapsulated by a delegate instance is called an invocation list. When a delegate instance is created

(Section 15.2) from a single method, it encapsulates that method, and its invocation list contains only one entry. However, when two non-null delegate instances are combined, their invocation lists are concatenated — in the order left operand then right operand — to form a new invocation list, which contains two or more entries.

Delegates are combined using the binary + (Section 7.7.4) and += operators (Section 7.13.2). A delegate can be removed from a combination of delegates, using the binary - (Section 7.7.5) and -= operators (Section 7.13.2). Delegates can be compared for equality (Section 7.9.8).

The following example shows the instantiation of a number of delegates, and their corresponding invocation lists:

```
delegate void D(int x);
class C
{
   public static void M1(int i) {...}
   public static void M2(int i) {...}
}
class Test
{
   static void Main() {
      D cd1 = new D(C.M1);      // M1
      D cd2 = new D(C.M2);      // M2
      D cd3 = cd1 + cd2;      // M1 + M2
      D cd4 = cd3 + cd1;       // M1 + M2 + M1
      D cd5 = cd4 + cd3;       // M1 + M2 + M1 + M1 + M2
   }
}
```

When `cd1` and `cd2` are instantiated, they each encapsulate one method. When `cd3` is instantiated, it has an invocation list of two methods, `M1` and `M2`, in that order. `cd4`'s invocation list contains `M1`, `M2`, and `M1`, in that order. Finally, `cd5`'s invocation list contains `M1`, `M2`, `M1`, `M1`, and `M2`, in that order. For more examples of combining (as well as removing) delegates, see Section 15.3.

15.2 Delegate instantiation

An instance of a delegate is created by a *delegate-creation-expression* (Section 7.5.10.3). The newly created delegate instance then refers to either:

- The static method referenced in the *delegate-creation-expression*, or
- The target object (which cannot be `null`) and instance method referenced in the *delegate-creation-expression*, or
- Another delegate

For example:

```
delegate void D(int x);
class C
{
   public static void M1(int i) {...}
   public void M2(int i) {...}
}
class Test
{
   static void Main() {
      D cd1 = new D(C.M1);      // static method
      Test t = new C();
      D cd2 = new D(t.M2);      // instance method
      D cd3 = new D(cd2);      // another delegate
   }
}
```

Once instantiated, delegate instances always refer to the same target object and method. Remember, when two delegates are combined, or one is removed from another, a new delegate results with its own invocation list; the invocation lists of the delegates combined or removed remain unchanged.

15.3 Delegate invocation

C# provides special syntax for invoking a delegate. When a non-null delegate instance whose invocation list contains one entry is invoked, it invokes the one method with the same arguments it was given, and returns the same value as the referred to method. See Section 7.5.5.2 for detailed information on delegate invocation. If an exception occurs during the invocation of such a delegate, and that exception is not caught within the method that was invoked, the search for an exception catch clause continues in the method that called the delegate, as if that method had directly called the method to which that delegate referred.

Invocation of a delegate instance whose invocation list contains multiple entries proceeds by invoking each of the methods in the invocation list, synchronously, in order. Each method so called is passed the same set of arguments as was given to the delegate instance. If such a delegate invocation includes reference parameters (Section 10.5.1.2), each method invocation will occur with a reference to the same variable; changes to that variable by one method in the invocation list will be visible to methods further down the invocation list. If the delegate invocation includes output parameters or a return value, their final value will come from the invocation of the last delegate in the list.

If an exception occurs during processing of the invocation of such a delegate, and that exception is not caught within the method that was invoked, the search for an exception catch clause continues in the method that called the delegate, and any methods further down the invocation list are not invoked.

Attempting to invoke a delegate instance whose value is null results in an exception of type `System.NullReferenceException`.

The following example shows how to instantiate, combine, remove, and invoke delegates:

```
using System;
delegate void D(int x);
class C
{
   public static void M1(int i) {
      Console.WriteLine("C.M1: " + i);
   }
   public static void M2(int i) {
      Console.WriteLine("C.M2: " + i);
   }
   public void M3(int i) {
      Console.WriteLine("C.M3: " + i);
   }
}
class Test
{
   static void Main() {
      D cd1 = new D(C.M1);
      cd1(-1);            // call M1
      D cd2 = new D(C.M2);
      cd2(-2);            // call M2
      D cd3 = cd1 + cd2;
      cd3(10);            // call M1 then M2
      cd3 += cd1;
      cd3(20);            // call M1, M2, then M1
      C c = new C();
      D cd4 = new D(c.M3);
      cd3 += cd4;
      cd3(30);            // call M1, M2, M1, then M3
      cd3 -= cd1;         // remove last M1
      cd3(40);            // call M1, M2, then M3
      cd3 -= cd4;
      cd3(50);            // call M1 then M2
      cd3 -= cd2;
      cd3(60);            // call M1
      cd3 -= cd2;         // impossible removal is benign
      cd3(60);            // call M1
      cd3 -= cd1;         // invocation list is empty so cd3 is null
      //      cd3(70);      // System.NullReferenceException thrown
      cd3 -= cd1;         // impossible removal is benign
   }
}
```

As shown in the statement `cd3 += cd1;`, a delegate can be present in an invocation list multiple times. In this case, it is simply invoked once per occurrence. In an invocation list such as this, when that delegate is removed, the last occurrence in the invocation list is the one actually removed.

Immediately prior to the execution of the final statement, `cd3 -= cd1;`, the delegate `cd3` refers to an empty invocation list. Attempting to remove a delegate from an empty list (or to remove a non-existent delegate from a non-empty list) is not an error.

The output produced is:

```
C.M1: -1
C.M2: -2
C.M1: 10
C.M2: 10
C.M1: 20
C.M2: 20
C.M1: 20
C.M1: 30
C.M2: 30
C.M1: 30
C.M3: 30
C.M1: 40
C.M2: 40
C.M3: 40
C.M1: 50
C.M2: 50
C.M1: 60
C.M1: 60
```

16. Exceptions

Exceptions in C# provide a structured, uniform, and type-safe way of handling both system level and application level error conditions. The exception mechanism in C# is quite similar to that of C++, with a few important differences:

- In C#, all exceptions must be represented by an instance of a class type derived from `System.Exception`. In C++, any value of any type can be used to represent an exception.
- In C#, a finally block (Section 8.10) can be used to write termination code that executes in both normal execution and exceptional conditions. Such code is difficult to write in C++ without duplicating code.
- In C#, system-level exceptions such as overflow, divide-by-zero, and null dereferences have well defined exception classes and are on a par with application-level error conditions.

16.1 Causes of exceptions

Exception can be thrown in two different ways.

- A `throw` statement (Section 8.9.5) throws an exception immediately and unconditionally. Control never reaches the statement immediately following the `throw`.
- Certain exceptional conditions that arise during the processing of C# statements and expression cause an exception in certain circumstances when the operation cannot be completed normally. For example, an integer division operation (Section 7.7.2) throws a `System.DivideByZeroException` if the denominator is zero. See Section 16.4 for a list of the various exceptions that can occur in this way.

16.2 The System.Exception class

The `System.Exception` class is the base type of all exceptions. This class has a few notable properties that all exceptions share:

- `Message` is a read-only property of type `string` that contains a human-readable description of the reason for the exception.
- `InnerException` is a read-only property of type `Exception`. If its value is non-`null`, it refers to the exception that caused the current exception — that is, the current exception was raised in a catch block handling the `InnerException`. Otherwise, its value is null, indicating that this exception was not caused by another exception. The number of exception objects chained together in this manner can be arbitrary.

The value of these properties can be specified in calls to the instance constructor for `System.Exception`.

16.3 How exceptions are handled

Exceptions are handled by a `try` statement (Section 8.10).

When an exception occurs, the system searches for the nearest `catch` clause that can handle the exception, as determined by the run-time type of the exception. First, the current method is searched for a lexically enclosing `try` statement, and the associated catch clauses of the try statement are considered in order. If that fails, the method that called the current method is searched for a lexically enclosing `try` statement that encloses the point of the call to the current method. This search continues until a `catch` clause is found that can handle the current exception, by naming an exception class that is of the same class, or a base class, of the run-time type of the exception being thrown. A `catch` clause that doesn't name an exception class can handle any exception.

Once a matching catch clause is found, the system prepares to transfer control to the first statement of the catch clause. Before execution of the catch clause begins, the system first executes, in order, any `finally` clauses that were associated with try statements more nested that than the one that caught the exception.

If no matching catch clause is found, one of two things occurs:

- If the search for a matching catch clause reaches a static constructor (Section 10.11) or static field initializer, then a `System.TypeInitializationException` is thrown at the point that triggered the invocation of the static constructor. The inner exception of the `System.TypeInitializationException` contains the exception that was originally thrown.
- If the search for matching catch clauses reaches the code that initially started the thread, then execution of the thread is terminated. The impact of such termination is implementation-defined.

Exceptions that occur during destructor execution are worth special mention. If an exception occurs during destructor execution, and that exception is not caught, then the execution of that destructor is terminated and the destructor of the base class (if any) is called. If there is no base class (as in the case of the `object` type) or if there is no base class destructor, then the exception is discarded.

16.4 Common Exception Classes

The following exceptions are thrown by certain C# operations.

`System.ArithmeticException`	A base class for exceptions that occur during arithmetic operations, such as `System.DivideByZeroException` and `System.OverflowException`.
`System.ArrayTypeMismatchException`	Thrown when a store into an array fails because the actual type of the stored element is incompatible with the actual type of the array.
`System.DivideByZeroException`	Thrown when an attempt to divide an integral value by zero occurs.
`System.IndexOutOfRangeException`	Thrown when an attempt to index an array via an index that is less than zero or outside the bounds of the array.
`System.InvalidCastException`	Thrown when an explicit conversion from a base type or interface to a derived type fails at run time.
`System.NullReferenceException`	Thrown when a `null` reference is used in a way that causes the referenced object to be required.
`System.OutOfMemoryException`	Thrown when an attempt to allocate memory (via `new`) fails.
`System.OverflowException`	Thrown when an arithmetic operation in a `checked` context overflows.
`System.StackOverflowException`	Thrown when the execution stack is exhausted by having too many pending method calls; typically indicative of very deep or unbounded recursion.
`System.TypeInitializationException`	Thrown when a static constructor throws an exception, and no catch clauses exists to catch it.

17. Attributes

Much of the C# language enables the programmer to specify declarative information about the entities defined in the program. For example, the accessibility of a method in a class is specified by decorating it with the *method-modifiers* `public`, `protected`, `internal`, and `private`.

C# enables programmers to invent new kinds of declarative information, called attributes. Programmers can then attach attributes to various program entities, and retrieve attribute information in a run-time environment. For instance, a framework might define a `HelpAttribute` attribute that can be placed on certain program elements (such as classes and methods) to provide a mapping from those program elements to their documentation.

Attributes are defined through the declaration of attribute classes (Section 17.1), which may have positional and named parameters (Section 17.1.2). Attributes are attached to entities in a C# program using attribute specifications (Section 17.2), and can be retrieved at run-time as attribute instances (Section 17.3).

17.1 Attribute classes

A class that derives from the abstract class `System.Attribute`, whether directly or indirectly, is an attribute class. The declaration of an attribute class defines a new kind of attribute that can be placed on a declaration. By convention, attribute classes are named with a suffix of `Attribute`. Uses of an attribute may either include or omit this suffix.

17.1.1 Attribute usage

The attribute `AttributeUsage` (Section 17.4.1) is used to describe how an attribute class can be used.

`AttributeUsage` has a positional parameter (Section 17.1.2) that enables an attribute class to specify the kinds of declarations on which it can be used. The example

```
using System;
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Interface)]
public class SimpleAttribute: Attribute
{
   ...
}
```

defines an attribute class named `SimpleAttribute` that can be placed on *class-declarations* and *interface-declarations* only. The example

```
[Simple] class Class1 {...}
[Simple] interface Interface1 {...}
```

shows several uses of the `Simple` attribute. Although this attribute is defined with the name `SimpleAttribute`, when this attribute is used, the `Attribute` suffix may be omitted, resulting in the short name `Simple`. Thus, the example above is semantically equivalent to the following:

```
[SimpleAttribute] class Class1 {...}
[SimpleAttribute] interface Interface1 {...}
```

`AttributeUsage` has a named parameter (Section 17.1.2) called `AllowMultiple`, which indicates whether the attribute can be specified more than once for a given entity. If `AllowMultiple` for an attribute class is true, then that attribute class is a multi-use attribute class, and can be specified more than once on an entity. If `AllowMultiple` for an attribute class is false or it is unspecified, then that attribute class is a single-use attribute class, and can be specified at most once on an entity.

The example

```
using System;
[AttributeUsage(AttributeTargets.Class, AllowMultiple = true)]
public class AuthorAttribute: Attribute
{
   private string name;
   public AuthorAttribute(string name) {
      this.name = name;
   }
   public string Name {
      get { return name; }
   }
}
```

defines a multi-use attribute class named `AuthorAttribute`. The example

```
[Author("Brian Kernighan"), Author("Dennis Ritchie")]
class Class1
{
   ...
}
```

shows a class declaration with two uses of the `Author` attribute.

`AttributeUsage` has another named parameter called `Inherited`, which indicates whether the attribute, when specified on a base class, is also inherited by classes that derive from that base class. If `Inherited` for an attribute class is true, then that attribute is inherited. If `Inherited` for an attribute class is false or it is unspecified, then that attribute is not inherited.

An attribute class `X` not having an `AttributeUsage` attribute attached to it, as in

```
using System;
class X: Attribute {...}
```

is equivalent to the following:

```
using System;
[AttributeUsage(
   AttributeTargets.All,
   AllowMultiple = false,
   Inherited = true)
]
class X: Attribute {...}
```

17.1.2 Positional and named parameters

Attribute classes can have positional parameters and named parameters. Each public instance constructor for an attribute class defines a valid sequence of positional parameters for that attribute class. Each non-static public read-write field and property for an attribute class defines a named parameter for the attribute class.

The example

```
using System;
[AttributeUsage(AttributeTargets.Class)]
public class HelpAttribute: Attribute
{
   public HelpAttribute(string url) {      // Positional parameter
      ...
   }
   public string Topic {                  // Named parameter
      get {...}
      set {...}
   }
   public string Url {
      get {...}
   }
```

```
}
```

defines an attribute class named `HelpAttribute` that has one positional parameter, `url`, and one named parameter, `Topic`. Although it is non-static and public, the property `Url` does not define a named parameter, since it is not read-write.

This attribute class might be used as follows:

```
[Help("http://www.example.com/.../Class1.htm")]
class Class1
{
   ...
}
[Help("http://www.example.com/.../Misc.htm", Topic = "Class2")]
class Class2
{
   ...
}
```

17.1.3 Attribute parameter types

The types of positional and named parameters for an attribute class are limited to the attribute parameter types, which are:

- One of the following types: `bool`, `byte`, `char`, `double`, `float`, `int`, `long`, `short`, `string`.
- The type `object`.
- The type `System.Type`.
- An enum type, provided it has public accessibility and the types in which it is nested (if any) also have public accessibility (Section 17.2).
- Single-dimensional arrays of the above types.

17.2 Attribute specification

Attribute specification is the application of a previously defined attribute to a declaration. An attribute is a piece of additional declarative information that is specified for a declaration. Attributes can be specified at global scope (to specify attributes on the containing assembly or module) and for *type-declarations* (Section 9.5), *class-member-declarations* (Section 10.2), *interface-member-declarations* (Section 13.2), *struct-member-declarations* (Section 11.2), *enum-member-declarations* (Section 14.3), *accessor-declarations* for properties (Section 10.6.2), *event-accessor-declarations* (Section 10.7.1), and *formal-parameter-lists* (Section 10.5.1).

Attributes are specified in attribute sections. An attribute section consists of a pair of square brackets, which surround a comma-separated list of one or more attributes. The order in which attributes are specified in such a list, and the order in which sections attached to the same program entity are arranged, is not significant. For instance, the attribute specifications `[A][B]`, `[B][A]`, `[A, B]`, and `[B, A]` are equivalent.

  named-argument-list , *named-argument*

named-argument:
  identifier = *attribute-argument-expression*
attribute-argument-expression:
  expression

An attribute consists of an *attribute-name* and an optional list of positional and named arguments. The positional arguments (if any) precede the named arguments. A positional argument consists of an *attribute-argument-expression*; a named argument consists of a name, followed by an equal sign, followed by an *attribute-argument-expression*, which, together, are constrained by the same rules as simple assignment. The order of named arguments is not significant.

The *attribute-name* identifies an attribute class. If the form of *attribute-name* is *type-name* then this name must refer to an attribute class. Otherwise, a compile-time error occurs. The example

```
class Class1 {}
[Class1] class Class2 {}   // Error
```

results in a compile-time error because it attempts to use `Class1` as an attribute class when `Class1` is not an attribute class.

Certain contexts permit the specification of an attribute on more than one target. A program can explicitly specify the target by including an *attribute-target-specifier*. When an attribute is placed at the global level, a *global-attribute-target-specifier* is required. In all other locations, a reasonable default is applied, but an *attribute-target-specifier* can be used to affirm or override the default in certain ambiguous cases (or to just affirm the default in non-ambiguous cases). Thus, typically, *attribute-target-specifier*s can be omitted except at the global level. The potentially ambiguous contexts are resolved as follows:

- An attribute specified at global scope can apply either to the target assembly or the target module. No default exists for this context, so an *attribute-target-specifier* is always required in this context. The presence of the `assembly` *attribute-target-specifier* indicates that the attribute applies to the target assembly; the presence of the `module` *attribute-target-specifier* indicates that the attribute applies to the target module.
- An attribute specified on a delegate declaration can apply either to the delegate being declared or to its return value. In the absence of an *attribute-target-specifier*, the attribute applies to the delegate. The presence of the `type` *attribute-target-specifier* indicates that the attribute applies to the delegate; the presence of the `return` *attribute-target-specifier* indicates that the attribute applies to the return value.
- An attribute specified on a method declaration can apply either to the method being declared or to its return value. In the absence of an *attribute-target-specifier*, the attribute applies to the method. The presence of the `method` *attribute-target-specifier* indicates that the attribute applies to the method; the presence of the `return` *attribute-target-specifier* indicates that the attribute applies to the return value.
- An attribute specified on an operator declaration can apply either to the operator being declared or to its return value. In the absence of an *attribute-target-specifier*, the attribute applies to the operator. The presence of the `method` *attribute-target-specifier* indicates that the attribute applies to the operator; the presence of the `return` *attribute-target-specifier* indicates that the attribute applies to the return value.
- An attribute specified on an event declaration that omits event accessors can apply to the event being declared, to the associated field (if the event is not abstract), or to the associated add and remove methods. In the absence of an *attribute-target-specifier*, the attribute applies to the event. The presence of the `event` *attribute-target-specifier* indicates that the

attribute applies to the event; the presence of the `field` *attribute-target-specifier* indicates that the attribute applies to the field; and the presence of the `method` *attribute-target-specifier* indicates that the attribute applies to the methods.

- An attribute specified on a get accessor declaration for a property or indexer declaration can apply either to the associated method or to its return value. In the absence of an *attribute-target-specifier*, the attribute applies to the method. The presence of the `method` *attribute-target-specifier* indicates that the attribute applies to the method; the presence of the `return` *attribute-target-specifier* indicates that the attribute applies to the return value.
- An attribute specified on a set accessor for a property or indexer declaration can apply either to the associated method or to its lone implicit parameter. In the absence of an *attribute-target-specifier*, the attribute applies to the method. The presence of the `method` *attribute-target-specifier* indicates that the attribute applies to the method; the presence of the `param` *attribute-target-specifier* indicates that the attribute applies to the parameter.
- An attribute specified on an add or remove accessor declaration for an event declaration can apply either to the associated method or to its lone parameter. In the absence of an *attribute-target-specifier*, the attribute applies to the method. The presence of the `method` *attribute-target-specifier* indicates that the attribute applies to the method; the presence of the `param` *attribute-target-specifier* indicates that the attribute applies to the parameter.

In other contexts, inclusion of an *attribute-target-specifier* is permitted but unnecessary. For instance, a class declaration may either include or omit the specifier type:

```
[type: Author("Brian Kernighan")]
class Class1 {}
[Author("Dennis Ritchie")]
class Class2 {}
```

It is an error to specify an invalid *attribute-target-specifier*. For instance, the specifier param cannot be used on a class declaration:

```
[param: Author("Brian Kernighan")]      // Error
class Class1 {}
```

By convention, attribute classes are named with a suffix of `Attribute`. An *attribute-name* of the form *type-name* may either include or omit this suffix. If an attribute class is found both with and without this suffix, an ambiguity is present, and a compile-time error results. If the *attribute-name* is spelled such that its right-most identifier is a verbatim identifier (Section 2.4.2), then only an attribute without a suffix is matched, thus enabling such an ambiguity to be resolved. The example

```
using System;
[AttributeUsage(AttributeTargets.All)]
public class X: Attribute
{}
[AttributeUsage(AttributeTargets.All)]
public class XAttribute: Attribute
{}
[X]                  // Error: ambiguity
class Class1 {}
[XAttribute]         // Refers to XAttribute
class Class2 {}
[@X]                  // Refers to X
class Class3 {}
[@XAttribute]         // Refers to XAttribute
class Class4 {}
```

shows two attribute classes named `X` and `XAttribute`. The attribute `[X]` is ambiguous, since it could refer to either `X` or `XAttribute`. Using a verbatim identifier allows the exact intent to be specified in such rare cases. The attribute `[XAttribute]` is not ambiguous (although it would be if there was an attribute class named `XAttributeAttribute`!). If the declaration for class `X` is removed, then both attributes refer to the attribute class named `XAttribute`, as follows:

```
using System;
[AttributeUsage(AttributeTargets.All)]
```

```
public class XAttribute: Attribute
{}
[X]                  // Refers to XAttribute
class Class1 {}
[XAttribute]         // Refers to XAttribute
class Class2 {}
[@X]                  // Error: no attribute named "X"
class Class3 {}
```

It is a compile-time error to use a single-use attribute class more than once on the same entity. The example

```
using System;
[AttributeUsage(AttributeTargets.Class)]
public class HelpStringAttribute: Attribute
{
   string value;
   public HelpStringAttribute(string value) {
      this.value = value;
   }
   public string Value {
      get {...}
   }
}
[HelpString("Description of Class1")]
[HelpString("Another description of Class1")]
public class Class1 {}
```

results in a compile-time error because it attempts to use `HelpString`, which is a single-use attribute class, more than once on the declaration of `Class1`.

An expression `E` is an *attribute-argument-expression* if all of the following statements are true:

- The type of `E` is an attribute parameter type (Section 17.1.3).
- At compile-time, the value of `E` can be resolved to one of the following:
    - A constant value.
    - A `System.Type` object.
    - A one-dimensional array of *attribute-argument-expressions*.

For example:

```
using System;
[AttributeUsage(AttributeTargets.Class)]
public class TestAttribute: Attribute
{
   public int P1 {
      get {...}
      set {...}
   }
   public Type P2 {
      get {...}
      set {...}
   }
   public object P3 {
      get {...}
      set {...}
   }
}
[Test(P1 = 1234, P3 = new int[] {1, 3, 5}, P2 = typeof(float))]
class MyClass {}
```

17.3 Attribute instances

An attribute instance is an instance that represents an attribute at run-time. An attribute is defined with an attribute class, positional arguments, and named arguments. An attribute instance is an instance of the attribute class that is initialized with the positional and named arguments.

Retrieval of an attribute instance involves both compile-time and run-time processing, as described in the following sections.

17.3.1 Compilation of an attribute

The compilation of an *attribute* with attribute class `T`, *positional-argument-list* `P` and *named-argument-list* `N`, consists of the following steps:

- Follow the compile-time processing steps for compiling an object-creation-expression of the form new `T(P)`. These steps either result in a compile-time error or determine an instance constructor `C` on `T` that can be invoked at run-time.
- If `C` does not have public accessibility, then a compile-time error occurs.
- For each *named-argument* `Arg` in `N`:
  - Let `Name` be the *identifier* of the *named-argument* `Arg`.
  - `Name` must identify a non-static read-write public field or property on `T`. If `T` has no such field or property, then a compile-time error occurs.
- Keep the following information for run-time instantiation of the attribute: the attribute class `T`, the instance constructor `C` on `T`, the *positional-argument-list* `P` and the *named-argument-list* `N`.

17.3.2 Run-time retrieval of an attribute instance

Compilation of an *attribute* yields an attribute class `T`, an instance constructor `C` on T, a *positional-argument-list* `P`, and a *named-argument-list* `N`. Given this information, an attribute instance can be retrieved at run-time using the following steps:

- Follow the run-time processing steps for executing an *object-creation-expression* of the form `new T(P)`, using the instance constructor `C` as determined at compile-time. These steps either result in an exception, or produce an instance `O` of `T`.
- For each *named-argument* `Arg` in `N, in order`:
  - Let `Name` be the *identifier* of the *named-argument* `Arg`. If `Name` does not identify a non-static public read-write field or property on `O`, then an exception is thrown.
  - Let `Value` be the result of evaluating the *attribute-argument-expression* of `Arg`.
  - If `Name` identifies a field on `O`, then set this field to `Value`.
  - Otherwise, `Name` identifies a property on `O`. Set this property to `Value`.
  - The result is `O`, an instance of the attribute class `T` that has been initialized with the *positional-argument-list* `P` and the *named-argument-list* `N`.

17.4 Reserved attributes

A small number of attributes affect the language in some way. These attributes include:

- `System.AttributeUsageAttribute` (Section 17.4.1), which is used to describe the ways in which an attribute class can be used.
- `System.Diagnostics.ConditionalAttribute` (Section 17.4.2), which is used to define conditional methods.
- `System.ObsoleteAttribute` (Section 17.4.3), which is used to mark a member as obsolete.

17.4.1 The AttributeUsage attribute

The attribute `AttributeUsage` is used to describe the manner in which the attribute class can be used.

A class that is decorated with the `AttributeUsage` attribute must derive from `System.Attribute`, either directly or indirectly. Otherwise, a compile-time error occurs.

```
namespace System
{
   [AttributeUsage(AttributeTargets.Class)]
   public class AttributeUsageAttribute: Attribute
   {
      public AttributeUsageAttribute(AttributeTargets validOn) {...}
      public virtual bool AllowMultiple { get {...} set {...} }
      public virtual bool Inherited { get {...} set {...} }
      public virtual AttributeTargets ValidOn { get {...} }
   }
   public enum AttributeTargets
   {
      Assembly    = 0x0001,
      Module       = 0x0002,
      Class       = 0x0004,
      Struct       = 0x0008,
      Enum          = 0x0010,
      Constructor = 0x0020,
      Method       = 0x0040,
      Property    = 0x0080,
      Field       = 0x0100,
      Event       = 0x0200,
      Interface    = 0x0400,
      Parameter    = 0x0800,
      Delegate    = 0x1000,
      ReturnValue = 0x2000,
      All = Assembly | Module | Class | Struct | Enum | Constructor |
         Method | Property | Field | Event | Interface | Parameter |
         Delegate | ReturnValue
   }
}
```

17.4.2 The Conditional attribute

The attribute `Conditional` enables the definition of conditional methods. The `Conditional` attribute indicates a condition by testing a conditional compilation symbol. Calls to a conditional method are either included or omitted depending on whether this symbol is defined at the point of the call. If the symbol is defined, the call is included; otherwise, the call (including evaluation of the parameters of the call) is omitted.

```
namespace System.Diagnostics
{
   [AttributeUsage(AttributeTargets.Method, AllowMultiple = true)]
   public class ConditionalAttribute: Attribute
   {
      public ConditionalAttribute(string conditionString) {...}
      public string ConditionString { get {...} }
   }
}
```

A conditional method is subject to the following restrictions:

- The conditional method must be a method in a class or struct declaration. A compile-time error occurs if the `Conditional` attribute is specified on a method in an interface declaration.
- The conditional method must have a return type of `void`.
- The conditional method must not be marked with the `override` modifier. A conditional method may be marked with the `virtual` modifier, however. Overrides of such a method are implicitly conditional, and must not be explicitly marked with a `Conditional` attribute.
- The conditional method must not be an implementation of an interface method. Otherwise, a compile-time error occurs.

In addition, a compile-time error occurs if a conditional method is used in a *delegate-creation-expression*. The example

```
#define DEBUG
using System;
using System.Diagnostics;
class Class1
{
   [Conditional("DEBUG")]
   public static void M() {
      Console.WriteLine("Executed Class1.M");
   }
}
class Class2
{
   public static void Test() {
      Class1.M();
   }
}
```

declares `Class1.M` as a conditional method. `Class2`'s `Test` method calls this method. Since the conditional compilation symbol `DEBUG` is defined, if `Class2.Test` is called, it will call `M`. If the symbol `DEBUG` had not been defined, then `Class2.Test` would not call `Class1.M`.

It is important to note that the inclusion or exclusion of a call to a conditional method is controlled by the conditional compilation symbols at the point of the call. In the example

File `class1.cs`:

```
using System.Diagnostics;
class Class1
{
   [Conditional("DEBUG")]
   public static void F() {
      Console.WriteLine("Executed Class1.F");
   }
```

```
}
```

File `class2.cs`:

```
#define DEBUG
class Class2
{
   public static void G() {
      Class1.F();            // F is called
   }
}
```

File `class3.cs`:

```
#undef DEBUG
class Class3
{
   public static void H() {
      Class1.F();            // F is not called
   }
}
```

the classes `Class2` and `Class3` each contain calls to the conditional method `Class1.F`, which is conditional based on whether or not `DEBUG` is defined. Since this symbol is defined in the context of `Class2` but not `Class3`, the call to `F` in `Class2` is included, while the call to F in `Class3` is omitted.

The use of conditional methods in an inheritance chain can be confusing. Calls made to a conditional method through `base`, of the form `base.M`, are subject to the normal conditional method call rules. In the example

File `class1.cs`:

```
using System;
using System.Diagnostics;
class Class1
{
   [Conditional("DEBUG")]
   public virtual void M() {
      Console.WriteLine("Class1.M executed");
   }
}
```

File `class2.cs`:

```
using System;
class Class2: Class1
{
   public override void M() {
      Console.WriteLine("Class2.M executed");
      base.M();                  // base.M is not called!
   }
}
```

File `class3.cs`:

```
#define DEBUG
using System;
class Class3
{
   public static void Test() {
      Class2 c = new Class2();
      c.M();                     // M is called
   }
}
```

`Class2` includes a call to the `M` defined in its base class. This call is omitted because the base method is conditional based on the presence of the symbol `DEBUG`, which is undefined. Thus, the method writes to the console "`Class2.M executed`" only. Judicious use of *pp-declaration*s can eliminate such problems.

17.4.3 The Obsolete attribute

The attribute `Obsolete` is used to mark types and members of types that should no longer be used.

```
namespace System
{
   [AttributeUsage(
      AttributeTargets.Class |
      AttributeTargets.Struct |
       AttributeTargets.Enum |
      AttributeTargets.Interface |
      AttributeTargets.Delegate |
      AttributeTargets.Method |
      AttributeTargets.Constructor |
      AttributeTargets.Property |
      AttributeTargets.Field |
      AttributeTargets.Event,
      Inherited = false)
   ]
   public class ObsoleteAttribute: Attribute
   {
      public ObsoleteAttribute() {...}
      public ObsoleteAttribute(string message) {...}
      public ObsoleteAttribute(string message, bool error) {...}
      public string Message { get {...} }
      public bool IsError { get {...} }
   }
}
```

If a program uses a type or member that is decorated with the `Obsolete` attribute, the compiler issues a warning or an error. Specifically, the compiler issues a warning if no error parameter is provided, or if the error parameter is provided and has the value false. The compiler issues an error if the error parameter is specified and has the value true.

In the example

```
[Obsolete("This class is obsolete; use class B instead")]
class A
{
   public void F() {}
}
class B
{
   public void F() {}
}
class Test
{
   static void Main() {
      A a = new A();       // Warning
      a.F();
   }
}
```

the class `A` is decorated with the `Obsolete` attribute. Each use of `A` in `Main` results in a warning that includes the specified message, "This class is obsolete; use class B instead."

17.5 Attributes for Interoperation

Note This section is applicable only to the Microsoft .NET implementation of C#.

17.5.1 Interoperation with COM and Win32 components

The .NET runtime provides a large number of attributes that enable C# programs to interoperate with components written using COM and Win32 DLLs. For example, the `DllImport` attribute can be used on a `static extern` method to indicate that the implementation of the method is to be found in a Win32 DLL. These attributes are found in the `System.Runtime.InteropServices` namespace, and detailed documentation for these attributes is found in the .NET runtime documentation.

17.5.2 Interoperation with other .NET languages

The following section describes the `IndexerName` attribute.

17.5.2.1 The IndexerName attribute

Indexers are implemented in .NET using indexed properties, and have a name in the .NET metadata. If no `IndexerName` attribute is present for an indexer, then the name `Item` is used by default. The `IndexerName` attribute enables a developer to override this default and specify a different name.

```
namespace System.Runtime.CompilerServices.CSharp
{
   [AttributeUsage(AttributeTargets.Property)]
   public class IndexerNameAttribute: Attribute
   {
      public IndexerNameAttribute(string indexerName) {...}
      public string Value { get {...} }
   }
}
```

A. Unsafe code

The core C# language, as defined in the preceding chapters, differs notably from C and C++ in its omission of pointers as a data type. Instead, C# provides references and the ability to create objects that are managed by a garbage collector. This design, coupled with other features, makes C# a much safer language than C or C++. In the core C# language it is simply not possible to have an uninitialized variable, a "dangling" pointer, or an expression that indexes an array beyond its bounds. Whole categories of bugs that routinely plague C and C++ programs are thus eliminated.

While practically every pointer type construct in C or C++ has a reference type counterpart in C#, nonetheless, there are situations where access to pointer types becomes a necessity. For example, interfacing with the underlying operating system, accessing a memory-mapped device, or implementing a time-critical algorithm may not be possible or practical without access to pointers. To address this need, C# provides the ability to write unsafe code.

In unsafe code it is possible to declare and operate on pointers, to perform conversions between pointers and integral types, to take the address of variables, and so forth. In a sense, writing unsafe code is much like writing C code within a C# program.

Unsafe code is in fact a "safe" feature from the perspective of both developers and users. Unsafe code must be clearly marked with the modifier `unsafe`, so developers can't possibly use unsafe features accidentally, and the execution engine works to ensure that unsafe code cannot be executed in an untrusted environment.

A.1 Unsafe contexts

The unsafe features of C# are available only in *unsafe contexts*. An unsafe context is introduced by including an `unsafe` modifier in the declaration of a type or member, or by employing an *unsafe-statement*:

- A declaration of a class, struct, interface, or delegate may include an `unsafe` modifier, in which case the entire textual extent of that type declaration (including the body of the class, struct, or interface) is considered an unsafe context.
- A declaration of a field, method, property, event, indexer, operator, instance constructor, destructor, or static constructor may include an `unsafe` modifier, in which case the entire textual extent of that member declaration is considered an unsafe context.
- An *unsafe-statement* enables the use of an unsafe context within a *block*. The entire textual extent of the associated *block* is considered an unsafe context.

The associated grammar extensions are shown below. For brevity, ellipses (...) are used to represent productions that appear in preceding chapters.

class-modifier:
  ...
  unsafe
struct-modifier:
  ...
  unsafe
interface-modifier:
  ...
  unsafe
delegate-modifier:
  ...
  unsafe
field-modifier:
  ...
  unsafe
method-modifier:
  ...
  unsafe
property-modifier:
  ...
  unsafe
event-modifier:
  ...
  unsafe
indexer-modifier:
  ...
  unsafe
operator-modifier:
  ...
  unsafe
constructor-modifier:
  ...
  unsafe
destructor-declaration:
  attributes$_{opt}$ extern$_{opt}$ unsafe$_{opt}$ ~ *identifier* ( ) *destructor-body*
  attributes$_{opt}$ unsafe$_{opt}$ extern$_{opt}$ ~ *identifier* ( ) *destructor-body*
static-constructor-declaration:
  attributes$_{opt}$ extern$_{opt}$ unsafe$_{opt}$ static *identifier* ( ) *static-constructor-body*
  attributes$_{opt}$ unsafe$_{opt}$ extern$_{opt}$ static *identifier* ( ) *static-constructor-body*
embedded-statement:
  ...
  unsafe-statement
unsafe-statement:
  unsafe *block*

In the example

```
public unsafe struct Node
{
   public int Value;
   public Node* Left;
   public Node* Right;
}
```

the `unsafe` modifier specified in the struct declaration causes the entire textual extent of the struct declaration to become an unsafe context. Thus, it is possible to declare the `Left` and `Right` fields to be of a pointer type. The example above could also be written

```
public struct Node
{
   public int Value;
   public unsafe Node* Left;
   public unsafe Node* Right;
}
```

Here, the `unsafe` modifiers in the field declarations cause those declarations to be considered unsafe contexts.

Other than establishing an unsafe context, thus permitting the use of pointer types, the `unsafe` modifier has no effect on a type or a member. In the example

```
public class A
{
   public unsafe virtual void F() {
      char* p;
      ...
   }
}
public class B: A
{
   public override void F() {
      base.F();
      ...
   }
}
```

the `unsafe` modifier on the `F` method in `A` simply causes the textual extent of `F` to become an unsafe context in which the unsafe features of the language can be used. In the override of `F` in `B`, there is no need to re-specify the `unsafe` modifier — unless, of course, the `F` method in `B` itself needs access to unsafe features.

The situation is slightly different when a pointer type is part of the method's signature

```
public unsafe class A
{
   public virtual void F(char* p) {...}
}
public class B: A
{
   public unsafe override void F(char* p) {...}
}
```

Here, because `F`'s signature includes a pointer type, it can only be written in an unsafe context. However, the unsafe context can be introduced by either making the entire class unsafe, as is the case in `A`, or by including an `unsafe` modifier in the method declaration, as is the case in `B`.

A.2 Pointer types

In an unsafe context, a *type* (Section 4) may be a *pointer-type* as well as a *value-type* or a *reference-type*.

type:
  value-type
  reference-type
  pointer-type

A *pointer-type* is written as an *unmanaged-type* or the keyword `void`, followed by a `*` token:

pointer-type:
  unmanaged-type `*`
  void `*`
unmanaged-type:
  type

The type specified before the `*` in a pointer type is called the referent type of the pointer type. It represents the type of the variable to which a value of the pointer type points.

Unlike references (values of reference types), pointers are not tracked by the garbage collector — the garbage collector has no knowledge of pointers and the data to which they point. For this reason a pointer is not permitted to point to a reference or to a struct that contains references, and the referent type of a pointer must be an *unmanaged-type*.

An *unmanaged-type* is any type that isn't a *reference-type* and doesn't contain *reference-type* fields at any level of nesting. In other words, an *unmanaged-type* is one of the following:

- `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, or `bool`.
- Any *enum-type*.
- Any *pointer-type*.
- Any user-defined *struct-type* that contains fields of *unmanaged-types* only.

The intuitive rule for mixing of pointers and references is that referents of references (objects) are permitted to contain pointers, but referents of pointers are not permitted to contain references.

Some examples of pointer types are given in the table below:

Example	Description
`byte*`	Pointer to `byte`
`char*`	Pointer to `char`
`int**`	Pointer to pointer to `int`
`int*[]`	Single-dimensional array of pointers to `int`
`void*`	Pointer to unknown type

For a given implementation, all pointer types must have the same size and representation.

Unlike C and C++, when multiple pointers are declared in the same declaration, in C# the `*` is written along with the underlying type only, not as a prefix punctuator on each pointer name. For example

```
int* pi, pj;   // NOT as int *pi, *pj;
```

The value of a pointer having type `T*` represents the *address* of a variable of type `T`. The pointer indirection operator `*` (Section A.5.1) may be used to access this variable. For example, given

a variable `P` of type `int*`, the expression `*P` denotes the `int` variable found at the address contained in `P`.

Like an object reference, a pointer may be `null`. Applying the indirection operator to a `null` pointer results in implementation-defined behavior. A pointer with value `null` is represented by all-bits-zero.

The `void*` type represents a pointer to an unknown type. Because the referent type is unknown, the indirection operator cannot be applied to a pointer of type `void*, nor can any arithmetic be performed on such a pointer`. However, a pointer of type `void*` can be cast to any other pointer type (and vice versa).

Pointer types are a separate category of types. Unlike reference types and value types, pointer types do not inherit from `object` and no conversions exist between pointer types and `object`. In particular, boxing and unboxing (Section 4.3) are not supported for pointers. However, conversions are permitted between different pointer types and between pointer types and the integral types. This is described in Section A.4.

A pointer type may be used as the type of a volatile field (Section 10.4.3).

Although pointers can be passed as `ref` or `out` parameters, doing so can cause undefined behavior, since the pointer may well be set to point to a local variable which no longer exists when the called method returns, or the fixed object to which it used to point, is no longer fixed. For example:

```
using System;
class Test
{
   static int value = 20;
   unsafe static void F(out int* pi1, ref int* pi2) {
      int i = 10;
      pi1 = &i;
      fixed (int* pj = &value) {
         // ...
         pi2 = pj;
      }
   }
   static void Main() {
      int i = 10;
      unsafe {
         int* px1;
         int* px2 = &i;
         F(out px1, ref px2);
         Console.WriteLine("*px1 = {0}, *px2 = {1}",
            *px1, *px2);   // undefined behavior
      }
   }
}
```

A method can return a value of some type, and that type can be a pointer. For example, when given a pointer to a contiguous sequence of `int`s, that sequence's element count, and some other `int` value, the following method returns the address of that value in that sequence, if a match occurs; otherwise it returns `null`:

```
unsafe static int* Find(int* pi, int size, int value) {
   for (int i = 0; i < size; ++i) {
      if (*pi == value)
         return pi;
      ++pi;
   }
   return null;
}
```

In an unsafe context, several constructs are available for operating on pointers:

- The `*` operator may be used to perform pointer indirection (Section A.5.1).
- The `->` operator may be used to access a member of a struct through a pointer (Section A.5.2).
- The `[]` operator may be used to index a pointer (Section A.5.3).
- The `&` operator may be used to obtain the address of a variable (Section A.5.4).
- The `++` and `--` operators may be used to increment and decrement pointers (Section A.5.5).

- The `+` and `-` operators may be used to perform pointer arithmetic (Section A.5.6).
- The `==`, `!=`, `<`, `>`, `<=`, and `=>` operators may be used to compare pointers (Section A.5.7).
- The `stackalloc` operator may be used to allocate memory from the call stack (Section A.7).
- The `fixed` statement may be used to temporarily fix a variable so its address can be obtained (Section A.6).

A.3 Fixed and moveable variables

The address-of operator (Section A.5.4) and the `fixed` statement (Section A.6) divide variables into two categories: Fixed variables and moveable variables.

Fixed variables reside in storage locations that are unaffected by operation of the garbage collector. (Examples of fixed variables include local variables, value parameters, and variables created by dereferencing pointers.) On the other hand, moveable variables reside in storage locations that are subject to relocation or disposal by the garbage collector. (Examples of moveable variables include fields in objects and elements of arrays.)

The `&` operator (Section A.5.4) permits the address of a fixed variable to be obtained without restrictions. However, because a moveable variable is subject to relocation or disposal by the garbage collector, the address of a moveable variable can only be obtained using a `fixed` statement (Section A.6), and that address remains valid only for the duration of that `fixed` statement.

In precise terms, a fixed variable is one of the following:

- A variable resulting from a *simple-name* (Section 7.5.2) that refers to a local variable or a value parameter.
- A variable resulting from a *member-access* (Section 7.5.4) of the form `V.I`, where `V` is a fixed variable of a *struct-type*.
- A variable resulting from a *pointer-indirection-expression* (Section A.5.1) of the form `*P`, a *pointer-member-access* (Section A.5.2) of the form `P->I`, or a *pointer-element-access* (Section A.5.3) of the form `P[E]`.

All other variables are classified as moveable variables.

Note that a static field is classified as a moveable variable. Also note that a `ref` or `out` parameter is classified as a moveable variable, even if the argument given for the parameter is a fixed variable. Finally, note that a variable produced by dereferencing a pointer is always classified as a fixed variable.

A.4 Pointer conversions

In an unsafe context, the set of available implicit conversions (Section 6.1) is extended to include the following implicit pointer conversions:

- From any *pointer-type* to the type `void*`.
- From the null type to any *pointer-type*.

Additionally, in an unsafe context, the set of available explicit conversions (Section 6.2) is extended to include the following explicit pointer conversions:

- From any *pointer-type* to any other *pointer-type*.
- From `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, or `ulong` to any *pointer-type*.
- From any *pointer-type* to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, or `ulong`.

Finally, in an unsafe context, the set of standard implicit conversions (Section 6.3.1) includes the following pointer conversion:

- From any *pointer-type* to the type `void*`.

Conversions between two pointer types never change the actual pointer value. In other words, a conversion from one pointer type to another has no effect on the underlying address given by the pointer.

When one pointer type is converted to another, if the resulting pointer is not correctly aligned for the pointed-to type, the behavior is undefined if the result is dereferenced. In general, the concept "correctly aligned" is transitive: if a pointer to type `A` is correctly aligned for a pointer to type `B`, which, in turn, is correctly aligned for a pointer to type `C`, then a pointer to type `A` is correctly aligned for a pointer to type `C`.

Consider the following case in which a variable having one type is accessed via a pointer to a different type:

```
char c = 'A';
char* pc = &c;
void* pv = pc;
int* pi = (int*)pv;
int i = *pi;      // undefined
*pi = 123456;      // undefined
```

When a pointer type is converted to a pointer to byte, the result points to the lowest addressed byte of the variable. Successive increments of the result, up to the size of the variable, yield pointers to the remaining bytes of that variable. For example, the following method displays each of the eight bytes in a double as a hexadecimal value:

```
using System;
class Test
{
   unsafe static void Main() {
      double d = 123.456e23;
      unsafe {
         byte* pb = (byte*)&d;
         for (int i = 0; i < sizeof(double); ++i)
            Console.Write("{0:X2} ", *pb++);
         Console.WriteLine();
      }
   }
}
```

Of course, the output produced depends on endianness.

Mappings between pointers and integers are implementation-defined. However, on 32- and 64-bit CPU architectures with a linear address space, conversions of pointers to or from integral types typically behave exactly like conversions of `uint` or `ulong` values, respectively, to or from those integral types.

A.5 Pointers in expressions

In an unsafe context an expression may yield a result of a pointer type, but outside an unsafe context it is a compile-time error for an expression to be of a pointer type. In precise terms, outside an unsafe context a compile-time error occurs if any *simple-name* (Section 7.5.2), *member-access* (Section 7.5.4), *invocation-expression* (Section 7.5.5), or *element-access* (Section 7.5.6) is of a pointer type.

In an unsafe context, the *primary-no-array-creation-expression* (Section 7.5) and *unary-expression* (Section 7.6) productions permit the following additional constructs:

primary-no-array-creation-expression:
  ...
  pointer-member-access
  pointer-element-access
  sizeof-expression
unary-expression:
  ...
  pointer-indirection-expression
  addressof-expression

These constructs are described in the following sections. The precedence and associativity of the unsafe operators is implied by the grammar.

A.5.1 Pointer indirection

A *pointer-indirection-expression* consists of an asterisk (`*`) followed by a *unary-expression*.

pointer-indirection-expression:
  `*` *unary-expression*

The unary `*` operator denotes *pointer indirection* and is used to obtain the variable to which a pointer points. The result of evaluating `*P`, where `P` is an expression of a pointer type `T*`, is a variable of type `T`. It is a compile-time error to apply the unary `*` operator to an expression of type `void*` or to an expression that isn't of a pointer type.

The effect of applying the unary `*` operator to a `null` pointer is implementation-defined. In particular, there is no guarantee that this operation throws a `System.NullReferenceException`.

If an invalid value has been assigned to the pointer, the behavior of the unary `*` operator is undefined. Among the invalid values for dereferencing a pointer by the unary `*` operator are an address inappropriately aligned for the type pointed to (see example in Section A.4), and the address of a variable after the end of its lifetime.

For purposes of definite assignment analysis, a variable produced by evaluating an expression of the form `*P` is considered initially assigned (Section 5.3.1).

A.5.2 Pointer member access

A *pointer-member-access* consists of a *primary-expression*, followed by a "`->`" token, followed by an *identifier*.

pointer-member-access:
  primary-expression `->` *identifier*

In a pointer member access of the form `P->I`, `P` must be an expression of a pointer type other than `void*`, and `I` must denote an accessible member of the type to which `P` points.

A pointer member access of the form `P->I` is evaluated exactly as `(*P).I`. For a description of the pointer indirection operator (`*`), see Section A.5.1. For a description of the member access operator (`.`), see Section 7.5.4.

In the example

```
using System;
struct Point
{
   public int x;
   public int y;
   public override string ToString() {
      return "(" + x + "," + y + ")";
   }
}
class Test
{
   static void Main() {
      Point point;
      unsafe {
         Point* p = &point;
         p->x = 10;
         p->y = 20;
         Console.WriteLine(p->ToString());
      }
   }
}
```

the `->` operator is used to access fields and invoke a method of a struct through a pointer. Because the operation `P->I` is precisely equivalent to `(*P).I`, the `Main` method could equally well have been written:

```
class Test
{
   static void Main() {
      Point point;
      unsafe {
         Point* p = &point;
         (*p).x = 10;
         (*p).y = 20;
         Console.WriteLine((*p).ToString());
      }
   }
}
```

A.5.3 Pointer element access

A *pointer-element-access* consists of a *primary-no-array-creation-expression* followed by an expression enclosed in "`[`" and "`]`".

pointer-element-access:
  primary-no-array-creation-expression [*expression*]

In a pointer element access of the form `P[E]`, `P` must be an expression of a pointer type other than `void*`, and `E` must be an expression of a type that can be implicitly converted to `int`, `uint`, `long`, or `ulong`.

A pointer element access of the form `P[E]` is evaluated exactly as `*(P + E)`. For a description of the pointer indirection operator (`*`), see Section A.5.1. For a description of the pointer addition operator (`+`), see Section A.5.6.

In the example

```
class Test
{
   static void Main() {
      unsafe {
         char* p = stackalloc char[256];
         for (int i = 0; i < 256; i++) p[i] = (char)i;
      }
   }
}
```

a pointer element access is used to initialize the character buffer in a `for` loop. Because the operation `P[E]` is precisely equivalent to `*(P + E)`, the example could equally well have been written:

```
class Test
{
   static void Main() {
      unsafe {
         char* p = stackalloc char[256];
         for (int i = 0; i < 256; i++) *(p + i) = (char)i;
      }
   }
}
```

The pointer element access operator does not check for out-of-bounds errors and the behavior when accessing an out-of-bounds element is undefined. This is the same as C and C++.

A.5.4 The address-of operator

An *addressof-expression* consists of an ampersand (`&`) followed by a *unary-expression*.

addressof-expression:
  & *unary-expression*

Given an expression `E` that is of a type `T` and is classified as a fixed variable (Section A.3), the construct `&E` computes the address of the variable given by `E`. The type of the result is `T*` and is classified as a value. A compile-time error occurs if `E` is not classified as a variable, if `E` is classified as a volatile field, or if `E` denotes a moveable variable. In the last case, a fixed statement (Section A.6) can be used to temporarily "fix" the variable before obtaining its address.

The `&` operator does not require its argument to be definitely assigned, but following an `&` operation, the variable to which the operator is applied is considered definitely assigned in the execution path in which the operation occurs. It is the responsibility of the programmer to ensure that correct initialization of the variable actually does take place in this situation.

In the example

```
using System;
class Test
{
   static void Main() {
      int i;
      unsafe {
         int* p = &i;
         *p = 123;
      }
      Console.WriteLine(i);
   }
}
```

`i` is considered definitely assigned following the `&i` operation used to initialize `p`. The assignment to `*p` in effect initializes `i`, but the inclusion of this initialization is the responsibility of the programmer, and no compile-time error would occur if the assignment was removed.

The rules of definite assignment for the `&` operator exist such that redundant initialization of local variables can be avoided. For example, many external APIs take a pointer to a structure that is filled in by the API. Calls to such APIs typically pass the address of a local struct variable, and without the rule, redundant initialization of the struct variable would be required.

As stated in Section 7.5.4, outside an instance constructor or static constructor for a struct or class that defines a `readonly` field, that field is considered a value, not a variable. As such, its address cannot be taken. Similarly, the address of a constant cannot be taken.

A.5.5 Pointer increment and decrement

In an unsafe context, the `++` (Section 7.5.9) and -- operators (Section 7.6.5) can be applied to pointer variables of all types except `void*`. Thus, for every pointer type `T*`, the following operators are implicitly defined:

```
T* operator ++(T* x);
T* operator --(T* x);
```

The operators produce the same results as x + 1 and x - 1, respectively (Section A.5.6). In other words, for a pointer variable of type `T*`, the `++` operator adds `sizeof(T)` to the address contained in the variable, and the –– operator subtracts `sizeof(T)` from the address contained in the variable.

If a pointer increment or decrement operation overflows the domain of the pointer type, the result is implementation-defined, but no exceptions are produced.

A.5.6 Pointer arithmetic

In an unsafe context, the `+` (Section 7.7.4) and `-` operators (Section 7.7.5) can be applied to values of all pointer types except `void*`. Thus, for every pointer type `T*`, the following operators are implicitly defined:

```
T* operator +(T* x, int y);
T* operator +(T* x, uint y);
T* operator +(T* x, long y);
T* operator +(T* x, ulong y);
T* operator +(int x, T* y);
T* operator +(uint x, T* y);
T* operator +(long x, T* y);
T* operator +(ulong x, T* y);
T* operator -(T* x, int y);
T* operator -(T* x, uint y);
T* operator -(T* x, long y);
T* operator -(T* x, ulong y);
long operator -(T* x, T* y);
```

Given an expression `P` of a pointer type `T*` and an expression `N` of type `int`, `uint`, `long`, or `ulong`, the expressions `P + N` and `N + P` compute the pointer value of type `T*` that results from adding `N * sizeof(T)` to the address given by `P`. Likewise, the expression `P - N` computes the pointer value of type `T*` that results from subtracting `N * sizeof(T)` from the address given by `P`.

Given two expressions, `P` and `Q`, of a pointer type `T*`, the expression `P - Q` computes the difference between the addresses given by `P` and `Q` and then divides that difference by `sizeof(T)`. The type of the result is always `long`. In effect, `P - Q` is computed as `((long)(P) - (long)(Q)) / sizeof(T)`.

For example:

```
using System;
class Test
{
   static void Main() {
      unsafe {
         int* values = stackalloc int[20];
         int* p = &values[1];
         int* q = &values[15];
         Console.WriteLine("p - q = {0}", p - q);
         Console.WriteLine("q - p = {0}", q - p);
      }
   }
}
```

which produces the output:

```
p - q = -14
q - p = 14
```

If a pointer arithmetic operation overflows the domain of the pointer type, the result is truncated in an implementation-defined fashion, but no exceptions are produced.

A.5.7 Pointer comparison

In an unsafe context, the `==`, `!=`, `<`, `>`, `<=`, and `=>` operators (Section 7.9) can be applied to values of all pointer types. The pointer comparison operators are:

```
bool operator ==(void* x, void* y);
bool operator !=(void* x, void* y);
bool operator <(void* x, void* y);
bool operator >(void* x, void* y);
bool operator <=(void* x, void* y);
bool operator >=(void* x, void* y);
```

Because an implicit conversion exists from any pointer type to the `void*` type, operands of any pointer type can be compared using these operators. The comparison operators compare the addresses given by the two operands as if they were unsigned integers.

A.5.8 The sizeof operator

The `sizeof` operator returns the number of bytes occupied by a variable of a given type. The type specified as an operand to `sizeof` must be an *unmanaged-type* (Section A.2).

sizeof-expression:
  sizeof (*unmanaged-type*)

The result of the `sizeof` operator is a value of type `int`. For certain predefined types, the `sizeof` operator yields a constant value as shown in the table below.

Expression	Result
`sizeof(sbyte)`	1
`sizeof(byte)`	1
`sizeof(short)`	2
`sizeof(ushort)`	2
`sizeof(int)`	4
`sizeof(uint)`	4
`sizeof(long)`	8
`sizeof(ulong)`	8
`sizeof(char)`	2
`sizeof(float)`	4
`sizeof(double)`	8
`sizeof(bool)`	1

For all other types, the result of the `sizeof` operator is implementation-defined and is classified as a value, not a constant.

The order in which members are packed into a struct is unspecified.

For alignment purposes, there may be unnamed padding at the beginning of a struct, within a struct, and at the end of the struct. The contents of the bits used as padding are indeterminate.

When applied to an operand that has struct type, the result is the total number of bytes in a variable of that type, including any padding.

A.6 The fixed statement

In an unsafe context, the *embedded-statement* (Section 8) production permits an additional construct, the `fixed` statement, which is used to "fix" a moveable variable such that its address remains constant for the duration of the statement.

embedded-statement:
  ...
  fixed-statement
fixed-statement:
  fixed (*pointer-type* *fixed-pointer-declarators*) *embedded-statement*
fixed-pointer-declarators:
  fixed-pointer-declarator
  fixed-pointer-declarators , *fixed-pointer-declarator*
fixed-pointer-declarator:
  identifier = *fixed-pointer-initializer*
fixed-pointer-initializer:
  & *variable-reference*
  expression

Each *fixed-pointer-declarator* declares a local variable of the given *pointer-type* and initializes that local variable with the address computed by the corresponding *fixed-pointer-initializer*. A local variable declared in a `fixed` statement is accessible in any *fixed-pointer-initializer*s occurring to the right of that variable's declaration, and in the *embedded-statement* of the `fixed` statement. A local variable declared by a `fixed` statement is considered read-only. A compile-time error occurs if the embedded statement attempts to modify this local variable (via assignment or the ++ and -- operators) or pass it as a `ref` or `out` parameter.

A *fixed-pointer-initializer* can be one of the following:

- The token "`&`" followed by a *variable-reference* (Section 5.4) to a moveable variable (Section A.3) of an unmanaged type `T`, provided the type `T*` is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes the address of the given variable, and the variable is guaranteed to remain at a fixed address for the duration of the `fixed` statement.
- An expression of an *array-type* with elements of an unmanaged type `T`, provided the type `T*` is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes the address of the first element in the array, and the entire array is guaranteed to remain at a fixed address for the duration of the `fixed` statement. The behavior of the `fixed` statement is implementation-defined if the array expression is null or if the array has zero elements.
- An expression of type `string`, provided the type `char*` is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes the address of the first character in the string, and the entire string is guaranteed to remain at a fixed address for the duration of the `fixed` statement. The behavior of the `fixed` statement is implementation-defined if the string expression is null.

For each address computed by a *fixed-pointer-initializer* the `fixed` statement ensures that the variable referenced by the address is not subject to relocation or disposal by the garbage collector for the duration of the `fixed` statement. For example, if the address computed by a *fixed-pointer-initializer* references a field of an object or an element of an array instance, the `fixed` statement guarantees that the containing object instance is not relocated or disposed of during the lifetime of the statement.

It is the programmer's responsibility to ensure that pointers created by `fixed` statements do not survive beyond execution of those statements. For example, when pointers created by `fixed` statements are passed to external APIs, it is the programmer's responsibility to ensure that the APIs retain no memory of these pointers.

Fixed objects may cause fragmentation of the heap (because they can't be moved). For that reason, objects should be fixed only when absolutely necessary and then only for the shortest amount of time possible.

The example

```
class Test
{
   static int x;
   int y;
   unsafe static void F(int* p) {
      *p = 1;
   }
   static void Main() {
      Test t = new Test();
```

```
      int[] a = new int[10];
      unsafe {
         fixed (int* p = &x) F(p);
         fixed (int* p = &t.y) F(p);
         fixed (int* p = &a[0]) F(p);
         fixed (int* p = a) F(p);
      }
   }
}
```

demonstrates several uses of the `fixed` statement. The first statement fixes and obtains the address of a static field, the second statement fixes and obtains the address of an instance field, and the third statement fixes and obtains the address of an array element. In each case it would have been an error to use the regular `&` operator since the variables are all classified as moveable variables.

The third and fourth `fixed` statements in the example above produce identical results. In general, for an array instance `a`, specifying `&a[0]` in a `fixed` statement is the same as simply specifying `a`.

Here's another example of the `fixed` statement, this time using `string`:

```
class Test
{
   static string name = "xx";
   unsafe static void F(char* p) {
      for (int i = 0; p[i] != '\0'; ++i)
         Console.WriteLine(p[i]);
   }
   static void Main() {
      unsafe {
         fixed (char* p = name) F(p);
         fixed (char* p = "xx") F(p);
      }
   }
}
```

In an unsafe context array elements of single-dimensional arrays are stored in increasing index order, starting with index `0` and ending with index `Length - 1`. For multi-dimensional arrays, array elements are stored such that the indices of the rightmost dimension are increased first, then the next left dimension, and so on to the left. Within a `fixed` statement that obtains a pointer `p` to an array instance `a`, the pointer values ranging from `p` to `p + a.Length - 1` represent addresses of the elements in the array. Likewise, the variables ranging from `p[0]` to `p[a.Length - 1]` represent the actual array elements. Given the way in which arrays are stored, we can treat an array of any dimension as though it were linear.

For example:

```
using System;
class Test
{
   static void Main() {
      int[,,] a = new int[2,3,4];
      unsafe {
         fixed (int* p = a) {
            for (int i = 0; i < a.Length; ++i)   // treat as linear
               p[i] = i;
         }
      }
      for (int i = 0; i < 2; ++i)
         for (int j = 0; j < 3; ++j) {
            for (int k = 0; k < 4; ++k)
               Console.Write("[{0},{1},{2}] = {3,2} ", i, j, k, a[i,j,k]);
            Console.WriteLine();
         }
   }
}
```

which produces the output:

```
[0,0,0] =  0 [0,0,1] =  1 [0,0,2] =  2 [0,0,3] =  3
[0,1,0] =  4 [0,1,1] =  5 [0,1,2] =  6 [0,1,3] =  7
[0,2,0] =  8 [0,2,1] =  9 [0,2,2] = 10 [0,2,3] = 11
[1,0,0] = 12 [1,0,1] = 13 [1,0,2] = 14 [1,0,3] = 15
[1,1,0] = 16 [1,1,1] = 17 [1,1,2] = 18 [1,1,3] = 19
[1,2,0] = 20 [1,2,1] = 21 [1,2,2] = 22 [1,2,3] = 23
```

In the example

```
class Test
{
   unsafe static void Fill(int* p, int count, int value) {
      for (; count != 0; count--) *p++ = value;
   }
   static void Main() {
      int[] a = new int[100];
      unsafe {
         fixed (int* p = a) Fill(p, 100, -1);
      }
   }
}
```

a `fixed` statement is used to fix an array so its address can be passed to a method that takes a pointer.

A `char*` value produced by fixing a string instance always points to a null-terminated string. Within a fixed statement that obtains a pointer `p` to a string instance `s`, the pointer values ranging from `p` to `p + s.Length - 1` represent addresses of the characters in the string, and the pointer value `p + s.Length` always points to a null character (the character with value `'\0'`).

Modifying objects of managed type through fixed pointers can result in undefined behavior. For example, because strings are immutable, it is the programmer's responsibility to ensure that the characters referenced by a pointer to a fixed string are not modified.

The automatic null-termination of strings is particularly convenient when calling external APIs that expect "C-style" strings. Note, however, that a string instance is permitted to contain null characters. If such null characters are present, the string will appear truncated when treated as a null-terminated `char*`.

A.7 Stack allocation

In an unsafe context, a local variable declaration (Section 8.5.1) may include a stack allocation initializer that allocates memory from the call stack.

local-variable-initializer:
  expression
  array-initializer
  stackalloc-initializer
stackalloc-initializer:
  stackalloc *unmanaged-type* [*expression*]

The *unmanaged-type* indicates the type of the items that will be stored in the newly allocated location, and the *expression* indicates the number of these items. Taken together, these specify the required allocation size. Since the size of a stack allocation cannot be negative, it is a compile-time error to specify the number of items as a *constant-expression* that evaluates to a negative value.

A stack allocation initializer of the form `stackalloc T[E]` requires `T` to be an unmanaged type (Section A.2) and `E` to be an expression of type `int`. The construct allocates `E * sizeof(T)` bytes from the call stack and returns a pointer, of type `T*`, to the newly allocated block. If `E` is a negative value, then the behavior is undefined. If `E` is zero, then no allocation is made, and the pointer returned is implementation-defined. If there is not enough memory available to allocate a block of the given size, a `System.StackOverflowException` is thrown.

The content of the newly allocated memory is undefined.

Stack allocation initializers are not permitted in `catch` or `finally` blocks (Section 8.10).

There is no way to explicitly free memory allocated using `stackalloc`. All stack allocated memory blocks created during the execution of a function member are automatically discarded when that function member returns. This corresponds to the `alloca` function, an extension commonly found in C and C++ implementations.

In the example

```
using System;
class Test
{
   static string IntToString(int value) {
      int n = value >= 0? value: -value;
      unsafe {
         char* buffer = stackalloc char[16];
         char* p = buffer + 16;
         do {
            *--p = (char)(n % 10 + '0');
            n /= 10;
         } while (n != 0);
         if (value < 0) *--p = '-';
         return new string(p, 0, (int)(buffer + 16 - p));
      }
   }
   static void Main() {
      Console.WriteLine(IntToString(12345));
      Console.WriteLine(IntToString(-999));
   }
}
```

a `stackalloc` initializer is used in the `IntToString` method to allocate a buffer of 16 characters on the stack. The buffer is automatically discarded when the method returns.

A.8 Dynamic memory allocation

Except for the `stackalloc` operator, C# provides no predefined constructs for managing non-garbage collected memory. Such services are typically provided by supporting class libraries or imported directly from the underlying operating system. For example, the `Memory` class below illustrates how the heap functions of an underlying operating system might be accessed from C#:

```
using System;
using System.Runtime.InteropServices;
public unsafe class Memory
{
   // Handle for the process heap. This handle is used in all calls to the
   // HeapXXX APIs in the methods below.
   static int ph = GetProcessHeap();
   // Private instance constructor to prevent instantiation.
   private Memory() {}
   // Allocates a memory block of the given size. The allocated memory is
   // automatically initialized to zero.
   public static void* Alloc(int size) {
      void* result = HeapAlloc(ph, HEAP_ZERO_MEMORY, size);
      if (result == null) throw new OutOfMemoryException();
      return result;
   }
   // Copies count bytes from src to dst. The source and destination
   // blocks are permitted to overlap.
   public static void Copy(void* src, void* dst, int count) {
      byte* ps = (byte*)src;
      byte* pd = (byte*)dst;
      if (ps > pd) {
         for (; count != 0; count--) *pd++ = *ps++;
      }
      else if (ps < pd) {
         for (ps += count, pd += count; count != 0; count--) *--pd = *--ps;
      }
   }
   // Frees a memory block.
   public static void Free(void* block) {
      if (!HeapFree(ph, 0, block)) throw new InvalidOperationException();
   }
   // Re-allocates a memory block. If the reallocation request is for a
   // larger size, the additional region of memory is automatically
   // initialized to zero.
   public static void* ReAlloc(void* block, int size) {
      void* result = HeapReAlloc(ph, HEAP_ZERO_MEMORY, block, size);
      if (result == null) throw new OutOfMemoryException();
      return result;
   }
   // Returns the size of a memory block.
   public static int SizeOf(void* block) {
      int result = HeapSize(ph, 0, block);
      if (result == -1) throw new InvalidOperationException();
      return result;
   }
   // Heap API flags
   const int HEAP_ZERO_MEMORY = 0x00000008;
   // Heap API functions
   [DllImport("kernel32")]
   static extern int GetProcessHeap();
   [DllImport("kernel32")]
   static extern void* HeapAlloc(int hHeap, int flags, int size);
   [DllImport("kernel32")]
   static extern bool HeapFree(int hHeap, int flags, void* block);
   [DllImport("kernel32")]
   static extern void* HeapReAlloc(int hHeap, int flags,
      void* block, int size);
   [DllImport("kernel32")]
   static extern int HeapSize(int hHeap, int flags, void* block);
```

```
}
```

An example that uses the `Memory` class is given below:

```
class Test
{
   static void Main() {
      unsafe {
         byte* buffer = (byte*)Memory.Alloc(256);
         try {
            for (int i = 0; i < 256; i++) buffer[i] = (byte)i;
            byte[] array = new byte[256];
            fixed (byte* p = array) Memory.Copy(buffer, p, 256);
         }
         finally {
            Memory.Free(buffer);
         }
         for (int i = 0; i < 256; i++) Console.WriteLine(array[i]);
      }
   }
}
```

The example allocates 256 bytes of memory through `Memory.Alloc` and initializes the memory block with values increasing from 0 to 255. It then allocates a 256 element byte array and uses `Memory.Copy` to copy the contents of the memory block into the byte array. Finally, the memory block is freed using `Memory.Free` and the contents of the byte array are output on the console.

B. Documentation comments

C# provides a mechanism for programmers to document their code using a special comment syntax that contains XML text. In source code files, comments having a certain form can be used to direct a tool to produce XML from those comments and the source code elements, which they precede. Comments using such syntax are called documentation comments. They must immediately precede a user-defined type (such as a class, delegate, or interface) or a member (such as a field, event, property, or method). The XML generation tool is called the documentation generator. (This generator could be, but need not be, the C# compiler itself.) The output produced by the documentation generator is called the documentation file. A documentation file is used as input to a documentation viewer; a tool intended to produce some sort of visual display of type information and its associated documentation.

This specification suggests a set of tags to be used in documentation comments, but use of these tags is not required, and other tags may be used if desired, as long the rules of well-formed XML are followed.

B.1 Introduction

Comments having a special form can be used to direct a tool to produce XML from those comments and the source code elements, which they precede. Such comments are single-line comments that start with three slashes (`///`), or delimited comments that start with a slash and two stars (`/**`). They must immediately precede a user-defined type (such as a class, delegate, or interface) or a member (such as a field, event, property, or method) that they annotate. Attribute sections (Section 17.2) are considered part of declarations, so documentation comments must precede attributes applied to a type or member.

Syntax:

single-line-doc-comment:
  /// input-characters$_{opt}$

  delimited-doc-comment:

  */** delimited-comment-charactersopt */*

In a *single-line-doc-comment*, if there is a *whitespace* character following the `///` characters on each of the *single-line-doc-comment*s adjacent to the current *single-line-doc-comment*, then that *whitespace* character is not included in the XML output.

In a *delimited-doc-comment*, if the first non-whitespace character on the second line is an asterisk and the same pattern of optional whitespace characters and an asterisk character is repeated at the beginning of each of the line within the *delimited-doc-comment*, then the characters of the repeated pattern are not included in the XML output. The pattern may include whitespace characters after, as well as before, the asterisk character.

Example:

```
/// <remarks>Class <c>Point</c> models a point in a two-dimensional
/// plane.</remarks>
///
public class Point
{
   /// <remarks>method <c>draw</c> renders the point.</remarks>
   void draw() {...}
}
```

The text within documentation comments must be well formed according to the rules of XML (http://www.w3.org/TR/REC-xml). If the XML is ill formed, a warning is generated and the documentation file will contain a comment saying that an error was encountered.

Although developers are free to create their own set of tags, a recommended set is defined in Appendix B.2. Some of the recommended tags have special meanings:

- The `<param>` tag is used to describe parameters. If such a tag is used, the documentation generator must verify that the specified parameter exists and that all parameters are described in documentation comments. If such verification fails, the documentation generator issues a warning.
- The `cref` attribute can be attached to any tag to provide a reference to a code element. The documentation generator must verify that this code element exists. If the verification fails, the documentation generator issues a warning. When looking for a name described in a `cref` attribute, the documentation generator must respect namespace visibility according to `using` statements appearing within the source code.
- The `<summary>` tag is intended to be used by a documentation viewer to display additional information about a type or member.
- The `<include>` tag includes information from an external XML file.

Note carefully that the documentation file does not provide full information about the type and members (for example, it does not contain any type information). To get such information about a type or member, the documentation file must be used in conjunction with reflection on the actual type or member.

B.2 Recommended tags

The documentation generator must accept and process any tag that is valid according to the rules of XML. The following tags provide commonly used functionality in user documentation. (Of course, other tags are possible.)

Tag	Section	Purpose
`<c>`	B.2.1	Set text in a code-like font
`<code>`	B.2.2	Set one or more lines of source code or program output
`<example>`	B.2.3	Indicate an example
`<exception>`	B.2.4	Identifies the exceptions a method can throw
`<include>`	B.2.5	Includes XML from an external file
`<list>`	B.2.6	Create a list or table
`<para>`	B.2.7	Permit structure to be added to text
`<param>`	B.2.8	Describe a parameter for a method or constructor
`<paramref>`	B.2.9	Identify that a word is a parameter name
`<permission>`	B.2.10	Document the security accessibility of a member
`<remarks>`	B.2.11	Describe a type
`<returns>`	B.2.12	Describe the return value of a method
`<see>`	B.2.13	Specify a link
`<seealso>`	B.2.14	Generate a *See Also* entry
`<summary>`	B.2.15	Describe a member of a type
`<value>`	B.2.16	Describe a property

B.2.1 <c>

This tag provides a mechanism to indicate that a fragment of text within a description should be set in a special font such as that used for a block of code. For lines of actual code, use `<code>` (B.2.2).

Syntax:

```
<c>text</c>
```

Example:

```
/// <remarks>Class <c>Point</c> models a point in a two-dimensional
/// plane.</remarks>
public class Point
{
   // ...
}
```

B.2.2 <code>

This tag is used to set one or more lines of source code or program output in some special font. For small code fragments in narrative, use <c> (B.2.1).

Syntax:

```
<code>source code or program output</code>
```

Example:

```
/// <summary>This method changes the point's location by
///   the given x- and y-offsets.
/// <example>For example:
/// <code>
///   Point p = new Point(3,5);
///   p.Translate(-1,3);
/// </code>
/// results in <c>p</c>'s having the value (2,8).
/// </example>
/// </summary>
public void Translate(int xor, int yor) {
   X += xor;
   Y += yor;
}
```

B.2.3 <example>

This tag allows example code within a comment, to specify how a method or other library member may be used. Ordinarily, this would also involve use of the tag `<code>` (B.2.2) as well.

Syntax:

```
<example>description</example>
```

Example:

See `<code>` (B.2.2) for an example.

B.2.4 <exception>

This tag provides a way to document the exceptions a method can throw.

Syntax:

```
<exception cref="member">description</exception>
```

where

`cref="member"`
: The name of a member. The documentation generator checks that the given member exists and translates *member* to the canonical element name in the documentation file.

`description`
: A description of the circumstances in which the exception is thrown.

Example:

```
public class DataBaseOperations
{
   /// <exception cref="MasterFileFormatCorruptException"></exception>
   /// <exception cref="MasterFileLockedOpenException"></exception>
   public static void ReadRecord(int flag) {
      if (flag == 1)
         throw new MasterFileFormatCorruptException();
      else if (flag == 2)
         throw new MasterFileLockedOpenException();
      // ...
   }
}
```

B.2.5 <include>

This tag allows including information from an XML document that is external to the source code file. The external file must be a well-formed XML document, and an `XPath` expression is applied to that document to specify what XML from that document to include. The `<include>` tag is then replaced with the selected XML from the external document.

Syntax:

```
<include file="filename" path="xpath" />
```

where

`file="filename"`
: The file name of an external XML file. The file name is interpreted relative to the file that contains the include tag.

`path="xpath"`
: An `XPath` expression that selects some of the XML in the external XML file.

Example:

If the source code contained a declaration like:

```
/// <include file="docs.xml" path='extradoc/class[@name="IntList"]/*' />
public class IntList { ... }
```

and the external file "docs.xml" had the following contents:

```
<?xml version="1.0"?>
<extradoc>
   <class name="IntList">
      <summary>
         Contains a list of integers.
      </summary>
   </class>
   <class name="StringList">
      <summary>
         Contains a list of integers.
      </summary>
   </class>
</extradoc>
```

then the same documentation is output as if the source code contained:

```
/// <summary>
///    Contains a list of integers.
/// </summary>
public class IntList { ... }
```

B.2.6 <list>

This tag is used to create a list or table of items. It may contain a `<listheader>` block to define the heading row of either a table or definition list. (When defining a table, only an entry for `term` in the heading need be supplied.)

Each item in the list is specified with an `<item>` block. When creating a definition list, both `term` and `description` must be specified. However, for a table, bulleted list, or numbered list, only `description` need be specified.

Syntax:

```
<list type="bullet" | "number" | "table">
   <listheader>
      <term>term</term>
      <description>description</description>
   </listheader>
   <item>
      <term>term</term>
      <description>description</description>
   </item>
   ...
   <item>
      <term>term</term>
      <description>description</description>
   </item>
</list>
```

where

`term`
: The term to define, whose definition is in `description`.

`description`
: Either an item in a bullet or numbered list, or the definition of a `term`.

Example:

```
public class MyClass
{
   /// <remarks>Here is an example of a bulleted list:
   /// <list type="bullet">
   /// <item>
   /// <description>Item 1.</description>
   /// </item>
   /// <item>
   /// <description>Item 2.</description>
   /// </item>
   /// </list>
   /// </remarks>
   public static void Main () {
      // ...
   }
}
```

B.2.7 <para>

This tag is for use inside other tags, such as `<remarks>` (B.2.11) or `<returns>` (B.2.12), and permits structure to be added to text.

Syntax:

```
<para>content</para>
```

where

`content`
The text of the paragraph.

Example:

```
/// <summary>This is the entry point of the Point class testing program.
/// <para>This program tests each method and operator, and
/// is intended to be run after any non-trvial maintenance has
/// been performed on the Point class.</para></summary>
public static void Main() {
   // ...
}
```

B.2.8 <param>

This tag is used to describe a parameter for a method, constructor, or indexer.

Syntax:

```
<param name="name">description</param>
```

where

`name`
: The name of the parameter.

`description`
: A description of the parameter.

Example:

```
/// <summary>This method changes the point's location to
///   the given coordinates.</summary>
/// <param><c>xor</c> is the new x-coordinate.</param>
/// <param><c>yor</c> is the new y-coordinate.</param>
public void Move(int xor, int yor) {
   X = xor;
   Y = yor;
}
```

B.2.9 <paramref>

This tag is used to indicate that a word is a parameter. The documentation file can be processed to format this parameter in some distinct way.

Syntax:

```
<paramref name="name"/>
```

where

`name`
The name of the parameter.

Example:

```
/// <summary>This constructor initializes the new Point to
///   (<paramref name="xor"/>,<paramref name="yor"/>).</summary>
/// <param><c>xor</c> is the new Point's x-coordinate.</param>
/// <param><c>yor</c> is the new Point's y-coordinate.</param>
public Point(int xor, int yor) {
   X = xor;
   Y = yor;
}
```

B.2.10 <permission>

This tag allows the security accessibility of a member to be documented.

Syntax:

```
<permission cref="member">description</permission>
```

where

`cref="member"`
: The name of a member. The documentation generator checks that the given code element exists and translates *member* to the canonical element name in the documentation file.

`description`
: A description of the access to the member.

Example:

```
/// <permission cref="System.Security.PermissionSet">Everyone can
/// access this method.</permission>
public static void Test() {
   // ...
}
```

B.2.11 <remarks>

This tag is used to specify overview information about a type. (Use `<summary>` (B.2.15) to describe the members of a type.)

Syntax:

```
<remarks>description</remarks>
```

where

`description`
The text of the remarks.

Example:

```
/// <remarks>Class <c>Point</c> models a point in a
/// two-dimensional plane.</remarks>
public class Point
{
   // ...
}
```

B.2.12 <returns>

This tag is used to describe the return value of a method.

Syntax:

```
<returns>description</returns>
```

where

`description`
A description of the return value.

Example:

```
/// <summary>Report a point's location as a string.</summary>
/// <returns>A string representing a point's location, in the form (x,y),
///   without any leading, trailing, or embedded whitespace.</returns>
public override string ToString() {
   return "(" + X + "," + Y + ")";
}
```

B.2.13 <see>

This tag allows a link to be specified within text. Use `<seealso>` (B.2.14) to indicate text that is to appear in a *See Also* section.

Syntax:

```
<see cref="member"/>
```

where

`cref="member"`
The name of a member. The documentation generator checks that the given code element exists and changes *member* to the element name in the generated documentation file.

Example:

```
/// <summary>This method changes the point's location to
///   the given coordinates.</summary>
/// <see cref="Translate"/>
public void Move(int xor, int yor) {
   X = xor;
   Y = yor;
}
/// <summary>This method changes the point's location by
///   the given x- and y-offsets.
/// </summary>
/// <see cref="Move"/>
public void Translate(int xor, int yor) {
   X += xor;
   Y += yor;
}
```

B.2.14 <seealso>

This tag allows an entry to be generated for the *See Also* section. Use `<see>` (B.2.13) to specify a link from within text.

Syntax:

```
<seealso cref="member"/>
```

where

`cref="member"`
The name of a member. The documentation generator checks that the given code element exists and changes *member* to the element name in the generated documentation file.

Example:

```
/// <summary>This method determines whether two Points have the same
///   location.</summary>
/// <seealso cref="operator=="/>
/// <seealso cref="operator!="/>
public override bool Equals(object o) {
   // ...
}
```

B.2.15 <summary>

This tag can be used to describe a member for a type. Use `<remarks>` (B.2.11) to describe the type itself.

Syntax:

```
<summary>description</summary>
```

where

`description`
A summary of the member.

Example:

```
/// <summary>This constructor initializes the new Point to (0,0).</summary>
public Point() : this(0,0) {
}
```

B.2.16 <value>

This tag allows a property to be described.

Syntax:

```
<value>property description</value>
```

where

`property description`
A description for the property.

Example:

```
/// <value>Property <c>X</c> represents the point's x-coordinate.</value>
public int X
{
   get { return x; }
   set { x = value; }
}
```

B.3 Processing the documentation file

The documentation generator generates an ID string for each element in the source code that is tagged with a documentation comment. This ID string uniquely identifies a source element. A documentation viewer can use an ID string to identify the corresponding metadata/reflection item to which the documentation applies.

The documentation file is not a hierarchical representation of the source code; rather, it is a flat list with a generated ID string for each element.

B.3.1 ID string format

The documentation generator observes the following rules when it generates the ID strings:

- No white space is placed in the string.
- The first part of the string identifies the kind of member being documented, via a single character followed by a colon. The following kinds of members are defined:

Character	Description
E	Event
F	Field
M	Method (including constructors, destructors, and operators)
N	Namespace
P	Property (including indexers)
T	Type (such as class, delegate, enum, interface, and struct)
!	Error string; the rest of the string provides information about the error. For example, the documentation generator generates error information for links that cannot be resolved.

- The second part of the string is the fully qualified name of the element, starting at the root of the namespace. The name of the element, its enclosing type(s), and namespace are separated by periods. If the name of the item itself has periods, they are replaced by `#` (`U+0023`) characters. (It is assumed that no element has this character in its name.)
- For methods and properties with arguments, the argument list follows, enclosed in parentheses. For those without arguments, the parentheses are omitted. The arguments are separated by commas. The encoding of each argument is the same as a CLI signature, as follows: Arguments are represented by their fully qualified name. For example, `int` becomes `System.Int32`, `string` becomes `System.String`, `object` becomes `System.Object`, and so on. Arguments having the `out` or `ref` modifier have an `@` following their type name. Arguments passed by value or via `params` have no special notation. Arguments that are arrays are represented as `[` *lowerbound* `:` *size* `,` … `,` *lowerbound* `:` *size* `]` where the number of commas is the rank less one, and the lower bounds and size of each dimension, if known, are represented in decimal. If a lower bound or size is not specified, it is omitted. If the lower bound and size for a particular dimension are omitted, the "`:`" is omitted as well. Jagged arrays are represented by one "`[]`" per level. Arguments that have pointer types other than void are represented using a `*` following the type name. A void pointer is represented using a type name of `System.Void`.

B.3.2 ID string examples

The following examples each show a fragment of C# code, along with the ID string produced from each source element capable of having a documentation comment:

- Types are represented using their fully qualified name.

```
enum Color { Red, Blue, Green }
namespace Acme
{
   interface IProcess {...}
   struct ValueType {...}
   class Widget: IProcess
   {
      public class NestedClass {...}
      public interface IMenuItem {...}
      public delegate void Del(int i);
      public enum Direction { North, South, East, West }
   }
}
"T:Color"
"T:Acme.IProcess"
"T:Acme.ValueType"
"T:Acme.Widget"
"T:Acme.Widget.NestedClass"
"T:Acme.Widget.IMenuItem"
"T:Acme.Widget.Del"
"T:Acme.Widget.Direction"
```

- Fields are represented by their fully qualified name.

```
namespace Acme
{
   struct ValueType
   {
      private int total;
   }
   class Widget: IProcess
   {
      public class NestedClass
      {
         private int value;
      }
      private string message;
      private static Color defaultColor;
      private const double PI = 3.14159;
      protected readonly double monthlyAverage;
      private long[] array1;
      private Widget[,] array2;
      private unsafe int *pCount;
      private unsafe float **ppValues;
   }
}
"F:Acme.ValueType.total"
"F:Acme.Widget.NestedClass.value"
"F:Acme.Widget.message"
"F:Acme.Widget.defaultColor"
"F:Acme.Widget.PI"
"F:Acme.Widget.monthlyAverage"
```

```
"F:Acme.Widget.array1"
"F:Acme.Widget.array2"
"F:Acme.Widget.pCount"
"F:Acme.Widget.ppValues"
```

- Constructors.

```
namespace Acme
{
   class Widget: IProcess
   {
      static Widget() {...}
      public Widget() {...}
      public Widget(string s) {...}
   }
}
"M:Acme.Widget.#cctor"
"M:Acme.Widget.#ctor"
"M:Acme.Widget.#ctor(System.String)"
```

- Destructors.

```
namespace Acme
{
   class Widget: IProcess
   {
      ~Widget() {...}
   }
}
"M:Acme.Widget.Finalize"
```

- Methods.

```
namespace Acme
{
   struct ValueType
   {
      public void M(int i) {...}
   }
   class Widget: IProcess
   {
      public class NestedClass
      {
         public void M(int i) {...}
      }
      public static void M0() {...}
      public void M1(char c, out float f, ref ValueType v) {...}
      public void M2(short[] x1, int[,] x2, long[][] x3) {...}
      public void M3(long[][] x3, Widget[][,,] x4) {...}
      public unsafe void M4(char *pc, Color **pf) {...}
      public unsafe void M5(void *pv, double *[][,] pd) {...}
      public void M6(int i, params object[] args) {...}
   }
}
"M:Acme.ValueType.M(System.Int32)"
"M:Acme.Widget.NestedClass.M(System.Int32)"
"M:Acme.Widget.M0"
"M:Acme.Widget.M1(System.Char,System.Single@,Acme.ValueType@)"
"M:Acme.Widget.M2(System.Int16[],System.Int32[0:,0:],System.Int64[][])"
```

```
"M:Acme.Widget.M3(System.Int64[][],Acme.Widget[0:,0:,0:][])"
"M:Acme.Widget.M4(System.Char*,Color**)"
"M:Acme.Widget.M5(System.Void*,System.Double*[0:,0:][])"
"M:Acme.Widget.M6(System.Int32,System.Object[])"
```

- Properties and indexers.

```
namespace Acme
{
   class Widget: IProcess
   {
      public int Width { get {...} set {...} }
      public int this[int i] { get {...} set {...} }
      public int this[string s, int i] { get {...} set {...} }
   }
}
"P:Acme.Widget.Width"
"P:Acme.Widget.Item(System.Int32)"
"P:Acme.Widget.Item(System.String,System.Int32)"
```

- Events.

```
namespace Acme
{
   class Widget: IProcess
   {
      public event Del AnEvent;
   }
}
"E:Acme.Widget.AnEvent"
```

- Unary operators.

```
namespace Acme
{
   class Widget: IProcess
   {
      public static Widget operator+(Widget x) {...}
   }
}
"M:Acme.Widget.op_UnaryPlus(Acme.Widget)"
```

The complete set of unary operator function names used is as follows: `op_UnaryPlus`, `op_UnaryNegation`, `op_LogicalNot`, `op_OnesComplement`, `op_Increment`, `op_Decrement`, `op_True`, and `op_False`.

- Binary operators.

```
namespace Acme
{
   class Widget: IProcess
   {
      public static Widget operator+(Widget x1, Widget x2) {...}
   }
}
"M:Acme.Widget.op_Addition(Acme.Widget,Acme.Widget)"
```

The complete set of binary operator function names used is as follows: `op_Addition`, `op_Subtraction`, `op_Multiply`, `op_Division`, `op_Modulus`, `op_BitwiseAnd`, `op_BitwiseOr`, `op_ExclusiveOr`, `op_LeftShift`, `op_RightShift`, `op_Equality`, `op_Inequality`, `op_LessThan`, `op_LessThanOrEqual`, `op_GreaterThan`, and `op_GreaterThanOrEqual`.

- Conversion operators have a trailing "~" followed by the return type.

```
namespace Acme
{
   class Widget: IProcess
   {
      public static explicit operator int(Widget x) {...}
      public static implicit operator long(Widget x) {...}
   }
}
"M:Acme.Widget.op_Explicit(Acme.Widget)~System.Int32"
"M:Acme.Widget.op_Implicit(Acme.Widget)~System.Int64"
```

B.4 An example

The following topics provide an example.

B.4.1 C# source code

The following example shows the source code of a `Point` class:

```
namespace Graphics
{

/// <remarks>Class <c>Point</c> models a point in a two-dimensional plane.
/// </remarks>
public class Point
{
   /// <summary>Instance variable <c>x</c> represents the point's
   ///   x-coordinate.</summary>
   private int x;
   /// <summary>Instance variable <c>y</c> represents the point's
   ///   y-coordinate.</summary>
   private int y;
   /// <value>Property <c>X</c> represents the point's x-coordinate.</value>
   public int X
   {
      get { return x; }
      set { x = value; }
   }
   /// <value>Property <c>Y</c> represents the point's y-coordinate.</value>
   public int Y
   {
      get { return y; }
      set { y = value; }
   }
   /// <summary>This constructor initializes the new Point to
   ///   (0,0).</summary>
   public Point() : this(0,0) {}
   /// <summary>This constructor initializes the new Point to
   ///   (<paramref name="xor"/>,<paramref name="yor"/>).</summary>
   /// <param><c>xor</c> is the new Point's x-coordinate.</param>
   /// <param><c>yor</c> is the new Point's y-coordinate.</param>
   public Point(int xor, int yor) {
      X = xor;
      Y = yor;
   }
   /// <summary>This method changes the point's location to
   ///   the given coordinates.</summary>
   /// <param><c>xor</c> is the new x-coordinate.</param>
   /// <param><c>yor</c> is the new y-coordinate.</param>
   /// <see cref="Translate"/>
   public void Move(int xor, int yor) {
      X = xor;
      Y = yor;
   }
   /// <summary>This method changes the point's location by
   ///   the given x- and y-offsets.
   /// <example>For example:
   /// <code>
   ///   Point p = new Point(3,5);
   ///   p.Translate(-1,3);
   /// </code>
   /// results in <c>p</c>'s having the value (2,8).
   /// </example>
   /// </summary>
   /// <param><c>xor</c> is the relative x-offset.</param>
   /// <param><c>yor</c> is the relative y-offset.</param>
   /// <see cref="Move"/>
   public void Translate(int xor, int yor) {
      X += xor;
      Y += yor;
   }
```

```
    /// <summary>This method determines whether two Points have the same
    ///   location.</summary>
    /// <param><c>o</c> is the object to be compared to the current object.
    /// </param>
    /// <returns>True if the Points have the same location and they have
    ///   the exact same type; otherwise, false.</returns>
    /// <seealso cref="operator=="/>
    /// <seealso cref="operator!="/>
    public override bool Equals(object o) {
       if (o == null) {
          return false;
       }
       if (this == o) {
          return true;
       }
       if (GetType() == o.GetType()) {
          Point p = (Point)o;
          return (X == p.X) && (Y == p.Y);
       }
       return false;
    }
    /// <summary>Report a point's location as a string.</summary>
    /// <returns>A string representing a point's location, in the form (x,y),
    ///   without any leading, training, or embedded whitespace.</returns>
    public override string ToString() {
       return "(" + X + "," + Y + ")";
    }
    /// <summary>This operator determines whether two Points have the same
    ///   location.</summary>
    /// <param><c>p1</c> is the first Point to be compared.</param>
    /// <param><c>p2</c> is the second Point to be compared.</param>
    /// <returns>True if the Points have the same location and they have
    ///   the exact same type; otherwise, false.</returns>
    /// <seealso cref="Equals"/>
    /// <seealso cref="operator!="/>
    public static bool operator==(Point p1, Point p2) {
       if ((object)p1 == null || (object)p2 == null) {
          return false;
       }

       if (p1.GetType() == p2.GetType()) {
          return (p1.X == p2.X) && (p1.Y == p2.Y);
       }

       return false;
    }
    /// <summary>This operator determines whether two Points have the same
    ///   location.</summary>
    /// <param><c>p1</c> is the first Point to be compared.</param>
    /// <param><c>p2</c> is the second Point to be compared.</param>
    /// <returns>True if the Points do not have the same location and the
    ///   exact same type; otherwise, false.</returns>
    /// <seealso cref="Equals"/>
    /// <seealso cref="operator=="/>
    public static bool operator!=(Point p1, Point p2) {
       return !(p1 == p2);
    }
    /// <summary>This is the entry point of the Point class testing
    /// program.
    /// <para>This program tests each method and operator, and
    /// is intended to be run after any non-trvial maintenance has
    /// been performed on the Point class.</para></summary>
    public static void Main() {
       // class test code goes here
    }
 }
 }
```

B.4.2 Resulting XML

Here is the output produced by one documentation generator when given the source code for class `Point`, shown above:

```
<?xml version="1.0"?>
<doc>
    <assembly>
        <name>Point</name>
    </assembly>
    <members>
        <member name="T:Graphics.Point">
            <remarks>Class <c>Point</c> models a point in a two-dimensional
            plane.
            </remarks>
        </member>
        <member name="F:Graphics.Point.x">
            <summary>Instance variable <c>x</c> represents the point's
            x-coordinate.</summary>
        </member>
        <member name="F:Graphics.Point.y">
            <summary>Instance variable <c>y</c> represents the point's
            y-coordinate.</summary>
        </member>
        <member name="M:Graphics.Point.#ctor">
            <summary>This constructor initializes the new Point to

C. Grammar

This appendix contains summaries of the lexical and syntactic grammars found in the main document, and of the grammar extensions for unsafe code. Grammar productions appear here in the same order that they appear in the main document.

C.1 Lexical grammar

input:
  input-section$_{opt}$
input-section:
  input-section-part
  input-section *input-section-part*
input-section-part:
  input-elements$_{opt}$ *new-line*
  pp-directive
input-elements:
  input-element
  input-elements *input-element*
input-element:
  whitespace
  comment
  token

C.1.1 Line terminators

new-line:
  Carriage return character (U+000D)
  Line feed character (U+000A)
  Carriage return character (U+000D) followed by line feed character (U+000A)
  Line separator character (U+2028)
  Paragraph separator character (U+2029)

C.1.2 White space

whitespace:
  Any character with Unicode class Zs
  Horizontal tab character (U+0009)
  Vertical tab character (U+000B)
  Form feed character (U+000C)

C.1.3 Comments

comment:
  single-line-comment
  delimited-comment
single-line-comment:
  // *input-characters*$_{opt}$
input-characters:
  input-character
  input-characters *input-character*
input-character:
  Any Unicode character except a *new-line-character*
new-line-character:
  Carriage return character (U+000D)
  Line feed character (U+000A)
  Line separator character (U+2028)
  Paragraph separator character (U+2029)
delimited-comment:
  /* *delimited-comment-characters*$_{opt}$ */
delimited-comment-characters:
  delimited-comment-character
  delimited-comment-characters *delimited-comment-character*

delimited-comment-character:
  not-asterisk
  * *not-slash*
not-asterisk:
  Any Unicode character except *
not-slash:
  Any Unicode character except /

C.1.4 Tokens

token:
  identifier
  keyword
  integer-literal
  real-literal
  character-literal
  string-literal
  operator-or-punctuator

C.1.5 Unicode character escape sequences

unicode-escape-sequence:
  \u *hex-digit* *hex-digit* *hex-digit* *hex-digit*
  \U *hex-digit* *hex-digit* *hex-digit* *hex-digit* *hex-digit* *hex-digit* *hex-digit* *hex-digit*

C.1.6 Identifiers

identifier:
  available-identifier
  @ *identifier-or-keyword*
available-identifier:
  An *identifier-or-keyword* that is not a *keyword*
identifier-or-keyword:
  identifier-start-character *identifier-part-characters*$_{opt}$
identifier-start-character:
  letter-character
  _ (the underscore character U+005F)
identifier-part-characters:
  identifier-part-character
  identifier-part-characters *identifier-part-character*
identifier-part-character:
  letter-character
  decimal-digit-character
  connecting-character
  combining-character
  formatting-character
letter-character:
  A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Nl
  A *unicode-escape-sequence* representing a character of classes Lu, Ll, Lt, Lm, Lo, or Nl
combining-character:
  A Unicode character of classes Mn or Mc
  A *unicode-escape-sequence* representing a character of classes Mn or Mc
decimal-digit-character:
  A Unicode character of the class Nd
  A *unicode-escape-sequence* representing a character of the class Nd
connecting-character:
  A Unicode character of the class Pc
  A *unicode-escape-sequence* representing a character of the class Pc
formatting-character:
  A Unicode character of the class Cf
  A *unicode-escape-sequence* representing a character of the class Cf

C.1.7 Keywords

keyword: one of

abstract	as	base	bool	break	byte	case
catch	char	checked	class	const	continue	decimal
default	delegate	do	double	else	enum	event
explicit	extern	false	finally	fixed	float	for
foreach	goto	if	implicit	in	int	interface
internal	is	lock	long	namespace	new	null
object	operator	out	override	params	private	protected
public	readonly	ref	return	sbyte	sealed	short
sizeof	stackalloc	static	string	struct	switch	this
throw	true	try	typeof	uint	ulong	unchecked
unsafe	ushort	using	virtual	void	volatile	while

C.1.8 Literals

literal:
  boolean-literal
  integer-literal
  real-literal
  character-literal
  string-literal
  null-literal
boolean-literal:
  true
  false
integer-literal:
  decimal-integer-literal
  hexadecimal-integer-literal
decimal-integer-literal:
  decimal-digits *integer-type-suffix*$_{opt}$
decimal-digits:
  decimal-digit
  decimal-digits *decimal-digit*
decimal-digit: one of
  0 1 2 3 4 5 6 7 8 9
integer-type-suffix: one of
  U u L l UL Ul uL ul LU Lu lU lu
hexadecimal-integer-literal:
  0x *hex-digits* *integer-type-suffix*$_{opt}$
  0X *hex-digits* *integer-type-suffix*$_{opt}$
hex-digits:
  hex-digit
  hex-digits *hex-digit*
hex-digit: one of
  0 1 2 3 4 5 6 7 8 9 A B C D E F a b c d e f
real-literal:
  decimal-digits . *decimal-digits* *exponent-part*$_{opt}$ *real-type-suffix*$_{opt}$
  . *decimal-digits* *exponent-part*$_{opt}$ *real-type-suffix*$_{opt}$
  decimal-digits *exponent-part* *real-type-suffix*$_{opt}$
  decimal-digits *real-type-suffix*
exponent-part:
  e *sign*$_{opt}$ *decimal-digits*
  E *sign*$_{opt}$ *decimal-digits*
sign: one of
  + -
real-type-suffix: one of
  F f D d M m
character-literal:

' *character* '

character:
single-character
simple-escape-sequence
hexadecimal-escape-sequence
unicode-escape-sequence

single-character:
Any character except ' (U+0027), \ (U+005C), and *new-line-character*

simple-escape-sequence: one of
\' \" \\ \0 \a \b \f \n \r \t \v

hexadecimal-escape-sequence:
\x *hex-digit* $hex\text{-}digit_{opt}$ $hex\text{-}digit_{opt}$ $hex\text{-}digit_{opt}$

string-literal:
regular-string-literal
verbatim-string-literal

regular-string-literal:
" $regular\text{-}string\text{-}literal\text{-}characters_{opt}$ "

regular-string-literal-characters:
regular-string-literal-character
regular-string-literal-characters *regular-string-literal-character*

regular-string-literal-character:
single-regular-string-literal-character
simple-escape-sequence
hexadecimal-escape-sequence
unicode-escape-sequence

single-regular-string-literal-character:
Any character except " (U+0022), \ (U+005C), and *new-line-character*

verbatim-string-literal:
@" $verbatim\text{-}string\text{-}literal\text{-}characters_{opt}$ "

verbatim-string-literal-characters:
verbatim-string-literal-character
verbatim-string-literal-characters *verbatim-string-literal-character*

verbatim-string-literal-character:
single-verbatim-string-literal-character
quote-escape-sequence

single-verbatim-string-literal-character:
any character except "

quote-escape-sequence:
""

null-literal:
null

C.1.9 Operators and punctuators

operator-or-punctuator: one of
{ } [ ] ( ) . , : ;
+ - * / % & | ^ ! ~
= < > ? ++ -- && || << >>
== != <= >= += -= *= /= %= &=
|= ^= <<= >>= ->

C.1.10 Pre-processing directives

pp-directive:
pp-declaration
pp-conditional
pp-line
pp-diagnostic
pp-region

pp-new-line:
$whitespace_{opt}$ $single\text{-}line\text{-}comment_{opt}$ *new-line*

conditional-symbol:

Any *identifier-or-keyword* except true or false

pp-expression:
whitespace$_{opt}$ *pp-or-expression* *whitespace*$_{opt}$

pp-or-expression:
pp-and-expression
pp-or-expression *whitespace*$_{opt}$ || *whitespace*$_{opt}$ *pp-and-expression*

pp-and-expression:
pp-equality-expression
pp-and-expression *whitespace*$_{opt}$ && *whitespace*$_{opt}$ *pp-equality-expression*

pp-equality-expression:
pp-unary-expression
pp-equality-expression *whitespace*$_{opt}$ == *whitespace*$_{opt}$ *pp-unary-expression*
pp-equality-expression *whitespace*$_{opt}$!= *whitespace*$_{opt}$ *pp-unary-expression*

pp-unary-expression:
pp-primary-expression
! *whitespace*$_{opt}$ *pp-unary-expression*

pp-primary-expression:
true
false
conditional-symbol
(*whitespace*$_{opt}$ *pp-expression* *whitespace*$_{opt}$)

pp-declaration:
whitespace$_{opt}$ # *whitespace*$_{opt}$ define *whitespace* *conditional-symbol* *pp-new-line*
whitespace$_{opt}$ # *whitespace*$_{opt}$ undef *whitespace* *conditional-symbol* *pp-new-line*

pp-conditional:
pp-if-section *pp-elif-sections*$_{opt}$ *pp-else-section*$_{opt}$ *pp-endif*

pp-if-section:
whitespace$_{opt}$ # *whitespace*$_{opt}$ if *whitespace* *pp-expression* *pp-new-line* *conditional-section*$_{opt}$

pp-elif-sections:
pp-elif-section
pp-elif-sections *pp-elif-section*

pp-elif-section:
whitespace$_{opt}$ # *whitespace*$_{opt}$ elif *whitespace* *pp-expression* *pp-new-line* *conditional-section*$_{opt}$

pp-else-section:
whitespace$_{opt}$ # *whitespace*$_{opt}$ else *pp-new-line* *conditional-section*$_{opt}$

pp-endif:
whitespace$_{opt}$ # *whitespace*$_{opt}$ endif *pp-new-line*

conditional-section:
input-section
skipped-section

skipped-section:
skipped-section-part
skipped-section *skipped-section-part*

skipped-section-part:
skipped-characters$_{opt}$ *new-line*
pp-directive

skipped-characters:
whitespace$_{opt}$ *not-number-sign* *input-characters*$_{opt}$

not-number-sign:
Any *input-character* except #

pp-line:
whitespace$_{opt}$ # *whitespace*$_{opt}$ line *whitespace* *line-indicator* *pp-new-line*

line-indicator:
decimal-digits *whitespace* *file-name*
decimal-digits
default

file-name:
" *file-name-characters* "

file-name-characters:

file-name-character
file-name-characters *file-name-character*
file-name-character:
Any *input-character* except "
pp-diagnostic:
whitespace$_{opt}$ # *whitespace*$_{opt}$ error *pp-message*
whitespace$_{opt}$ # *whitespace*$_{opt}$ warning *pp-message*
pp-message:
new-line
whitespace *input-characters*$_{opt}$ *new-line*
pp-region:
pp-start-region *conditional-section*$_{opt}$ *pp-end-region*
pp-start-region:
whitespace$_{opt}$ # *whitespace*$_{opt}$ region *pp-message*
pp-end-region:
whitespace$_{opt}$ # *whitespace*$_{opt}$ endregion *pp-message*

C.2 Syntactic grammar

C.2.1 Basic concepts

namespace-name:

C# Tutorials

The C# tutorials provide an overview of the basics of the language and identify important language features. Each tutorial includes one or more sample programs. The tutorials discuss the sample code plus provide additional background information. They also link to the corresponding sample abstract topics, where you can download and run the sample programs.

> **Note** The C# tutorials do not teach how to create a graphical user interface for your program like a Windows Form or a Web Forms page. To get started in that area, see the Visual C# Walkthroughs.

Tutorial	Description	Level
Hello World	Shows a Hello World application.	Simple
Command Line Parameters	Shows simple command-line processing; also shows array indexing.	Simple
Arrays	Shows how to use arrays.	Simple
Properties	Shows how properties are declared and used; also demonstrates abstract properties.	Simple
Libraries	Shows how to use compiler options to create a DLL library from multiple source files; also, how to use them in other programs.	Simple
Versioning	Shows the use of **override** and **new** to support versioning.	Simple
Collection Classes	Shows how to make collection classes that can be used with **foreach**.	Intermediate
Structs	Shows how to use structs in C#.	Intermediate
Indexers	Shows how to use array notation to access an object.	Intermediate
Indexed Properties	Shows how to implement a class that uses indexed properties. Indexed properties allow you to use a class that represents an array-like collection of several different kinds of things.	Intermediate
User-Defined Conversions	Shows how to define conversions to and from user-defined types.	Intermediate
Operator Overloading	Shows how user-defined classes can overload operators.	Intermediate
Delegates	Shows how delegates are declared, mapped, and combined.	Intermediate
Events	Shows how to use events in C#.	Intermediate
Explicit Interface Implementation	Demonstrates how to explicitly implement interface members.	Intermediate
Conditional Methods	Demonstrates conditional methods, which provide a powerful mechanism by which calls to methods can be included or omitted depending on whether a symbol is defined.	Intermediate
XML Documentation	Shows how to document code by using XML.	Intermediate
Platform Invoke	Shows how to call platform invokes (exported DLL functions) from C#.	Advanced
COM Interop Part 1	Shows how to use C# to interoperate with COM objects. Covers a C# client.	Advanced
COM Interop Part 2	Shows how to use C# to interoperate with COM objects. Covers a C# server.	Advanced
Attributes	Shows how to create custom attribute classes, use them in code, and query them through reflection.	Advanced
Security	Discusses .NET Framework security and shows two ways to modify security permissions in C#: permission classes and permission attributes.	Advanced
Threading	Demonstrates various thread activities such as creating and executing a thread, synchronizing threads, interacting between threads, using a thread pool, and using a mutex object.	Advanced
Unsafe Code	Shows how to use pointers.	Advanced
OLE DB	Shows how to use OLE DB in C# by connecting to a Microsoft Access database.	Advanced

Hello World Tutorial

This tutorial shows several versions of a Hello World program in C#.

Sample Files

See Hello World Sample to download and build the sample files discussed in this tutorial.

Further Reading

Main

1.1 Getting started

3.3 Declarations

Tutorial

The following examples show different ways of writing the C# Hello World program.

Example 1

```
// Hello1.cs
public class Hello1
{
   public static void Main()
   {
      System.Console.WriteLine("Hello, World!");
   }
}
```

Output

```
Hello, World!
```

Code Discussion

- Every `Main` method must be contained inside a class (`Hello1` in this case).
- The **System.Console** class contains a **WriteLine** method that can be used to display a string to the console.

Example 2

To avoid fully qualifying classes throughout a program, you can use the `using` directive as shown below:

```
// Hello2.cs
using System;

public class Hello2
{
   public static void Main()
   {
      Console.WriteLine("Hello, World!");
   }
}
```

Output

```
Hello, World!
```

Example 3

If you need access to the command line parameters passed in to your application, simply change the signature of the `Main` method to include them as shown below. This example counts and displays the command line arguments.

```
// Hello3.cs
// arguments: A B C D
using System;

public class Hello3
{
   public static void Main(string[] args)
   {
      Console.WriteLine("Hello, World!");
      Console.WriteLine("You entered the following {0} command line arguments:",
         args.Length );
      for (int i=0; i < args.Length; i++)
      {
         Console.WriteLine("{0}", args[i]);
      }
   }
}
```

Output

```
Hello, World!
You entered the following 4 command line arguments:
A
B
C
D
```

Example 4

To return a return code, change the signature of the `Main` method as shown below:

```
// Hello4.cs
using System;

public class Hello4
{
   public static int Main(string[] args)
   {
      Console.WriteLine("Hello, World!");
      return 0;
   }
}
```

Output

```
Hello, World!
```

Command Line Parameters Tutorial

This tutorial shows how the command line can be accessed and two ways of accessing the array of command line parameters.

Sample Files

See Command Line Parameters Sample to download and build the sample files discussed in this tutorial.

Further Reading

- The C# Version of Hello World!
- foreach, in
- String.Length Property

Tutorial

The following examples show two different approaches to using the command line arguments passed to an application.

Example 1

This example demonstrates how to print out the command line arguments.

```
// cmdline1.cs
// arguments: A B C
using System;

public class CommandLine
{
   public static void Main(string[] args)
   {
       // The Length property is used to obtain the length of the array.
       // Notice that Length is a read-only property:
       Console.WriteLine("Number of command line parameters = {0}",
          args.Length);
       for(int i = 0; i < args.Length; i++)
       {
           Console.WriteLine("Arg[{0}] = [{1}]", i, args[i]);
       }
   }
}
```

Output

Run the program using some arguments like this: `cmdline1 A B C`.

The output will be:

```
Number of command line parameters = 3
Arg[0] = [A]
Arg[1] = [B]
Arg[2] = [C]
```

Example 2

Another approach to iterating over the array is to use the **foreach** statement as shown in this example. The **foreach** statement can be used to iterate over an array or over a .NET Framework collection class. It provides a simple way to iterate over collections.

```
// cmdline2.cs
// arguments: John Paul Mary
using System;

public class CommandLine2
```

```
{
   public static void Main(string[] args)
   {
       Console.WriteLine("Number of command line parameters = {0}",
          args.Length);
       foreach(string s in args)
       {
          Console.WriteLine(s);
       }
   }
}
```

Output

Run the program using some arguments like this: `cmdline2 John Paul Mary`.

The output will be:

```
Number of command line parameters = 3
John
Paul
Mary
```

Arrays Tutorial

This tutorial describes arrays and shows how they work in C#.

Sample Files

See Arrays Sample to download and build the sample files discussed in this tutorial.

Further Reading

- Arrays
- 12. Arrays
- foreach, in
- Collection Classes Tutorial

Tutorial

This tutorial is divided into the following sections:

- Arrays in General
- Declaring Arrays
- Initializing Arrays
- Accessing Array Members
- Arrays are Objects
- Using foreach with Arrays

Arrays in General

C# arrays are zero indexed; that is, the array indexes start at zero. Arrays in C# work similarly to how arrays work in most other popular languages There are, however, a few differences that you should be aware of.

When declaring an array, the square brackets ([]) must come after the type, not the identifier. Placing the brackets after the identifier is not legal syntax in C#.

```
int[] table; // not int table[];
```

Another detail is that the size of the array is not part of its type as it is in the C language. This allows you to declare an array and assign any array of **int** objects to it, regardless of the array's length.

```
int[] numbers; // declare numbers as an int array of any size
numbers = new int[10];  // numbers is a 10-element array
numbers = new int[20];  // now it's a 20-element array
```

Declaring Arrays

C# supports single-dimensional arrays, multidimensional arrays (rectangular arrays), and array-of-arrays (jagged arrays). The following examples show how to declare different kinds of arrays:

Single-dimensional arrays:

```
int[] numbers;
```

Multidimensional arrays:

```
string[,] names;
```

Array-of-arrays (jagged):

```
byte[][] scores;
```

Declaring them (as shown above) does not actually create the arrays. In C#, arrays are objects (discussed later in this tutorial) and must be instantiated. The following examples show how to create arrays:

Single-dimensional arrays:

```
int[] numbers = new int[5];
```

Multidimensional arrays:

```
string[,] names = new string[5,4];
```

Array-of-arrays (jagged):

```
byte[][] scores = new byte[5][];
for (int x = 0; x < scores.Length; x++)
{
   scores[x] = new byte[4];
}
```

You can also have larger arrays. For example, you can have a three-dimensional rectangular array:

```
int[,,] buttons = new int[4,5,3];
```

You can even mix rectangular and jagged arrays. For example, the following code declares a single-dimensional array of three-dimensional arrays of two-dimensional arrays of type **int**:

```
int[][,,][,] numbers;
```

Example

The following is a complete C# program that declares and instantiates arrays as discussed above.

```
// arrays.cs
using System;
class DeclareArraysSample
{
    public static void Main()
    {
        // Single-dimensional array
        int[] numbers = new int[5];

        // Multidimensional array
        string[,] names = new string[5,4];

        // Array-of-arrays (jagged array)
        byte[][] scores = new byte[5][];

        // Create the jagged array
        for (int i = 0; i < scores.Length; i++)
        {
            scores[i] = new byte[i+3];
        }

        // Print length of each row
        for (int i = 0; i < scores.Length; i++)
        {
            Console.WriteLine("Length of row {0} is {1}", i, scores[i].Length);
        }
    }
}
```

Output

```
Length of row 0 is 3
Length of row 1 is 4
Length of row 2 is 5
Length of row 3 is 6
Length of row 4 is 7
```

Initializing Arrays

C# provides simple and straightforward ways to initialize arrays at declaration time by enclosing the initial values in curly braces ({}). The following examples show different ways to initialize different kinds of arrays.

> **Note** If you do not initialize an array at the time of declaration, the array members are automatically initialized to the default initial value for the array type. Also, if you declare the array as a field of a type, it will be set to the default value null when you instantiate the type.

Single-Dimensional Array

```
int[] numbers = new int[5] {1, 2, 3, 4, 5};
string[] names = new string[3] {"Matt", "Joanne", "Robert"};
```

You can omit the size of the array, like this:

```
int[] numbers = new int[] {1, 2, 3, 4, 5};
string[] names = new string[] {"Matt", "Joanne", "Robert"};
```

You can also omit the **new** operator if an initializer is provided, like this:

```
int[] numbers = {1, 2, 3, 4, 5};
string[] names = {"Matt", "Joanne", "Robert"};
```

Multidimensional Array

```
int[,] numbers = new int[3, 2] { {1, 2}, {3, 4}, {5, 6} };
string[,] siblings = new string[2, 2] { {"Mike","Amy"}, {"Mary","Albert"} };
```

You can omit the size of the array, like this:

```
int[,] numbers = new int[,] { {1, 2}, {3, 4}, {5, 6} };
string[,] siblings = new string[,] { {"Mike","Amy"}, {"Mary","Albert"} };
```

You can also omit the **new** operator if an initializer is provided, like this:

```
int[,] numbers = { {1, 2}, {3, 4}, {5, 6} };
string[,] siblings = { {"Mike", "Amy"}, {"Mary", "Albert"} };
```

Jagged Array (Array-of-Arrays)

You can initialize jagged arrays like this example:

```
int[][] numbers = new int[2][] { new int[] {2,3,4}, new int[] {5,6,7,8,9} };
```

You can also omit the size of the first array, like this:

```
int[][] numbers = new int[][] { new int[] {2,3,4}, new int[] {5,6,7,8,9} };
```

-or-

```
int[][] numbers = { new int[] {2,3,4}, new int[] {5,6,7,8,9} };
```

Notice that there is no initialization syntax for the elements of a jagged array.

Accessing Array Members

Accessing array members is straightforward and similar to how you access array members in C/C++. For example, the following code creates an array called `numbers` and then assigns a `5` to the fifth element of the array:

```
int[] numbers = {10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 0};
numbers[4] = 5;
```

The following code declares a multidimensional array and assigns `5` to the member located at `[1, 1]`:

```
int[,] numbers = { {1, 2}, {3, 4}, {5, 6}, {7, 8}, {9, 10} };
numbers[1, 1] = 5;
```

The following is a declaration of a single-dimension jagged array that contains two elements. The first element is an array of two integers, and the second is an array of three integers:

```
int[][] numbers = new int[][] { new int[] {1, 2}, new int[] {3, 4, 5}
};
```

The following statements assign 58 to the first element of the first array and 667 to the second element of the second array:

```
numbers[0][0] = 58;
numbers[1][1] = 667;
```

Arrays are Objects

In C#, arrays are actually objects. **System.Array** is the abstract base type of all array types. You can use the properties, and other class members, that **System.Array** has. An example of this would be using the Length property to get the length of an array. The following code assigns the length of the `numbers` array, which is `5`, to a variable called `LengthOfNumbers`:

```
int[] numbers = {1, 2, 3, 4, 5};
int LengthOfNumbers = numbers.Length;
```

The **System.Array** class provides many other useful methods/properties, such as methods for sorting, searching, and copying arrays.

Using foreach on Arrays

C# also provides the **foreach** statement. This statement provides a simple, clean way to iterate through the elements of an array. For example, the following code creates an array called `numbers` and iterates through it with the **foreach** statement:

```
int[] numbers = {4, 5, 6, 1, 2, 3, -2, -1, 0};
foreach (int i in numbers)
{
   System.Console.WriteLine(i);
}
```

With multidimensional arrays, you can use the same method to iterate through the elements, for example:

```
int[,] numbers = new int[3, 2] {{9, 99}, {3, 33}, {5, 55}};
foreach(int i in numbers)
{
```

```
    Console.Write("{0} ", i);
}
```

The output of this example is:

```
9 99 3 33 5 55
```

However, with multidimensional arrays, using a nested **for** loop gives you more control over the array elements.

Tutorial

This tutorial includes two examples. The first example shows how to declare and use read/write properties. The second example demonstrates abstract properties and shows how to override these properties in subclasses.

Example 1

This sample shows a `Person` class that has two properties: `Name` (string) and `Age` (int). Both properties are read/write.

```
// person.cs
using System;
class Person
{
    private string myName ="N/A";
    private int myAge = 0;

    // Declare a Name property of type string:
    public string Name
    {
        get
        {
           return myName;
        }
        set
        {
           myName = value;
        }
    }

    // Declare an Age property of type int:
    public int Age
    {
        get
        {
           return myAge;
        }
        set
        {
           myAge = value;
        }
    }

    public override string ToString()
    {
        return "Name = " + Name + ", Age = " + Age;
    }

    public static void Main()
    {
        Console.WriteLine("Simple Properties");
```

```
        // Create a new Person object:
        Person person = new Person();

        // Print out the name and the age associated with the person:
        Console.WriteLine("Person details - {0}", person);

        // Set some values on the person object:
        person.Name = "Joe";
        person.Age = 99;
        Console.WriteLine("Person details - {0}", person);

        // Increment the Age property:
        person.Age += 1;
        Console.WriteLine("Person details - {0}", person);
    }
}
```

Output

```
Simple Properties
Person details - Name = N/A, Age = 0
Person details - Name = Joe, Age = 99
Person details - Name = Joe, Age = 100
```

Code Discussion

- Notice the way that the properties are declared, for example, consider the `Name` property:

  ```
  public string Name
  {
      get
      {
         return myName;
      }
      set
      {
         myName = value;
      }
  }
  ```

  The Set and Get methods of a property are contained inside the property declaration. You can control whether a property is read/write, read-only, or write-only by controlling whether a Get or Set method is included.

- Once the properties are declared, they can be used as if they were fields of the class. This allows for a very natural syntax when both getting and setting the value of a property, as in the following statements:

  ```
  person.Name = "Joe";
  person.Age = 99;
  ```

- Note that in a property Set method a special `value` variable is available. This variable contains the value that the user specified, for example:

  ```
  myName = value;
  ```

- Notice the clean syntax for incrementing the `Age` property on a `Person` object:

  ```
  person.Age += 1;
  ```

  If separate Set and Get methods were used to model properties, the equivalent code might look like this:

```
person.SetAge(person.GetAge() + 1);
```

- The ToString method is overridden in this example:

```
public override string ToString()
{
    return "Name = " + Name + ", Age = " + Age;
}
```

Notice that ToString is not explicitly used in the program. It is invoked by default by the WriteLine calls.

Example 2

The following example shows how to define abstract properties. An abstract property declaration does not provide an implementation of the property accessors. The example demonstrates how to override these properties in subclasses.

This sample consists of three files. In the Properties Sample, these files are compiled into a single compilation but in this tutorial, each file is compiled individually and its resulting assembly referenced by the next compilation:

- `abstractshape.cs`: The `Shape` class that contains an abstract `Area` property.
- `shapes.cs`: The subclasses of the `Shape` class.
- `shapetest.cs`: A test program to display the areas of some `Shape`-derived objects.

To compile the example, use the command line:

```
csc abstractshape.cs shapes.cs shapetest.cs
```

This will create the executable file shapetest.exe.

File 1 - abstractshape.cs

This file declares the `Shape` class that contains the `Area` property of the type double

```
// abstractshape.cs
// compile with: /target:library
// csc /target:library abstractshape.cs
using System;

public abstract class Shape
{
   private string myId;

   public Shape(string s)
   {
      Id = s;   // calling the set accessor of the Id property
   }

   public string Id
   {
      get
      {
         return myId;
      }

      set
      {
         myId = value;
      }
   }

   // Area is a read-only property - only a get accessor is needed:
   public abstract double Area
   {
```

```
      get;
   }

   public override string ToString()
   {
      return Id + " Area = " + string.Format("{0:F2}",Area);
   }
}
```

Code Discussion

- Modifiers on the property are placed on the property declaration itself, for example:

  ```
  public abstract double Area
  ```

- When declaring an abstract property (such as `Area` in this example), you simply indicate what property accessors are available, but do not implement them. In this example, only a Get accessor is available, so the property is read-only.

File 2 - shapes.cs

The following code shows three subclasses of `Shape` and how they override the `Area` property to provide their own implementation.

```
// shapes.cs
// compile with: /target:library /reference:abstractshape.dll
public class Square : Shape
{
   private int mySide;

   public Square(int side, string id) : base(id)
   {
      mySide = side;
   }

   public override double Area
   {
      get
      {
         // Given the side, return the area of a square:
         return mySide * mySide;
      }
   }
}

public class Circle : Shape
{
   private int myRadius;

   public Circle(int radius, string id) : base(id)
   {
      myRadius = radius;
   }

   public override double Area
   {
      get
      {
         // Given the radius, return the area of a circle:
         return myRadius * myRadius * System.Math.PI;
      }
   }
}

public class Rectangle : Shape
{
   private int myWidth;
```

```
   private int myHeight;

   public Rectangle(int width, int height, string id) : base(id)
   {
      myWidth  = width;
      myHeight = height;
   }

   public override double Area
   {
      get
      {
         // Given the width and height, return the area of a rectangle:
         return myWidth * myHeight;
      }
   }
}
```

File 3 - shapetest.cs

The following code shows a test program that creates a number of `Shape`-derived objects and prints out their areas.

```
// shapetest.cs
// compile with: /reference:abstractshape.dll;shapes.dll
public class TestClass
{
   public static void Main()
   {
      Shape[] shapes =
         {
            new Square(5, "Square #1"),
            new Circle(3, "Circle #1"),
            new Rectangle( 4, 5, "Rectangle #1")
         };

      System.Console.WriteLine("Shapes Collection");
      foreach(Shape s in shapes)
      {
         System.Console.WriteLine(s);
      }

   }
}
```

Output

```
Shapes Collection
Square #1 Area = 25.00
Circle #1 Area = 28.27
Rectangle #1 Area = 20.00
```

Libraries Tutorial

This tutorial shows how to create and use libraries in C#.

Sample Files

See Libraries Sample to download and build the sample files discussed in this tutorial.

Further Reading

- Creating and Using C# DLLs
- C# Compiler Options

Tutorial

This tutorial demonstrates how to create a managed DLL file by using the necessary compiler options, and how to use the library by a client program.

Example

This example uses the following modules:

- The DLL library (`Functions.dll`), which is built from the following source files:

  `Factorial.cs`: Calculates and returns the factorial of a number.

  `DigitCounter.cs`: Counts the number of digits in the passed string.

- The client program (`FunctionTest.exe`), which uses the DLL, is compiled from the source file `FunctionClient.cs`. The program displays the factorial of the input arguments.

Building the Library

To build the library, make Functions the current directory and type the following at the command prompt:

```
csc /target:library /out:Functions.dll Factorial.cs DigitCounter.cs
```

where:

`/target:library`	Specifies that the output is a DLL and not an executable file (this also stops the compiler fro m looking for a default entry point).
`/out:Functions.dll`	Specifies that the output file name is `Functions.dll`. Normally the output name is the same name as the first C# source file on the command line (in this example, `Factorial`).
`Factorial.cs DigitCounter.cs`	Specifies the files to compile and place in the DLL.

Compiling the Client

To compile the program, make FunctionTest the current directory and type the following at the command prompt:

```
copy ..\Functions\Functions.dll .
csc /out:FunctionTest.exe /R:Functions.DLL FunctionClient.cs
```

where:

`/out:FunctionTest.exe`	Specifies that the output file name is `FunctionTest.exe`.
`/R:Functions.DLL`	Specifies that `Functions.DLL` must be included when resolving references. This DLL must be located in the current directory or have a fully qualified path.
`FunctionClient.cs`	Specifies the client source code.

This creates the executable file `FunctionTest.exe`.

File 1 - Factorial.cs

The following code calculates the factorial of the integer passed to the method (unlike Libraries Sample, compile this to a library).

```
// Factorial.cs
// compile with: /target:library
using System;

// Declares a namespace. You need to package your libraries according
// to their namespace so the .NET runtime can correctly load the classes.
namespace Functions
{
    public class Factorial
    {
// The "Calc" static method calculates the factorial value for the
// specified integer passed in:
        public static int Calc(int i)
        {
            return((i <= 1) ? 1 : (i * Calc(i-1)));
        }
    }
}
```

File 2 - DigitCounter.cs

The following code is used to count the number of digit characters in the passed string:

```
// DigitCounter.cs
// compile with: /target:library /out:Functions.dll /reference:Factorial.dll
using System;

// Declare the same namespace as the one in Factorial.cs. This simply
// allows types to be added to the same namespace.
namespace Functions
{
    public class DigitCount
    {
        // The NumberOfDigits static method calculates the number of
        // digit characters in the passed string:
        public static int NumberOfDigits(string theString)
        {
            int count = 0;
            for ( int i = 0; i < theString.Length; i++ )
            {
                if ( Char.IsDigit(theString[i]) )
                {
                    count++;
                }
            }
            return count;
        }
    }
}
```

File 3 - FunctionClient.cs

Once you build a library, it can be used by other programs. The following client program uses the classes defined in the library. The basic function of the program is to take each command-line parameter and attempt to compute the factorial value for each argument.

```
// FunctionClient.cs
// compile with: /reference:Functions.dll,Factorial.dll /out:FunctionTest.exe
// arguments: 3 5 10
using System;
// The following using directive makes the types defined in the Functions
// namespace available in this compilation unit:
```

```
using Functions;
class FunctionClient
{
    public static void Main(string[] args)
    {
        Console.WriteLine("Function Client");

        if ( args.Length == 0 )
        {
            Console.WriteLine("Usage: FunctionTest ... ");
            return;
        }

        for ( int i = 0; i < args.Length; i++ )
        {
            int num = Int32.Parse(args[i]);
            Console.WriteLine(
               "The Digit Count for String [{0}] is [{1}]",
               args[i],
               // Invoke the NumberOfDigits static method in the
               // DigitCount class:
               DigitCount.NumberOfDigits(args[i]));
            Console.WriteLine(
               "The Factorial for [{0}] is [{1}]",
                num,
               // Invoke the Calc static method in the Factorial class:
                Factorial.Calc(num) );
        }
    }
}
```

Output

The command line `FunctionTest 3 5 10` uses the program `FunctionTest` to calculate the factorial of the three integers 3, 5, and 10. It also displays the number of digits for each argument.

This run gives the output:

```
Function Client
The Digit Count for String [3] is [1]
The Factorial for [3] is [6]
The Digit Count for String [5] is [1]
The Factorial for [5] is [120]
The Digit Count for String [10] is [2]
The Factorial for [10] is [3628800]
```

> **Note** To run the client executable (`FunctionTest.exe`), the file `Functions.DLL` must be in the current directory, a child directory, or in the Global Assembly Cache. For more information see Global Assembly Cache.

Versioning Tutorial

This tutorial demonstrates versioning in C# through the use of the **override** and **new** keywords. Versioning maintains compatibility between base and derived classes as they evolve.

Sample Files

See Versioning Sample to download and build the sample files discussed in this tutorial.

Further Reading

- virtual
- override
- new
- 10.5.3 Virtual methods

Tutorial

The C# language is designed such that versioning between base and derived classes in different libraries can evolve and maintain backwards compatibility. This means, for example, that the introduction of a new member in a base class with the same name as a member in a derived class is not an error. It also means that a class must explicitly state whether a method is intended to override an inherited method, or whether a method is a new method that simply hides a similarly named inherited method.

In C#, methods are by default, not virtual. To make a method virtual, the **virtual** modifier has to be used in the method declaration of the base class. The derived class can then override the base virtual method by using the **override** keyword or hide the virtual method in the base class by using the **new** keyword. If neither the **override** keyword nor the **new** keyword is specified, the compiler will issue a warning and the method in the derived class will hide the method in the base class. The following example shows these concepts in action.

Example

```
// versioning.cs
// CS0114 expected
public class MyBase
{
   public virtual string Meth1()
   {
      return "MyBase-Meth1";
   }
   public virtual string Meth2()
   {
      return "MyBase-Meth2";
   }
   public virtual string Meth3()
   {
      return "MyBase-Meth3";
   }
}

class MyDerived : MyBase
{
   // Overrides the virtual method Meth1 using the override keyword:
   public override string Meth1()
   {
      return "MyDerived-Meth1";
   }
   // Explicitly hide the virtual method Meth2 using the new
   // keyword:
   public new string Meth2()
   {
      return "MyDerived-Meth2";
   }
   // Because no keyword is specified in the following declaration
   // a warning will be issued to alert the programmer that
```

```
    // the method hides the inherited member MyBase.Meth3():
    public string Meth3()
    {
       return "MyDerived-Meth3";
    }

    public static void Main()
    {
       MyDerived mD = new MyDerived();
       MyBase mB = (MyBase) mD;

       System.Console.WriteLine(mB.Meth1());
       System.Console.WriteLine(mB.Meth2());
       System.Console.WriteLine(mB.Meth3());
    }
 }
```

Output

```
MyDerived-Meth1
MyBase-Meth2
MyBase-Meth3
```

Code Discussion

Hiding a base class member from a derived class isn't an error in C#. This feature enables you to make changes in the base class without breaking other libraries that inherit this base class. For example, at some point you could have the following classes:

```
class Base {}
class Derived: Base
{
   public void F() {}
}
```

At some later point, the base class could evolve to add a void method `F()` as follows:

```
class Base
{
   public void F() {}
}
class Derived: Base
{
   public void F() {}
}
```

Thus, in C#, both the base and derived classes can evolve freely and maintain binary compatibility.

Collection Classes Tutorial

This tutorial shows how to implement a collection class that can be used with the **foreach** statement.

Sample Files

See Collection Classes Sample to download and build the sample files discussed in this tutorial.

Further Reading

- foreach, in
- 8.8.4 The foreach statement
- Command Line Parameters Tutorial
- Arrays Tutorial

Tutorial

The **foreach** statement is a convenient way to iterate over the elements of an array. It can also enumerate the elements of a collection, provided that the collection class has implemented the **System.Collections.IEnumerator** and **System.Collections.IEnumerable** interfaces.

Example 1

The following code sample illustrates how to write a collection class that can be used with **foreach**. The class is a string tokenizer, similar to the C run-time function **strtok**.

```
// tokens.cs
using System;
// The System.Collections namespace is made available:
using System.Collections;

// Declare the Tokens class:
public class Tokens : IEnumerable
{
   private string[] elements;

   Tokens(string source, char[] delimiters)
   {
      // Parse the string into tokens:
      elements = source.Split(delimiters);
   }

   // IEnumerable Interface Implementation:
   //   Declaration of the GetEnumerator() method
   //   required by IEnumerable
   public IEnumerator GetEnumerator()
   {
      return new TokenEnumerator(this);
   }

   // Inner class implements IEnumerator interface:
   private class TokenEnumerator : IEnumerator
   {
      private int position = -1;
      private Tokens t;

      public TokenEnumerator(Tokens t)
      {
         this.t = t;
      }

      // Declare the MoveNext method required by IEnumerator:
      public bool MoveNext()
      {
         if (position < t.elements.Length - 1)
```

```
         {
            position++;
            return true;
         }
         else
         {
            return false;
         }
      }

      // Declare the Reset method required by IEnumerator:
      public void Reset()
      {
         position = -1;
      }

      // Declare the Current property required by IEnumerator:
      public object Current
      {
         get
         {
            return t.elements[position];
         }
      }
   }

   // Test Tokens, TokenEnumerator

   static void Main()
   {
      // Testing Tokens by breaking the string into tokens:
      Tokens f = new Tokens("This is a well-done program.",
         new char[] {' ','-'});
      foreach (string item in f)
      {
         Console.WriteLine(item);
      }
   }
}
```

Output

```
This
is
a
well
done
program.
```

Code Discussion

In the preceding example, the following code is used to `Tokens` by breaking "This is a well-done program." into tokens (using ' ' and '-' as separators) and enumerating those tokens with the **foreach** statement:

```
Tokens f = new Tokens("This is a well-done program.",
   new char[] {' ','-'});
foreach (string item in f)
{
   Console.WriteLine(item);
}
```

Notice that, internally, `Tokens` uses an array, which implements `IEnumerator` and `IEnumerable` itself. The code sample could have leveraged the array's enumeration methods as its own, but that would have defeated the purpose of this example.

In C#, it is not strictly necessary for a collection class to inherit from **IEnumerable** and **IEnumerator** in order to be compatible with **foreach**; as long as the class has the required `GetEnumerator`, `MoveNext`, `Reset`, and `Current` members, it will work with **foreach**. Omitting the interfaces has the advantage of allowing you to define the return type of `Current` to be more specific than **object**, thereby providing type-safety.

For example, starting with the sample code above, change the following lines:

```
public class Tokens  // no longer inherits from IEnumerable
public TokenEnumerator GetEnumerator()  // doesn't return an IEnumerator
public class TokenEnumerator  // no longer inherits from IEnumerator
public string Current  // type-safe: returns string, not object
```

Now, because `Current` returns a string, the compiler can detect when an incompatible type is used in a **foreach** statement:

```
foreach (int item in f)  // Error: cannot convert string to int
```

The disadvantage of omitting **IEnumerable** and **IEnumerator** is that the collection class is no longer interoperable with the **foreach** statements (or equivalents) of other common language runtime-compatible languages.

You can have the best of both worlds — type-safety within C# and interoperability with other common language runtime-compatible languages — by inheriting from **IEnumerable** and **IEnumerator** and using explicit interface implementation, as demonstrated in the following example.

Example 2

This sample is equivalent in function to Example 1, but it provides additional type-safety in C# while maintaining interoperability with other languages.

```
// tokens2.cs
using System;
using System.Collections;

public class Tokens: IEnumerable
{
   private string[] elements;

   Tokens(string source, char[] delimiters)
   {
      elements = source.Split(delimiters);
   }

   // IEnumerable Interface Implementation:

   public TokenEnumerator GetEnumerator() // non-IEnumerable version
   {
      return new TokenEnumerator(this);
   }

   IEnumerator IEnumerable.GetEnumerator() // IEnumerable version
   {
      return (IEnumerator) new TokenEnumerator(this);
   }

   // Inner class implements IEnumerator interface:

   public class TokenEnumerator: IEnumerator
   {
      private int position = -1;
      private Tokens t;

      public TokenEnumerator(Tokens t)
      {
         this.t = t;
      }
```

```
        public bool MoveNext()
        {
           if (position < t.elements.Length - 1)
           {
              position++;
              return true;
           }
           else
           {
              return false;
           }
        }

        public void Reset()
        {
           position = -1;
        }

        public string Current // non-IEnumerator version: type-safe
        {
           get
           {
              return t.elements[position];
           }
        }

        object IEnumerator.Current // IEnumerator version: returns object
        {
           get
           {
              return t.elements[position];
           }
        }
     }

     // Test Tokens, TokenEnumerator

     static void Main()
     {
        Tokens f = new Tokens("This is a well-done program.",
           new char [] {' ','-'});
        foreach (string item in f) // try changing string to int
        {
           Console.WriteLine(item);
        }
     }
  }
```

Structs Tutorial

This tutorial presents the syntax and usage of structs. It also covers the important differences between classes and structs.

Sample Files

See Structs Sample to download and build the sample files discussed in this tutorial.

Further Reading

- struct
- 1.8 Structs
- Structs Grammar in C. Grammar
- Value Types
- C# Attributes
- 17. Attributes
- StructLayoutAttribute Class

Tutorial

This tutorial includes two examples. The first example shows you how to declare and use structs, and the second example demonstrates the difference between structs and classes when instances are passed to methods. You are also introduced to the following topics:

- Structs vs. Classes
- Heap or Stack?
- Constructors and Inheritance
- Attributes on Structs

Example 1

This example declares a struct with three members: a property, a method, and a private field. It creates an instance of the struct and puts it to use:

```
// struct1.cs
using System;
struct SimpleStruct
{
    private int xval;
    public int X
    {
        get
        {
            return xval;
        }
        set
        {
            if (value < 100)
                xval = value;
        }
    }
    public void DisplayX()
    {
        Console.WriteLine("The stored value is: {0}", xval);
    }
}

class TestClass
{
    public static void Main()
    {
        SimpleStruct ss = new SimpleStruct();
        ss.X = 5;
```

```
        ss.DisplayX();
    }
}
```

Output

```
The stored value is: 5
```

Structs vs. Classes

Structs may seem similar to classes, but there are important differences that you should be aware of. First of all, classes are reference types and structs are value types. By using structs, you can create objects that behave like the built-in types and enjoy their benefits as well.

Heap or Stack?

When you call the New operator on a class, it will be allocated on the heap. However, when you instantiate a struct, it gets created on the stack. This will yield performance gains. Also, you will not be dealing with references to an instance of a struct as you would with classes. You will be working directly with the struct instance. Because of this, when passing a struct to a method, it's passed by value instead of as a reference.

Example 2

This example shows that when a struct is passed to a method, a copy of the struct is passed, but when a class instance is passed, a reference is passed.

```
// struct2.cs
using System;

class TheClass
{
    public int x;
}

struct TheStruct
{
    public int x;
}

class TestClass
{
    public static void structtaker(TheStruct s)
    {
        s.x = 5;
    }
    public static void classtaker(TheClass c)
    {
        c.x = 5;
    }
    public static void Main()
    {
        TheStruct a = new TheStruct();
        TheClass b = new TheClass();
        a.x = 1;
        b.x = 1;
        structtaker(a);
        classtaker(b);
        Console.WriteLine("a.x = {0}", a.x);
        Console.WriteLine("b.x = {0}", b.x);
    }
}
```

Output

```
a.x = 1
b.x = 5
```

Code Discussion

The output of the example shows that only the value of the class field was changed when the class instance was passed to the `classtaker` method. The struct field, however, did not change by passing its instance to the `structtaker` method. This is because a copy of the struct was passed to the `structtaker` method, while a reference to the class was passed to the `classtaker` method.

Constructors and Inheritance

Structs can declare constructors, but they must take parameters. It is an error to declare a default (parameterless) constructor for a struct. Struct members cannot have initializers. A default constructor is always provided to initialize the struct members to their default values.

When you create a struct object using the New operator, it gets created and the appropriate constructor is called. Unlike classes, structs can be instantiated without using the New operator. If you do not use New, the fields will remain unassigned and the object cannot be used until all the fields are initialized.

There is no inheritance for structs as there is for classes. A struct cannot inherit from another struct or class, and it cannot be the base of a class. Structs, however, inherit from the base class object. A struct can implement interfaces, and it does that exactly as classes do. Here's a code snippet of a struct implementing an interface:

```
interface IImage
{
    void Paint();
}

struct Picture : IImage
{
    public void Paint()
    {
         // painting code goes here
    }
    private int x, y, z;  // other struct members
}
```

Attributes on Structs

By using attributes you can customize how structs are laid out in memory. For example, you can create what's known as a union in C/C++ by using the **StructLayout(LayoutKind.Explicit)** and **FieldOffset** attributes.

```
using System.Runtime.InteropServices;
[StructLayout(LayoutKind.Explicit)]
struct TestUnion
{
    [FieldOffset(0)]
    public int i;
    [FieldOffset(0)]
    public double d;
    [FieldOffset(0)]
    public char c;
    [FieldOffset(0)]
    public byte b1;
}
```

In the preceding code segment, all of the fields of `TestUnion` start at the same location in memory.

The following is another example where fields start at different explicitly set locations:

```
using System.Runtime.InteropServices;
```

```
[StructLayout(LayoutKind.Explicit)]
struct TestExplicit
{
    [FieldOffset(0)]
    public long lg;
    [FieldOffset(0)]
    public int i1;
    [FieldOffset(4)]
    public int i2;
    [FieldOffset(8)]
    public double d;
    [FieldOffset(12)]
    public char c;
    [FieldOffset(14)]
    public byte b1;
}
```

The two **int** fields, `i1` and `i2`, share the same memory locations as `lg`. This sort of control over struct layout is useful when using platform invocation.

Conclusion

Structs are simple to use and can prove to be useful at times. Just keep in mind that they're created on the stack and that you're not dealing with references to them but dealing directly with them. Whenever you have a need for a type that will be used often and is mostly just a piece of data, structs might be a good option.

Tutorial

Defining an *indexer* allows you to create classes that act like "virtual arrays." Instances of that class can be accessed using the **[]** array access operator. Defining an indexer in C# is similar to defining operator **[]** in C++, but is considerably more flexible. For classes that encapsulate array- or collection-like functionality, using an indexer allows the users of that class to use the array syntax to access the class.

For example, suppose you want to define a class that makes a file appear as an array of bytes. If the file were very large, it would be impractical to read the entire file into memory, especially if you only wanted to read or change a few bytes. By defining a `FileByteArray` class, you could make the file appear similar to an array of bytes, but actually do file input and output when a byte was read or written.

In addition to the example below, an advanced topic on Creating an Indexed Property is discussed in this tutorial.

Example

In this example, the class `FileByteArray` makes it possible to access a file as if it were a byte array. The `Reverse` class reverses the bytes of the file. You can run this program to reverse the bytes of any text file including the program source file itself. To change the reversed file back to normal, run the program on the same file again.

```
// indexer.cs
// arguments: indexer.txt
using System;
using System.IO;

// Class to provide access to a large file
// as if it were a byte array.
public class FileByteArray
{
    Stream stream;      // Holds the underlying stream
                        // used to access the file.
// Create a new FileByteArray encapsulating a particular file.
    public FileByteArray(string fileName)
    {
        stream = new FileStream(fileName, FileMode.Open);
    }

    // Close the stream. This should be the last thing done
    // when you are finished.
    public void Close()
    {
        stream.Close();
        stream = null;
    }

    // Indexer to provide read/write access to the file.
    public byte this[long index]   // long is a 64-bit integer
    {
```

```
        // Read one byte at offset index and return it.
        get
        {
            byte[] buffer = new byte[1];
            stream.Seek(index, SeekOrigin.Begin);
            stream.Read(buffer, 0, 1);
            return buffer[0];
        }
        // Write one byte at offset index and return it.
        set
        {
            byte[] buffer = new byte[1] {value};
            stream.Seek(index, SeekOrigin.Begin);
            stream.Write(buffer, 0, 1);
        }
    }

    // Get the total length of the file.
    public long Length
    {
        get
        {
            return stream.Seek(0, SeekOrigin.End);
        }
    }
}

// Demonstrate the FileByteArray class.
// Reverses the bytes in a file.
public class Reverse
{
    public static void Main(String[] args)
    {
        // Check for arguments.
        if (args.Length == 0)
        {
            Console.WriteLine("indexer <filename>");
            return;
        }

        FileByteArray file = new FileByteArray(args[0]);
        long len = file.Length;

        // Swap bytes in the file to reverse it.
        for (long i = 0; i < len / 2; ++i)
        {
            byte t;

            // Note that indexing the "file" variable invokes the
            // indexer on the FileByteStream class, which reads
            // and writes the bytes in the file.
            t = file[i];
            file[i] = file[len - i - 1];
            file[len - i - 1] = t;
        }

        file.Close();
    }
}
```

Input: indexer.txt

To test the program you can use a text file with the following contents (this file is called `Test.txt` in the Indexers Sample).

```
public class Hello1
{
   public static void Main()
```

```
    {
       System.Console.WriteLine("Hello, World!");
    }
}
```

To reverse the bytes of this file, compile the program and then use the command line:

```
indexer indexer.txt
```

To display the reversed file, enter the command:

```
Type indexer.txt
```

Sample Output

```
}
}
;)"!dlroW ,olleH"(eniLetirW.elosnoC.metsyS
{
)(niaM diov citats cilbup
{
1olleH ssalc cilbup
```

Code Discussion

- Since an indexer is accessed using the **[]** operator, it does not have a name. For indexer declaration syntax, see Indexers.
- In the example above, the indexer is of type byte and takes a single index of type long (64-bit integer). The Get accessor defines the code to read a byte from the file, while the Set accessor defines the code to write a byte to the file. Inside the Set accessor, the predefined parameter value has the value that is being assigned to the virtual array element.
- An indexer must have at least one parameter. Although it is comparatively rare, an indexer can have more than one parameter in order to simulate a multidimensional "virtual array." Although integral parameters are the most common, the indexer parameter can be of any type. For example, the standard Dictionary class provides an indexer with a parameter of type Object.
- Although indexers are a powerful feature, it is important to use them only when the array-like abstraction makes sense. Always carefully consider whether using regular method(s) would be just as clear. For example, the following is a bad use of an indexer:

  ```
  class Employee
  {
      // VERY BAD STYLE: using an indexer to access
      // the salary of an employee.
      public double this[int year]
     {
          get
          {
              // return employee's salary for a given year.
          }
     }
  }
  ```

  Although legal, an indexer with only a Get accessor is rarely good style. Strongly consider using a method in this case.

- Indexers can be overloaded (for more information, see 10.8.1 Indexer overloading).

Tutorial

Suppose you want to write a class, `Document`, which encapsulates a lengthy section of text. To allow easy implementation of various operations such as checking spelling, you might want to view the document as a virtual array of words, as well as of characters.

The following example shows a technique for implementing such a class. For each "indexed property," you define a nested class, which contains a reference back to the main class instance. A **readonly** field on the main class provides access to an instance of the nested class that defines each virtual array. Each of the nested classes defines an indexer, as well as other collection-like methods (a `Count` property, for example). The following example shows this for "`Words`" and "`Characters`."

> **Note** Use this technique sparingly! Only use this pattern if the abstraction provided by using array indexing operations significantly clarifies code that uses your class, and if the indexers have both Get and Set accessors.

Example

In this example the `Document` class is defined. Two indexed properties, `Words` and `Characters`, are used to perform some text operations on the `Document` object.

```
// indexedproperty.cs
using System;

public class Document
{
    // Type allowing the document to be viewed like an array of words:
    public class WordCollection
    {
        readonly Document document;  // The containing document

        internal WordCollection(Document d)
        {
           document = d;
        }

        // Helper function -- search character array "text", starting at
        // character "begin", for word number "wordCount." Returns false
        // if there are less than wordCount words. Sets "start" and
        // length" to the position and length of the word within text:
        private bool GetWord(char[] text, int begin, int wordCount,
                                        out int start, out int length)
        {
            int end = text.Length;
            int count = 0;
            int inWord = -1;
            start = length = 0;
```

```
        for (int i = begin; i <= end; ++i)
        {
            bool isLetter = i < end && Char.IsLetterOrDigit(text[i]);

            if (inWord >= 0)
            {
                if (!isLetter)
                {
                    if (count++ == wordCount)
                    {
                        start = inWord;
                        length = i - inWord;
                        return true;
                    }
                    inWord = -1;
                }
            }
            else
            {
                if (isLetter)
                    inWord = i;
            }
        }
        return false;
    }

    // Indexer to get and set words of the containing document:
    public string this[int index]
    {
        get
        {
            int start, length;
            if (GetWord(document.TextArray, 0, index, out start,
                                                      out length))
                return new string(document.TextArray, start, length);
            else
                throw new IndexOutOfRangeException();
        }
        set
        {
            int start, length;
            if (GetWord(document.TextArray, 0, index, out start,
                                                     out length))
            {
                // Replace the word at start/length with the
                // string "value":
                if (length == value.Length)
                {
                    Array.Copy(value.ToCharArray(), 0,
                               document.TextArray, start, length);
                }
                else
                {
                    char[] newText =
                        new char[document.TextArray.Length +
                                 value.Length - length];
                    Array.Copy(document.TextArray, 0, newText,
                                                   0, start);
                    Array.Copy(value.ToCharArray(), 0, newText,
                                         start, value.Length);
                    Array.Copy(document.TextArray, start + length,
                               newText, start + value.Length,
                              document.TextArray.Length - start
                                                        - length);
                    document.TextArray = newText;
                }
            }
            else
```

```
                throw new IndexOutOfRangeException();
            }
        }

        // Get the count of words in the containing document:
        public int Count
        {
            get
            {
                int count = 0, start = 0, length = 0;
                while (GetWord(document.TextArray, start + length, 0,
                                                out start, out length))
                    ++count;
                return count;
            }
        }
    }

    // Type allowing the document to be viewed like an "array"
    // of characters:
    public class CharacterCollection
    {
        readonly Document document;  // The containing document

        internal CharacterCollection(Document d)
        {
          document = d;
        }

        // Indexer to get and set characters in the containing document:
        public char this[int index]
        {
            get
            {
                return document.TextArray[index];
            }
            set
            {
                document.TextArray[index] = value;
            }
        }

        // Get the count of characters in the containing document:
        public int Count
        {
            get
            {
                return document.TextArray.Length;
            }
        }
    }

    // Because the types of the fields have indexers,
    // these fields appear as "indexed properties":
    public readonly WordCollection Words;
    public readonly CharacterCollection Characters;

    private char[] TextArray;  // The text of the document.

    public Document(string initialText)
    {
        TextArray = initialText.ToCharArray();
        Words = new WordCollection(this);
        Characters = new CharacterCollection(this);
    }

    public string Text
    {
```

```
        get
        {
           return new string(TextArray);
        }
    }
}

class Test
{
    static void Main()
    {
        Document d = new Document(
           "peter piper picked a peck of pickled peppers. How many pickled peppers did peter
piper pick?"
        );

        // Change word "peter" to "penelope":
        for (int i = 0; i < d.Words.Count; ++i)
        {
            if (d.Words[i] == "peter")
                d.Words[i] = "penelope";
        }

        // Change character "p" to "P"
        for (int i = 0; i < d.Characters.Count; ++i)
        {
            if (d.Characters[i] == 'p')
                d.Characters[i] = 'P';
        }

        Console.WriteLine(d.Text);
    }
}
```

Output

```
PeneloPe PiPer Picked a Peck of Pickled PePPers. How many Pickled PePPers did PeneloPe PiPer
Pick?
```

Tutorial

C# allows programmers to declare conversions on classes or structs so that classes or structs can be converted to and/or from other classes or structs, or basic types. Conversions are defined like operators and are named for the type to which they convert.

In C#, conversions can be declared either as **implicit**, which occur automatically when required, or **explicit**, which require a cast to be called. All conversions must be **static**, and must either take the type the conversion is defined on, or return that type.

This tutorial introduces two examples. The first example shows how to declare and use conversions, and the second example demonstrates conversions between structs.

Example 1

In this example, a `RomanNumeral` type is declared, and several conversions to and from it are defined.

```
// conversion.cs
using System;

struct RomanNumeral
{
    public RomanNumeral(int value)
    {
       this.value = value;
    }
    // Declare a conversion from an int to a RomanNumeral. Note the
    // the use of the operator keyword. This is a conversion
    // operator named RomanNumeral:
    static public implicit operator RomanNumeral(int value)
    {
       // Note that because RomanNumeral is declared as a struct,
       // calling new on the struct merely calls the constructor
       // rather than allocating an object on the heap:
       return new RomanNumeral(value);
    }
    // Declare an explicit conversion from a RomanNumeral to an int:
    static public explicit operator int(RomanNumeral roman)
    {
       return roman.value;
    }
    // Declare an implicit conversion from a RomanNumeral to
    // a string:
    static public implicit operator string(RomanNumeral roman)
    {
       return("Conversion not yet implemented");
    }
    private int value;
```

```
}

class Test
{
    static public void Main()
    {
        RomanNumeral numeral;

        numeral = 10;

// Call the explicit conversion from numeral to int. Because it is
// an explicit conversion, a cast must be used:
        Console.WriteLine((int)numeral);

// Call the implicit conversion to string. Because there is no
// cast, the implicit conversion to string is the only
// conversion that is considered:
        Console.WriteLine(numeral);

// Call the explicit conversion from numeral to int and
// then the explicit conversion from int to short:
        short s = (short)numeral;

        Console.WriteLine(s);
    }
}
```

Output

```
10
Conversion not yet implemented
10
```

Example 2

This example defines two structs, `RomanNumeral` and `BinaryNumeral`, and demonstrates conversions between them.

```
// structconversion.cs
using System;

struct RomanNumeral
{
    public RomanNumeral(int value)
    {
        this.value = value;
    }
    static public implicit operator RomanNumeral(int value)
    {
        return new RomanNumeral(value);
    }
    static public implicit operator RomanNumeral(BinaryNumeral binary)
    {
        return new RomanNumeral((int)binary);
    }
    static public explicit operator int(RomanNumeral roman)
    {
         return roman.value;
    }
    static public implicit operator string(RomanNumeral roman)
    {
        return("Conversion not yet implemented");
    }
    private int value;
}
```

```
struct BinaryNumeral
{
    public BinaryNumeral(int value)
    {
        this.value = value;
    }
    static public implicit operator BinaryNumeral(int value)
    {
        return new BinaryNumeral(value);
    }
    static public implicit operator string(BinaryNumeral binary)
    {
        return("Conversion not yet implemented");
    }
    static public explicit operator int(BinaryNumeral binary)
    {
        return(binary.value);
    }

    private int value;
}

class Test
{
    static public void Main()
    {
        RomanNumeral roman;
        roman = 10;
        BinaryNumeral binary;
        // Perform a conversion from a RomanNumeral to a
        // BinaryNumeral:
        binary = (BinaryNumeral)(int)roman;
        // Performs a conversion from a BinaryNumeral to a RomanNumeral.
        // No cast is required:
        roman = binary;
        Console.WriteLine((int)binary);
        Console.WriteLine(binary);
    }
}
```

Output

```
10
Conversion not yet implemented
```

Code Discussion

- In the preceding example, the statement:

  ```
  binary = (BinaryNumeral)(int)roman;
  ```

  performs a conversion from a `RomanNumeral` to a `BinaryNumeral`. Because there is no direct conversion from `RomanNumeral` to `BinaryNumeral`, a cast is used to convert from a `RomanNumeral` to an **int**, and another cast to convert from an **int** to a `BinaryNumeral`.

- Also the statement:

  ```
  roman = binary;
  ```

  performs a conversion from a `BinaryNumeral` to a `RomanNumeral`. Because `RomanNumeral` defines an implicit conversion from `BinaryNumeral`, no cast is required.

Tutorial

Operator overloading permits user-defined operator implementations to be specified for operations where one or both of the operands are of a user-defined class or struct type. The tutorial contains two examples. The first example shows how to use operator overloading to create a complex number class that defines complex addition. The second example shows how to use operator overloading to implement a three-valued logical type.

Example 1

This example shows how you can use operator overloading to create a complex number class `Complex` that defines complex addition. The program displays the imaginary and the real parts of the numbers and the addition result using an override of the **ToString** method.

```
// complex.cs
using System;

public struct Complex
{
   public int real;
   public int imaginary;

   public Complex(int real, int imaginary)
   {
      this.real = real;
      this.imaginary = imaginary;
   }

   // Declare which operator to overload (+), the types
   // that can be added (two Complex objects), and the
   // return type (Complex):
   public static Complex operator +(Complex c1, Complex c2)
   {
      return new Complex(c1.real + c2.real, c1.imaginary + c2.imaginary);
   }
   // Override the ToString method to display an complex number in the suitable format:
   public override string ToString()
   {
      return(String.Format("{0} + {1}i", real, imaginary));
   }

   public static void Main()
   {
      Complex num1 = new Complex(2,3);
      Complex num2 = new Complex(3,4);

      // Add two Complex objects (num1 and num2) through the
      // overloaded plus operator:
```

```
        Complex sum = num1 + num2;

       // Print the numbers and the sum using the overriden ToString method:
        Console.WriteLine("First complex number:  {0}",num1);
        Console.WriteLine("Second complex number: {0}",num2);
        Console.WriteLine("The sum of the two numbers: {0}",sum);

    }
}
```

Output

```
First complex number:  2 + 3i
Second complex number: 3 + 4i
The sum of the two numbers: 5 + 7i
```

Example 2

This example shows how operator overloading can be used to implement a three-valued logical type. The possible values of this type are `DBBool.dbTrue`, `DBBool.dbFalse`, and `DBBool.dbNull`, where the `dbNull` member indicates an unknown value.

> **Note** Defining the True and False operators is only useful for types that represent True, False, and Null (neither True nor False), as used in databases.

```
// dbbool.cs
using System;

public struct DBBool
{
   // The three possible DBBool values:
   public static readonly DBBool dbNull = new DBBool(0);
   public static readonly DBBool dbFalse = new DBBool(-1);
   public static readonly DBBool dbTrue = new DBBool(1);
   // Private field that stores -1, 0, 1 for dbFalse, dbNull, dbTrue:
   int value;

   // Private constructor. The value parameter must be -1, 0, or 1:
   DBBool(int value)
   {
      this.value = value;
   }

   // Implicit conversion from bool to DBBool. Maps true to
   // DBBool.dbTrue and false to DBBool.dbFalse:
   public static implicit operator DBBool(bool x)
   {
      return x? dbTrue: dbFalse;
   }

   // Explicit conversion from DBBool to bool. Throws an
   // exception if the given DBBool is dbNull, otherwise returns
   // true or false:
   public static explicit operator bool(DBBool x)
   {
      if (x.value == 0) throw new InvalidOperationException();
      return x.value > 0;
   }

   // Equality operator. Returns dbNull if either operand is dbNull,
   // otherwise returns dbTrue or dbFalse:
   public static DBBool operator ==(DBBool x, DBBool y)
   {
      if (x.value == 0 || y.value == 0) return dbNull;
      return x.value == y.value? dbTrue: dbFalse;
```

```
    }

    // Inequality operator. Returns dbNull if either operand is
    // dbNull, otherwise returns dbTrue or dbFalse:
    public static DBBool operator !=(DBBool x, DBBool y)
    {
       if (x.value == 0 || y.value == 0) return dbNull;
       return x.value != y.value? dbTrue: dbFalse;
    }

    // Logical negation operator. Returns dbTrue if the operand is
    // dbFalse, dbNull if the operand is dbNull, or dbFalse if the
    // operand is dbTrue:
    public static DBBool operator !(DBBool x)
    {
       return new DBBool(-x.value);
    }

    // Logical AND operator. Returns dbFalse if either operand is
    // dbFalse, dbNull if either operand is dbNull, otherwise dbTrue:
    public static DBBool operator &(DBBool x, DBBool y)
    {
       return new DBBool(x.value < y.value? x.value: y.value);
    }

    // Logical OR operator. Returns dbTrue if either operand is
    // dbTrue, dbNull if either operand is dbNull, otherwise dbFalse:
    public static DBBool operator |(DBBool x, DBBool y)
    {
       return new DBBool(x.value > y.value? x.value: y.value);
    }

    // Definitely true operator. Returns true if the operand is
    // dbTrue, false otherwise:
    public static bool operator true(DBBool x)
    {
       return x.value > 0;
    }

    // Definitely false operator. Returns true if the operand is
    // dbFalse, false otherwise:
    public static bool operator false(DBBool x)
    {
       return x.value < 0;
    }

    // Overload the conversion from DBBool to string:
    public static implicit operator string(DBBool x)
    {
       return x.value > 0 ? "dbTrue"
            : x.value < 0 ? "dbFalse"
            : "dbNull";
    }

    // Override the Object.Equals(object o) method:
    public override bool Equals(object o)
    {
       try
       {
          return (bool) (this == (DBBool) o);
       }
       catch
       {
          return false;
       }
    }

    // Override the Object.GetHashCode() method:
```

```
   public override int GetHashCode()
   {
      return value;
   }

   // Override the ToString method to convert DBBool to a string:
   public override string ToString()
   {
      switch (value)
      {
         case -1:
            return "DBBool.False";
         case 0:
            return "DBBool.Null";
         case 1:
            return "DBBool.True";
         default:
            throw new InvalidOperationException();
      }
   }
}

class Test
{
   static void Main()
   {
      DBBool a, b;
      a = DBBool.dbTrue;
      b = DBBool.dbNull;

      Console.WriteLine( "!{0} = {1}", a, !a);
      Console.WriteLine( "!{0} = {1}", b, !b);
      Console.WriteLine( "{0} & {1} = {2}", a, b, a & b);
      Console.WriteLine( "{0} | {1} = {2}", a, b, a | b);
      // Invoke the true operator to determine the Boolean
      // value of the DBBool variable:
      if (b)
         Console.WriteLine("b is definitely true");
      else
         Console.WriteLine("b is not definitely true");
   }
}
```

Output

```
!DBBool.True = DBBool.False
!DBBool.Null = DBBool.Null
DBBool.True & DBBool.Null = DBBool.Null
DBBool.True | DBBool.Null = DBBool.True
b is not definitely true
```

Tutorial

A delegate in C# is similar to a function pointer in C or C++. Using a delegate allows the programmer to encapsulate a reference to a method inside a delegate object. The delegate object can then be passed to code which can call the referenced method, without having to know at compile time which method will be invoked. Unlike function pointers in C or C++, delegates are object-oriented, type-safe, and secure.

A delegate declaration defines a type that encapsulates a method with a particular set of arguments and return type. For static methods, a delegate object encapsulates the method to be called. For instance methods, a delegate object encapsulates both an instance and a method on the instance. If you have a delegate object and an appropriate set of arguments, you can invoke the delegate with the arguments.

An interesting and useful property of a delegate is that it does not know or care about the class of the object that it references. Any object will do; all that matters is that the method's argument types and return type match the delegate's. This makes delegates perfectly suited for "anonymous" invocation.

> **Note** Delegates run under the caller's security permissions, not the declarer's permissions.

This tutorial includes two examples:

- Example 1 shows how to declare, instantiate, and call a delegate.
- Example 2 shows how to combine two delegates.

In addition, it discusses the following topics:

- Delegates and Events
- Delegates vs. Interfaces

Example 1

The following example illustrates declaring, instantiating, and using a delegate. The `BookDB` class encapsulates a bookstore database that maintains a database of books. It exposes a method `ProcessPaperbackBooks`, which finds all paperback books in the database and calls a delegate for each one. The **delegate** type used is called `ProcessBookDelegate`. The `Test` class uses this class to print out the titles and average price of the paperback books.

The use of delegates promotes good separation of functionality between the bookstore database and the client code. The client code has no knowledge of how the books are stored or how the bookstore code finds paperback books. The bookstore code has no knowledge of what processing is done on the paperback books after it finds them.

```
// bookstore.cs
using System;

// A set of classes for handling a bookstore:
namespace Bookstore
{
   using System.Collections;

   // Describes a book in the book list:
```

```
   public struct Book
   {
      public string Title;        // Title of the book.
      public string Author;       // Author of the book.
      public decimal Price;       // Price of the book.
      public bool Paperback;      // Is it paperback?

      public Book(string title, string author, decimal price, bool paperBack)
      {
         Title = title;
         Author = author;
         Price = price;
         Paperback = paperBack;
      }
   }

   // Declare a delegate type for processing a book:
   public delegate void ProcessBookDelegate(Book book);

   // Maintains a book database.
   public class BookDB
   {
      // List of all books in the database:
      ArrayList list = new ArrayList();

      // Add a book to the database:
      public void AddBook(string title, string author, decimal price, bool paperBack)
      {
         list.Add(new Book(title, author, price, paperBack));
      }

      // Call a passed-in delegate on each paperback book to process it:
      public void ProcessPaperbackBooks(ProcessBookDelegate processBook)
      {
         foreach (Book b in list)
         {
            if (b.Paperback)
            // Calling the delegate:
               processBook(b);
         }
      }
   }
}

// Using the Bookstore classes:
namespace BookTestClient
{
   using Bookstore;

   // Class to total and average prices of books:
   class PriceTotaller
   {
      int countBooks = 0;
      decimal priceBooks = 0.0m;

      internal void AddBookToTotal(Book book)
      {
         countBooks += 1;
         priceBooks += book.Price;
      }

      internal decimal AveragePrice()
      {
         return priceBooks / countBooks;
      }
   }

   // Class to test the book database:
```

```
    class Test
    {
       // Print the title of the book.
       static void PrintTitle(Book b)
       {
          Console.WriteLine("   {0}", b.Title);
       }

       // Execution starts here.
       static void Main()
       {
          BookDB bookDB = new BookDB();

          // Initialize the database with some books:
          AddBooks(bookDB);

          // Print all the titles of paperbacks:
          Console.WriteLine("Paperback Book Titles:");
          // Create a new delegate object associated with the static
          // method Test.PrintTitle:
          bookDB.ProcessPaperbackBooks(new ProcessBookDelegate(PrintTitle));

          // Get the average price of a paperback by using
          // a PriceTotaller object:
          PriceTotaller totaller = new PriceTotaller();
          // Create a new delegate object associated with the nonstatic
          // method AddBookToTotal on the object totaller:
          bookDB.ProcessPaperbackBooks(new ProcessBookDelegate(totaller.AddBookToTotal));
          Console.WriteLine("Average Paperback Book Price: ${0:#.##}",
             totaller.AveragePrice());
       }

       // Initialize the book database with some test books:
       static void AddBooks(BookDB bookDB)
       {
          bookDB.AddBook("The C Programming Language",
             "Brian W. Kernighan and Dennis M. Ritchie", 19.95m, true);
          bookDB.AddBook("The Unicode Standard 2.0",
             "The Unicode Consortium", 39.95m, true);
          bookDB.AddBook("The MS-DOS Encyclopedia",
             "Ray Duncan", 129.95m, false);
          bookDB.AddBook("Dogbert's Clues for the Clueless",
             "Scott Adams", 12.00m, true);
       }
    }
 }
```

Output

```
 Paperback Book Titles:
    The C Programming Language
    The Unicode Standard 2.0
    Dogbert's Clues for the Clueless
 Average Paperback Book Price: $23.97
```

Code Discussion

- **Declaring a delegate** The following statement:

  ```
  public delegate void ProcessBookDelegate(Book book);
  ```

  declares a new delegate type. Each delegate type describes the number and types of the arguments, and the type of the return value of methods that it can encapsulate. Whenever a new set of argument types or return value type is needed, a new delegate type must be declared.

- **Instantiating a delegate** Once a delegate type has been declared, a delegate object must be created and associated with a particular method. Like all other objects, a new delegate object is created with a **new** expression. When creating a delegate, however, the argument passed to the **new** expression is special — it is written like a method call, but without the arguments to the method.

  The following statement:

  ```
  bookDB.ProcessPaperbackBooks(new ProcessBookDelegate(PrintTitle));
  ```

  creates a new delegate object associated with the static method `Test.PrintTitle`. The following statement:

  ```
  bookDB.ProcessPaperbackBooks(new
     ProcessBookDelegate(totaller.AddBookToTotal));
  ```

  creates a new delegate object associated with the nonstatic method `AddBookToTotal` on the object `totaller`. In both cases, this new delegate object is immediately passed to the `ProcessPaperbackBooks` method.

  Note that once a delegate is created, the method it is associated with never changes — delegate objects are immutable.

- **Calling a delegate** Once a delegate object is created, the delegate object is typically passed to other code that will call the delegate. A delegate object is called by using the name of the delegate object, followed by the parenthesized arguments to be passed to the delegate. An example of a delegate call is:

  ```
  processBook(b);
  ```

  A delegate can either be called synchronously, as in this example, or asynchronously by using BeginInvoke and EndInvoke methods.

Example 2

This example demonstrates composing delegates. A useful property of delegate objects is that they can be composed using the "**+**" operator. A composed delegate calls the two delegates it was composed from. Only delegates of the same type can be composed.

The "**-**" operator can be used to remove a component delegate from a composed delegate.

```
// compose.cs
using System;

delegate void MyDelegate(string s);

class MyClass
{
    public static void Hello(string s)
    {
        Console.WriteLine("  Hello, {0}!", s);
    }

    public static void Goodbye(string s)
    {
        Console.WriteLine("  Goodbye, {0}!", s);
    }

    public static void Main()
    {
        MyDelegate a, b, c, d;

        // Create the delegate object a that references
        // the method Hello:
        a = new MyDelegate(Hello);
        // Create the delegate object b that references
        // the method Goodbye:
        b = new MyDelegate(Goodbye);
```

```
        // The two delegates, a and b, are composed to form c:
        c = a + b;
        // Remove a from the composed delegate, leaving d,
        // which calls only the method Goodbye:
        d = c - a;

        Console.WriteLine("Invoking delegate a:");
        a("A");
        Console.WriteLine("Invoking delegate b:");
        b("B");
        Console.WriteLine("Invoking delegate c:");
        c("C");
        Console.WriteLine("Invoking delegate d:");
        d("D");
    }
}
```

Output

```
Invoking delegate a:
  Hello, A!
Invoking delegate b:
  Goodbye, B!
Invoking delegate c:
  Hello, C!
  Goodbye, C!
Invoking delegate d:
  Goodbye, D!
```

Delegates and Events

Delegates are ideally suited for use as events — notifications from one component to "listeners" about changes in that component. For more information on the use of delegates for events, see the Events Tutorial.

Delegates vs. Interfaces

Delegates and interfaces are similar in that they enable the separation of specification and implementation. Multiple independent authors can produce implementations that are compatible with an interface specification. Similarly, a delegate specifies the signature of a method, and authors can write methods that are compatible with the delegate specification. When should you use interfaces, and when should you use delegates?

Delegates are useful when:

- A single method is being called.
- A class may want to have multiple implementations of the method specification.
- It is desirable to allow using a static method to implement the specification.
- An event-like design pattern is desired (for more information, see the Events Tutorial).
- The caller has no need to know or obtain the object that the method is defined on.
- The provider of the implementation wants to "hand out" the implementation of the specification to only a few select components.
- Easy composition is desired.

Interfaces are useful when:

- The specification defines a set of related methods that will be called.
- A class typically implements the specification only once.
- The caller of the interface wants to cast to or from the interface type to obtain other interfaces or classes.

Tutorial

An *event* in C# is a way for a class to provide notifications to clients of that class when some interesting thing happens to an object. The most familiar use for events is in graphical user interfaces; typically, the classes that represent controls in the interface have events that are notified when the user does something to the control (for example, click a button).

Events, however, need not be used only for graphical interfaces. Events provide a generally useful way for objects to signal state changes that may be useful to clients of that object. Events are an important building block for creating classes that can be reused in a large number of different programs.

Events are declared using delegates. If you have not yet studied the Delegates Tutorial, you should do so before continuing. Recall that a delegate object encapsulates a method so that it can be called anonymously. An event is a way for a class to allow clients to give it delegates to methods that should be called when the event occurs. When the event occurs, the delegate(s) given to it by its clients are invoked.

In addition to the examples on declaring, invoking, and hooking up to events, this tutorial also introduces the following topics:

- Events and Inheritance
- Events in Interfaces
- .NET Framework Guidelines

Example 1

The following simple example shows a class, `ListWithChangedEvent`, which is similar to the standard `ArrayList` class, but also invokes a `Changed` event whenever the contents of the list change. Such a general-purpose class could be used in numerous ways in a large program.

For example, a word processor might maintain a list of the open documents. Whenever this list changes, many different objects in the word processor might need to be notified so that the user interface could be updated. By using events, the code that maintains the list of documents doesn't need to know who needs to be notified — once the list of documents is changed, the event is automatically invoked and every object that needs to be notified is correctly notified. By using events, the modularity of the program is increased.

```
// events1.cs
using System;
namespace MyCollections
{
   using System.Collections;

   // A delegate type for hooking up change notifications.
   public delegate void ChangedEventHandler(object sender, EventArgs e);

   // A class that works just like ArrayList, but sends event
   // notifications whenever the list changes.
   public class ListWithChangedEvent: ArrayList
   {
      // An event that clients can use to be notified whenever the
      // elements of the list change.
```

```
      public event ChangedEventHandler Changed;

      // Invoke the Changed event; called whenever list changes
      protected virtual void OnChanged(EventArgs e)
      {
         if (Changed != null)
            Changed(this, e);
      }

      // Override some of the methods that can change the list;
      // invoke event after each
      public override int Add(object value)
      {
         int i = base.Add(value);
         OnChanged(EventArgs.Empty);
         return i;
      }

      public override void Clear()
      {
         base.Clear();
         OnChanged(EventArgs.Empty);
      }

      public override object this[int index]
      {
         set
         {
            base[index] = value;
            OnChanged(EventArgs.Empty);
         }
      }
   }
}

namespace TestEvents
{
   using MyCollections;

   class EventListener
   {
      private ListWithChangedEvent List;

      public EventListener(ListWithChangedEvent list)
      {
         List = list;
         // Add "ListChanged" to the Changed event on "List".
         List.Changed += new ChangedEventHandler(ListChanged);
      }

      // This will be called whenever the list changes.
      private void ListChanged(object sender, EventArgs e)
      {
         Console.WriteLine("This is called when the event fires.");
      }

      public void Detach()
      {
         // Detach the event and delete the list
         List.Changed -= new ChangedEventHandler(ListChanged);
         List = null;
      }
   }

   class Test
   {
      // Test the ListWithChangedEvent class.
      public static void Main()
```

```
        {
        // Create a new list.
        ListWithChangedEvent list = new ListWithChangedEvent();

        // Create a class that listens to the list's change event.
        EventListener listener = new EventListener(list);

        // Add and remove items from the list.
        list.Add("item 1");
        list.Clear();
        listener.Detach();
        }
    }
}
```

Output

```
This is called when the event fires.
This is called when the event fires.
```

Code Discussion

- **Declaring an event** To declare an event inside a class, first a delegate type for the event must be declared, if none is already declared.

  ```
  public delegate void ChangedEventHandler(object sender, EventArgs e);
  ```

  The delegate type defines the set of arguments that are passed to the method that handles the event. Multiple events can share the same delegate type, so this step is only necessary if no suitable delegate type has already been declared.

  Next, the event itself is declared.

  ```
  public event ChangedEventHandler Changed;
  ```

  An event is declared like a field of delegate type, except that the keyword **event** precedes the event declaration, following the modifiers. Events usually are declared public, but any accessibility modifier is allowed.

- **Invoking an event** Once a class has declared an event, it can treat that event just like a field of the indicated delegate type. The field will either be null, if no client has hooked up a delegate to the event, or else it refers to a delegate that should be called when the event is invoked. Thus, invoking an event is generally done by first checking for null and then calling the event.

  ```
  if (Changed != null)
  Changed(this, e);
  ```

  Invoking an event can only be done from within the class that declared the event.

- **Hooking up to an event** From outside the class that declared it, an event looks like a field, but access to that field is very restricted. The only things that can be done are:
  - Compose a new delegate onto that field.
  - Remove a delegate from a (possibly composite) field.

  This is done with the **+=** and **-=** operators. To begin receiving event invocations, client code first creates a delegate of the event type that refers to the method that should be invoked from the event. Then it composes that delegate onto any other delegates that the event might be connected to using **+=**.

  ```
  // Add "ListChanged" to the Changed event on "List":
  List.Changed += new ChangedEventHandler(ListChanged);
  ```

  When the client code is done receiving event invocations, it removes its delegate from the event by using operator **-=**.

```
// Detach the event and delete the list:
List.Changed -= new ChangedEventHandler(ListChanged);
```

Events and Inheritance

When creating a general component that can be derived from, what seems to be a problem sometimes arises with events. Since events can only be invoked from within the class that declared them, derived classes cannot directly invoke events declared within the base class. Although this is sometimes what is desired, often it is appropriate to give the derived class the freedom to invoke the event. This is typically done by creating a protected invoking method for the event. By calling this invoking method, derived classes can invoke the event. For even more flexibility, the invoking method is often declared as virtual, which allows the derived class to override it. This allows the derived class to intercept the events that the base class is invoking, possibly doing its own processing of them.

In the preceding example, this has been done with the `OnChanged` method. A derived class could call or override this method if it needed to.

Events in Interfaces

One other difference between events and fields is that an event can be placed in an interface while a field cannot. When implementing the interface, the implementing class must supply a corresponding event in the class that implements the interface.

.NET Framework Guidelines

Although the C# language allows events to use any delegate type, the .NET Framework has some stricter guidelines on the delegate types that should be used for events. If you intend for your component to be used with the .NET Framework, you probably will want to follow these guidelines.

The .NET Framework guidelines indicate that the delegate type used for an event should take two parameters, an "object source" parameter indicating the source of the event, and an "e" parameter that encapsulates any additional information about the event. The type of the "e" parameter should derive from the **EventArgs** class. For events that do not use any additional information, the .NET Framework has already defined an appropriate delegate type: **EventHandler**.

Example 2

The following example is a modified version of Example 1 that follows the .NET Framework guidelines. The example uses the **EventHandler** delegate type.

```
// events2.cs
using System;
namespace MyCollections
{
   using System.Collections;

   // A class that works just like ArrayList, but sends event
   // notifications whenever the list changes:
   public class ListWithChangedEvent: ArrayList
   {
      // An event that clients can use to be notified whenever the
      // elements of the list change:
      public event EventHandler Changed;

      // Invoke the Changed event; called whenever list changes:
      protected virtual void OnChanged(EventArgs e)
      {
         if (Changed != null)
            Changed(this,e);
      }

      // Override some of the methods that can change the list;
      // invoke event after each:
      public override int Add(object value)
      {
         int i = base.Add(value);
         OnChanged(EventArgs.Empty);
```

```
            return i;
        }

        public override void Clear()
        {
            base.Clear();
            OnChanged(EventArgs.Empty);
        }

        public override object this[int index]
        {
            set
            {
                base[index] = value;
                OnChanged(EventArgs.Empty);
            }
        }
    }
}

namespace TestEvents
{
    using MyCollections;

    class EventListener
    {
        private ListWithChangedEvent List;

        public EventListener(ListWithChangedEvent list)
        {
            List = list;
            // Add "ListChanged" to the Changed event on "List":
            List.Changed += new EventHandler(ListChanged);
        }

        // This will be called whenever the list changes:
        private void ListChanged(object sender, EventArgs e)
        {
            Console.WriteLine("This is called when the event fires.");
        }

        public void Detach()
        {
            // Detach the event and delete the list:
            List.Changed -= new EventHandler(ListChanged);
            List = null;
        }
    }

    class Test
    {
        // Test the ListWithChangedEvent class:
        public static void Main()
        {
        // Create a new list:
        ListWithChangedEvent list = new ListWithChangedEvent();

        // Create a class that listens to the list's change event:
        EventListener listener = new EventListener(list);

        // Add and remove items from the list:
        list.Add("item 1");
        list.Clear();
        listener.Detach();
        }
    }
}
```

Output

```
This is called when the event fires.
This is called when the event fires.
```

Explicit Interface Implementation Tutorial

This tutorial demonstrates how to explicitly implement interface members and how to access those members from the interface instances.

Sample Files

See Explicit Interface Implementation Sample to download and build the sample files discussed in this tutorial.

Further Reading

- interface
- 13.4 Interface implementations
- 13.4.1 Explicit interface member implementations

Tutorial

A class that implements an interface can explicitly implement a member of that interface. When a member is explicitly implemented, it cannot be accessed through a class instance, but only through an instance of the interface. This tutorial contains two examples. The first example illustrates how to explicitly implement and access interface members. The second example shows how to implement two interfaces that have the same member names.

Example 1

This example declares an interface `IDimensions`, and a class `Box`, which explicitly implements the interface members `Length` and `Width`. The members are accessed through the interface instance `myDimensions`.

```
// explicit1.cs
interface IDimensions
{
   float Length();
   float Width();
}

class Box : IDimensions
{
   float lengthInches;
   float widthInches;

   public Box(float length, float width)
   {
      lengthInches = length;
      widthInches = width;
   }
   // Explicit interface member implementation:
   float IDimensions.Length()
   {
      return lengthInches;
   }
   // Explicit interface member implementation:
   float IDimensions.Width()
   {
      return widthInches;
   }

   public static void Main()
   {
      // Declare a class instance "myBox":
      Box myBox = new Box(30.0f, 20.0f);
      // Declare an interface instance "myDimensions":
      IDimensions myDimensions = (IDimensions) myBox;
      // Print out the dimensions of the box:
      /* The following commented lines would produce compilation
         errors because they try to access an explicitly implemented
         interface member from a class instance:                    */
```

```
      //System.Console.WriteLine("Length: {0}", myBox.Length());
      //System.Console.WriteLine("Width: {0}", myBox.Width());
      /* Print out the dimensions of the box by calling the methods
         from an instance of the interface:                        */
      System.Console.WriteLine("Length: {0}", myDimensions.Length());
      System.Console.WriteLine("Width: {0}", myDimensions.Width());
   }
}
```

Output

```
Length: 30
Width: 20
```

Code Discussion

- Notice that the following lines, in the Main method, are commented out because they would produce compilation errors. An interface member that is explicitly implemented cannot be accessed from a class instance:

  ```
  //System.Console.WriteLine("Length: {0}", myBox.Length());
  //System.Console.WriteLine("Width: {0}", myBox.Width());
  ```

- Notice also that the following lines, in the Main method, successfully print out the dimensions of the box because the methods are being called from an instance of the interface:

  ```
  System.Console.WriteLine("Length: {0}", myDimensions.Length());
  System.Console.WriteLine("Width: {0}", myDimensions.Width());
  ```

Example 2

Explicit interface implementation also allows the programmer to inherit two interfaces that share the same member names and give each interface member a separate implementation. This example displays the dimensions of a box in both metric and English units. The `Box` class inherits two interfaces `IEnglishDimensions` and `IMetricDimensions`, which represent the different measurement systems. Both interfaces have identical member names, `Length` and `Width`.

```
// explicit2.cs
// Declare the English units interface:
interface IEnglishDimensions
{
   float Length();
   float Width();
}
// Declare the metric units interface:
interface IMetricDimensions
{
   float Length();
   float Width();
}
// Declare the "Box" class that implements the two interfaces:
// IEnglishDimensions and IMetricDimensions:
class Box : IEnglishDimensions, IMetricDimensions
{
   float lengthInches;
   float widthInches;
   public Box(float length, float width)
   {
      lengthInches = length;
      widthInches = width;
   }
// Explicitly implement the members of IEnglishDimensions:
   float IEnglishDimensions.Length()
   {
```

```
      return lengthInches;
   }
   float IEnglishDimensions.Width()
   {
      return widthInches;
   }
// Explicitly implement the members of IMetricDimensions:
   float IMetricDimensions.Length()
   {
      return lengthInches * 2.54f;
   }
   float IMetricDimensions.Width()
   {
      return widthInches * 2.54f;
   }
   public static void Main()
   {
      // Declare a class instance "myBox":
      Box myBox = new Box(30.0f, 20.0f);
      // Declare an instance of the English units interface:
      IEnglishDimensions eDimensions = (IEnglishDimensions) myBox;
      // Declare an instance of the metric units interface:
      IMetricDimensions mDimensions = (IMetricDimensions) myBox;
      // Print dimensions in English units:
      System.Console.WriteLine("Length(in): {0}", eDimensions.Length());
      System.Console.WriteLine("Width (in): {0}", eDimensions.Width());
      // Print dimensions in metric units:
      System.Console.WriteLine("Length(cm): {0}", mDimensions.Length());
      System.Console.WriteLine("Width (cm): {0}", mDimensions.Width());
   }
}
```

Output

```
Length(in): 30
Width (in): 20
Length(cm): 76.2
Width (cm): 50.8
```

Code Discussion

If you want to make the default measurements in English units, implement the methods `Length` and `Width` normally, and explicitly implement the `Length` and `Width` methods from the `IMetricDimensions` interface:

```
// Normal implementation:
public float Length()
{
   return lengthInches;
}
public float Width()
{
   return widthInches;
}
// Explicit implementation:
float IMetricDimensions.Length()
{
   return lengthInches * 2.54f;
}
float IMetricDimensions.Width()
{
   return widthInches * 2.54f;
}
```

In this case, you can access the English units from the class instance and access the metric units from the interface instance:

```
System.Console.WriteLine("Length(in): {0}", myBox.Length());
System.Console.WriteLine("Width (in): {0}", myBox.Width());
System.Console.WriteLine("Length(cm): {0}", mDimensions.Length());
System.Console.WriteLine("Width (cm): {0}", mDimensions.Width());
```

Conditional Methods Tutorial

This tutorial demonstrates conditional methods, which provide a powerful mechanism by which calls to methods can be included or omitted depending on whether a preprocessor symbol is defined.

Sample Files

See Conditional Methods Sample to download and build the sample files discussed in this tutorial.

Further Reading

- Command-Line Arguments
- 17.4.2 The Conditional attribute
- Conditional
- #define
- /define (Preprocessor Definition)
- System.Diagnostics Namespace
- Debug.Assert Method
- Assertions in Managed Code

Tutorial

Conditional methods allow developers to create methods whose calls can be placed in the code and then either included or omitted during compilation based on a preprocessing symbol.

Suppose that you want to enable some assertion code in the debug builds and disable it in the retail builds. In C++, there is more than one way to have this functionality in your code, for example:

- Using **#ifdef**, define both debug and release versions of a macro. The debug version calls the tracing code, and the release version does nothing. Because C# doesn't support macros, this method doesn't work.
- Have two implementations of the code being called. That is, in the debug version, have full functionality, and in the retail version, have empty stubs for the methods. Users then choose which one to include when linking the project. The problem with this approach is that the retail builds contain calls to empty methods, and the configuration is more complex.

C# conditional methods provide a simple solution to this problem that is similar to the first approach listed above. There are two basic mechanisms to do this:

- **#define** the preprocessing identifier in the source code directly. (See an example of this approach in Conditional.)
- Define the preprocessing identifier on the C# command line via the /define option (/d). This approach is used in the following example.

Conditional methods are used in the .NET Framework. The **System.Diagnostics** namespace contains a number of classes that support tracing and debugging in applications. Use the **System.Diagnostics.Trace** and **System.Diagnostics.Debug** classes to add sophisticated tracing and debugging to your application (functionality that can be compiled out of your retail builds through the use of conditional methods).

The example below shows how to implement a very simple tracing mechanism using conditional methods. **System.Diagnostics.Trace** provides much more sophisticated tracing mechanisms, but it uses the fundamental mechanism below to provide this functionality.

Example

This example consists of two source files: the first file is the library that provides a tracing mechanism, and the second file is the client program that uses this library.

File #1: Creating Conditional Methods

The code below shows a simple library that provides a tracing mechanism that displays trace messages to the system console. Clients can embed trace calls in the code and then be able to control whether the tracing gets called by defining symbols in their own compilation phase.

```
// CondMethod.cs
// compile with: /target:library /d:DEBUG
using System;
using System.Diagnostics;
namespace TraceFunctions
{
   public class Trace
   {
       [Conditional("DEBUG")]
       public static void Message(string traceMessage)
       {
           Console.WriteLine("[TRACE] - " + traceMessage);
       }
   }
}
```

Code Discussion

The following line:

```
[Conditional("DEBUG")]
```

marks the `Message` method as being conditional (via the **Conditional** attribute). The **Conditional** attribute takes one parameter — the preprocessing identifier that controls whether the method call is included when clients are compiled. If the preprocessing identifier is defined, the method is called; otherwise, the call is never inserted in the client's code.

There are restrictions on which methods can be marked as conditional; see 17.4.2 The Conditional attribute in the *C# Language Specification* for more information.

File #2: Using the Conditional Method

The following client program uses the `Trace` class defined in file #1 to do some simple tracing.

```
// TraceTest.cs
// compile with: /reference:CondMethod.dll
// arguments: A B C
using System;
using TraceFunctions;

public class TraceClient
{
   public static void Main(string[] args)
   {
      Trace.Message("Main Starting");

      if (args.Length == 0)
      {
          Console.WriteLine("No arguments have been passed");
      }
      else
      {
          for( int i=0; i < args.Length; i++)
          {
              Console.WriteLine("Arg[{0}] is [{1}]",i,args[i]);
          }
      }

       Trace.Message("Main Ending");
   }
}
```

Code Discussion

Conditional code is included in client code depending on whether the preprocessing identifier is defined when the client code gets compiled.

Compiling with client code with the /d:DEBUG flag means that the compiler inserts the call to the `Trace` method. If the symbol is not defined, the call is never made.

Sample Run

The command:

```
tracetest A B C
```

gives the following output:

```
[TRACE] - Main Starting
Arg[0] is [A]
Arg[1] is [B]
Arg[2] is [C]
[TRACE] - Main Ending
```

The command:

```
tracetest
```

gives the following output:

```
[TRACE] - Main Starting
No arguments have been passed
[TRACE] - Main Ending
```

Tutorial

C# provides a mechanism for developers to document their code using XML. In source code files, lines that begin with /// and that precede a user-defined type such as a class, delegate, or interface; a member such as a field, event, property, or method; or a namespace declaration can be processed as comments and placed in a file.

Example

The following sample provides a basic overview of a type that has been documented. To compile the example, type the following command line:

```
csc XMLsample.cs /doc:XMLsample.xml
```

This will create the XML file XMLsample.xml, which you can view in your browser or by using the TYPE command.

```
// XMLsample.cs
// compile with: /doc:XMLsample.xml
using System;

/// <summary>
/// Class level summary documentation goes here.</summary>
/// <remarks>
/// Longer comments can be associated with a type or member
/// through the remarks tag</remarks>
public class SomeClass
{
   /// <summary>
   /// Store for the name property</summary>
   private string myName = null;

   /// <summary>
   /// The class constructor. </summary>
   public SomeClass()
   {
       // TODO: Add Constructor Logic here
   }

   /// <summary>
   /// Name property </summary>
   /// <value>
   /// A value tag is used to describe the property value</value>
   public string Name
   {
      get
      {
         if ( myName == null )
         {
```

```
            throw new Exception("Name is null");
         }

         return myName;
      }
   }

   /// <summary>
   /// Description for SomeMethod.</summary>
   /// <param name="s"> Parameter description for s goes here</param>
   /// <seealso cref="String">
   /// You can use the cref attribute on any tag to reference a type or member
   /// and the compiler will check that the reference exists. </seealso>
   public void SomeMethod(string s)
   {
   }

   /// <summary>
   /// Some other method. </summary>
   /// <returns>
   /// Return results are described through the returns tag.</returns>
   /// <seealso cref="SomeMethod(string)">
   /// Notice the use of the cref attribute to reference a specific method </seealso>
   public int SomeOtherMethod()
   {
      return 0;
   }

   /// <summary>
   /// The entry point for the application.
   /// </summary>
   /// <param name="args"> A list of command line arguments</param>
   public static int Main(String[] args)
   {
      // TODO: Add code to start application here

       return 0;
   }
}
```

Code Discussion

XML documentation starts with ///. When you create a new project, the wizards put some starter /// lines in for you. The processing of these comments has some restrictions:

- The documentation must be well-formed XML. If the XML is not well-formed, a warning is generated and the documentation file will contain a comment saying that an error was encountered. For more information on well-formed XML, see XML Glossary.
- Developers are free to create their own set of tags. There is a recommended set of tags (see the Further Reading section). Some of the recommended tags have special meanings:
    - The <param> tag is used to describe parameters. If used, the compiler will verify that the parameter exists and that all parameters are described in the documentation. If the verification failed, the compiler issues a warning.
    - The **cref** attribute can be attached to any tag to provide a reference to a code element. The compiler will verify that this code element exists. If the verification failed, the compiler issues a warning. The compiler also respects any **using** statements when looking for a type described in the **cref** attribute.
    - The <summary> tag is used by IntelliSense inside Visual Studio to display additional information about a type or member.

Sample Output

Here is the resulting XML file from the class above:

```
<?xml version="1.0"?>
<doc>
```

```
    <assembly>
        <name>xmlsample</name>
    </assembly>
    <members>
        <member name="T:SomeClass">
            <summary>
            Class level summary documentation goes here.</summary>
            <remarks>
            Longer comments can be associated with a type or member
            through the remarks tag</remarks>
        </member>
        <member name="F:SomeClass.myName">
            <summary>
            Store for the name property</summary>
        </member>
        <member name="M:SomeClass.#ctor">
            <summary>The class constructor.</summary>
        </member>
        <member name="M:SomeClass.SomeMethod(System.String)">
            <summary>
            Description for SomeMethod.</summary>
            <param name="s"> Parameter description for s goes here</param>
            <seealso cref="T:System.String">
            You can use the cref attribute on any tag to reference a type or member
            and the compiler will check that the reference exists. </seealso>
        </member>
        <member name="M:SomeClass.SomeOtherMethod">
            <summary>
            Some other method. </summary>
            <returns>
            Return results are described through the returns tag.</returns>
            <seealso cref="M:SomeClass.SomeMethod(System.String)">
            Notice the use of the cref attribute to reference a specific method </seealso>
        </member>
        <member name="M:SomeClass.Main(System.String[])">
            <summary>
            The entry point for the application.
            </summary>
            <param name="args"> A list of command line arguments</param>
        </member>
        <member name="P:SomeClass.Name">
            <summary>
            Name property </summary>
            <value>
            A value tag is used to describe the property value</value>
        </member>
    </members>
</doc>
```

Note The XML file does not provide full information about the type and members (for example, it does not contain any type information). To get full information about a type or member, the documentation file must be used in conjunction with reflection on the actual type or member.

Platform Invoke Tutorial

Platform Invocation Services (PInvoke) allows managed code to call unmanaged functions that are implemented in a DLL.

This tutorial shows you what you need to do to be able to call unmanaged DLL functions from C#. The attributes discussed in the tutorial allow you to call these functions and have data types be marshaled correctly.

Sample Files

See Platform Invoke Sample to download and build the sample files discussed in this tutorial.

Platform Invoke

Tutorial

There are two ways that C# code can directly call unmanaged code:

- Directly call a function exported from a DLL.
- Call an interface method on a COM object (for more information, see COM Interop Part 1: C# Client Tutorial).

For both techniques, you must provide the C# compiler with a declaration of the unmanaged function, and you may also need to provide the C# compiler with a description of how to marshal the parameters and return value to and from the unmanaged code.

The tutorial consists of the following topics:

- Calling a DLL Export Directly from C#
- Default Marshaling and Specifying Custom Marshaling for Parameters to Unmanaged Methods
- Specifying Custom Marshaling for User-Defined Structs
- Registering Callback Methods

The tutorial includes the following examples:

- Example 1 Using DllImport
- Example 2 Overriding Default Marshaling
- Example 3 Specifying Custom Marshaling

Calling a DLL Export Directly from C#

To declare a method as having an implementation from a DLL export, do the following:

- Declare the method with the **static** and **extern** C# keywords.
- Attach the **DllImport** attribute to the method. The **DllImport** attribute allows you to specify the name of the DLL that contains the method. The common practice is to name the C# method the same as the exported method, but you can also use a different name for the C# method.
- Optionally, specify custom marshaling information for the method's parameters and return value, which will override the .NET Framework default marshaling.

Example 1

This example shows you how to use the **DllImport** attribute to output a message by calling `puts` from `msvcrt.dll`.

```
// PInvokeTest.cs
```

```
using System;
using System.Runtime.InteropServices;

class PlatformInvokeTest
{
    [DllImport("msvcrt.dll")]
    public static extern int puts(string c);
    [DllImport("msvcrt.dll")]
    internal static extern int _flushall();

    public static void Main()
    {
        puts("Test");
        _flushall();
    }
}
```

Output

```
Test
```

Code Discussion

The preceding example shows the minimum requirements for declaring a C# method that is implemented in an unmanaged DLL. The method `PlatformInvokeTest.puts` is declared with the **static** and **extern** modifiers and has the **DllImport** attribute which tells the compiler that the implementation comes from `msvcrt.dll`, using the default name of `puts`. To use a different name for the C# method such as `putstring`, you must use the **EntryPoint** option in the **DllImport** attribute, that is:

```
[DllImport("msvcrt.dll", EntryPoint="puts")]
```

For more information on the syntax of the **DllImport** attribute, see DllImportAttribute Class.

Default Marshaling and Specifying Custom Marshaling for Parameters to Unmanaged Methods

When calling an unmanaged function from C# code, the common language runtime must marshal the parameters and return values.

For every .NET Framework type there is a default unmanaged type, which the common language runtime will use to marshal data across a managed to unmanaged function call. For example, the default marshaling for C# string values is to the type LPTSTR (pointer to TCHAR char buffer). You can override the default marshaling using the **MarshalAs** attribute in the C# declaration of the unmanaged function.

Example 2

This example uses the **DllImport** attribute to output a string. It also shows you how to override the default marshaling of the function parameters by using the **MarshalAs** attribute.

```
// Marshal.cs
using System;
using System.Runtime.InteropServices;

class PlatformInvokeTest
{
    [DllImport("msvcrt.dll")]
    public static extern int puts(
        [MarshalAs(UnmanagedType.LPStr)]
        string m);
    [DllImport("msvcrt.dll")]
    internal static extern int _flushall();

    public static void Main()
```

```
    {
        puts("Hello World!");
        _flushall();
    }
}
```

Output

When you run this example, the string,

```
Hello World!
```

will display at the console.

Code Discussion

In the preceding example, the default marshaling for the parameter to the `puts` function has been overridden from the default of LPTSTR to LPSTR.

The **MarshalAs** attribute can be placed on method parameters, method return values, and fields of structs and classes. To set the marshaling of a method return value, place the **MarshalAs** attribute in an attribute block on the method with the return attribute location override. For example, to explicitly set the marshaling for the return value of the `puts` method:

```
...
[DllImport("msvcrt.dll")]
[return : MarshalAs(UnmanagedType.I4)]
public static extern int puts(
...
```

For more information on the syntax of the **MarshalAs** attribute, see MarshalAsAttribute Class.

> **Note** The **In** and **Out** attributes can be used to annotate parameters to unmanaged methods. They behave in a similar manner to the **in** and **out** modifiers in MIDL source files. Note that the **Out** attribute is different from the C# parameter modifier, out. For more information on the **In** and **Out** attributes, see InAttribute Class and OutAttribute Class.

Specifying Custom Marshaling for User-Defined Structs

You can specify custom marshaling attributes for fields of structs and classes passed to or from unmanaged functions. You do this by adding **MarshalAs** attributes to the fields of the struct or class. You must also use the **StructLayout** attribute to set the layout of the struct, optionally to control the default marshaling of string members, and to set the default packing size.

Example 3

This example demonstrates how to specify custom marshaling attributes for a struct.

Consider the following C structure:

```
typedef struct tagLOGFONT
{
   LONG lfHeight;
   LONG lfWidth;
   LONG lfEscapement;
   LONG lfOrientation;
   LONG lfWeight;
   BYTE lfItalic;
   BYTE lfUnderline;
   BYTE lfStrikeOut;
   BYTE lfCharSet;
   BYTE lfOutPrecision;
   BYTE lfClipPrecision;
   BYTE lfQuality;
   BYTE lfPitchAndFamily;
```

```
    TCHAR lfFaceName[LF_FACESIZE];
} LOGFONT;
```

In C#, you can describe the preceding struct by using the **StructLayout** and **MarshalAs** attributes as follows:

```
// logfont.cs
// compile with: /target:module
using System;
using System.Runtime.InteropServices;

[StructLayout(LayoutKind.Sequential)]
public class LOGFONT
{
    public const int LF_FACESIZE = 32;
    public int lfHeight;
    public int lfWidth;
    public int lfEscapement;
    public int lfOrientation;
    public int lfWeight;
    public byte lfItalic;
    public byte lfUnderline;
    public byte lfStrikeOut;
    public byte lfCharSet;
    public byte lfOutPrecision;
    public byte lfClipPrecision;
    public byte lfQuality;
    public byte lfPitchAndFamily;
    [MarshalAs(UnmanagedType.ByValTStr, SizeConst=LF_FACESIZE)]
    public string lfFaceName;
}
```

For more information on the syntax of the **StructLayout** attribute, see StructLayoutAttribute Class.

The structure can then be used in C# code as shown below:

```
// pinvoke.cs
// compile with: /addmodule:logfont.netmodule
using System;
using System.Runtime.InteropServices;

class PlatformInvokeTest
{
      [DllImport("gdi32.dll", CharSet=CharSet.Auto)]
      public static extern IntPtr CreateFontIndirect(
            [In, MarshalAs(UnmanagedType.LPStruct)]
            LOGFONT lplf   // characteristics
            );

      [DllImport("gdi32.dll")]
      public static extern bool DeleteObject(
            IntPtr handle
            );

      public static void Main()
      {
            LOGFONT lf = new LOGFONT();
            lf.lfHeight = 9;
            lf.lfFaceName = "Arial";
            IntPtr handle = CreateFontIndirect(lf);

            if (IntPtr.Zero == handle)
            {
                  Console.WriteLine("Can't creates a logical font.");
            }
            else
            {
```

```
                    if (IntPtr.Size == 4)
                          Console.WriteLine("{0:X}", handle.ToInt32());
                    else
                          Console.WriteLine("{0:X}", handle.ToInt64());

                    // Delete the logical font created.
                    if (!DeleteObject(handle))
                         Console.WriteLine("Can't delete the logical font");
              }
        }
  }
```

Sample Run

```
C30A0AE5
```

Code Discussion

In the preceding example, the `CreateFontIndirect` method is using a parameter of the type LOGFONT. The **MarshalAs** and **In** attributes are used to qualify the parameter. The program displays the numeric value returned by the method as a hexadecimal uppercase string.

Registering Callback Methods

To register a managed callback that calls an unmanaged function, declare a delegate with the same argument list and pass an instance of it via PInvoke. On the unmanaged side it will appear as a function pointer. For more information about PInvoke and callback, see A Closer Look at Platform Invoke.

For example, consider the following unmanaged function, `MyFunction`, which requires callback as one of the arguments:

```
typedef void (__stdcall *PFN_MYCALLBACK)();
int __stdcall MyFunction(PFN_ MYCALLBACK callback);
```

To call `MyFunction` from managed code, declare the delegate, attach DllImport to the function declaration, and optionally marshal any parameters or the return value:

```
public delegate void MyCallback();
[DllImport("MYDLL.DLL")]
public static extern void MyFunction(MyCallback callback);
```

Also, make sure the lifetime of the delegate instance covers the lifetime of the unmanaged code; otherwise, the delegate will not be available after it is garbage-collected.

COM Interop Tutorials

This section introduces two tutorials on interoperability between managed code and COM components.

COM Interop provides backward compatibility to let you access existing COM components without requiring that the original component be modified. The following tutorial demonstrates backward compatibility:

- COM Interop Part 1: C# Client Tutorial

COM Interop also allows COM developers to access managed code as easily as they access other COM objects. The following tutorial demonstrates accessing a C# server from a COM client:

- COM Interop Part 2: C# Server Tutorial

C# Tutorials

COM Interop Part 1: C# Client Tutorial

COM Interop provides access to existing COM components without requiring that the original component be modified. When you want to incorporate COM code into a managed application, import the relevant COM types by using a COM Interop utility (TlbImp.exe) for that purpose. Once imported, the COM types are ready to use.

In addition, COM Interop allows COM developers to access managed objects as easily as they access other COM objects. Again, COM Interop provides a specialized utility (RegAsm.exe) that exports the managed types into a type library and registers the managed component as a traditional COM component.

At run time, the common language runtime marshals data between COM objects and managed objects as needed.

This tutorial shows how to use C# to interoperate with COM objects.

COM Interop Part 2: C# Server Tutorial covers using a C# server with a C++ COM client. For an overview of both tutorials, see COM Interop Tutorials.

Sample Files

See COM Interop Part 1 Sample to download and build the sample files discussed in this tutorial.

Tutorial

C# uses .NET Framework facilities to perform COM Interop. C# has support for:

- Creating COM objects.
- Determining if a COM interface is implemented by an object.
- Calling methods on COM interfaces.
- Implementing objects and interfaces that can be called by COM clients.

The .NET Framework handles reference-counting issues with COM Interop so there is no need to call or implement **AddRef** and **Release**.

This tutorial covers the following topics:

- Creating a COM Class Wrapper
- Declaring a COM coclass
- Creating a COM Object
- Declaring a COM Interface
- Using Casts Instead of QueryInterface
- Putting It All Together

Creating a COM Class Wrapper

For C# code to reference COM objects and interfaces, you need to include a .NET Framework definition for the COM interfaces in your C# build. The easiest way to do this is to use TlbImp.exe (Type Library Importer), a command-line tool included in the .NET Framework SDK. TlbImp converts a COM type library into .NET Framework metadata — effectively creating a managed wrapper that can be called from any managed language. .NET Framework metadata created with TlbImp can be included in a C# build via

the /R compiler option. If you are using the Visual Studio development environment, you only need to add a reference to the COM type library and the conversion is done for you automatically.

TlbImp performs the following conversions:

- COM coclasses are converted to C# classes with a parameterless constructor.
- COM structs are converted to C# structs with public fields.

A great way to check the output of TlbImp is to run the .NET Framework SDK command-line tool Ildasm.exe (Microsoft Intermediate Language Disassembler) to view the result of the conversion.

Although TlbImp is the preferred method for converting COM definitions to C#, it is not always possible to use it (for example, if there is no typelib for the COM definitions, or if TlbImp cannot handle the definitions in the typelib). In these cases, the alternative is to manually define the COM definitions in C# source code using C# attributes. Once you have created the C# source mapping, you simply compile the C# source code to produce the managed wrapper.

The main attributes you need to understand to perform COM mapping are:

- **ComImport** - Marks a class as an externally implemented COM class.
- **Guid** – Used to specify a universally unique identifier (UUID) for a class or an interface.
- **InterfaceType** – specifies whether an interface derives from **IUnknown** or **IDispatch**.
- **PreserveSig** – specifies whether the native return value should be converted from an HRESULT to a .NET Framework exception.

Each of these attributes is shown in the context of an actual example in this tutorial.

Declaring a COM coclass

COM coclasses are represented in C# as classes. These classes must have the **ComImport** attribute associated with them. The following restrictions apply to these classes:

- The class must not inherit from any other class.
- The class must implement no interfaces.
- The class must also have a **Guid** attribute that sets the globally unique identifier (GUID) for the class.

The following example declares a coclass in C#:

```
//
// declare FilgraphManager as a COM coclass
//
[ComImport, Guid("E436EBB3-524F-11CE-9F53-0020AF0BA770")]
class FilgraphManager
{
}
```

The C# compiler will add a parameterless constructor that you can call to create an instance of the COM coclass.

Creating a COM Object

COM coclasses are represented in C# as classes with a parameterless constructor. Creating an instance of this class using the **new** operator is the C# equivalent of calling **CoCreateInstance**. Using the class defined above, it is simple to instantiate the class:

```
class MainClass
{
    public static void Main()
    {
        //
        // Create an instance of a COM coclass - calls
        //
        // CoCreateInstance(E436EBB3-524F-11CE-9F53-0020AF0BA770,
        //                  NULL, CLSCTX_ALL,
        //                  IID_IUnknown, &f)
        //
        // returns null on failure.
        //
```

```
        FilgraphManager f = new FilgraphManager();
    }
}
```

Declaring a COM Interface

COM interfaces are represented in C# as interfaces with **ComImport** and **Guid** attributes. They cannot include any interfaces in their base interface list, and they must declare the interface member functions in the order that the methods appear in the COM interface.

COM interfaces declared in C# must include declarations for all members of their base interfaces with the exception of members of **IUnknown** and **IDispatch** — the .NET Framework automatically adds these. COM interfaces which derive from **IDispatch** must be marked with the **InterfaceType** attribute.

When calling a COM interface method from C# code, the common language runtime must marshal the parameters and return values to/from the COM object. For every .NET Framework type, there is a default type that the common language runtime will use to marshal when marshaling across a COM call. For example, the default marshaling for C# string values is to the native type LPTSTR (pointer to TCHAR char buffer). You can override the default marshaling using the **MarshalAs** attribute in the C# declaration of the COM interface.

In COM, a common way to return success or failure is to return an HRESULT and have an out parameter marked as "retval" in MIDL for the real return value of the method. In C# (and the .NET Framework), the standard way to indicate an error has occurred is to throw an exception.

By default, the .NET Framework provides an automatic mapping between the two styles of exception handling for COM interface methods called by the .NET Framework.

- The return value changes to the signature of the parameter marked retval (void if the method has no parameter marked as retval).
- The parameter marked as retval is left off of the argument list of the method.

Any non-success return value will cause a **System.COMException** exception to be thrown.

This example shows a COM interface declared in MIDL and the same interface declared in C# (note that the methods use the COM error-handling approach).

Here is the original MIDL version of the interface:

```
[
  odl,
  uuid(56A868B1-0AD4-11CE-B03A-0020AF0BA770),
  helpstring("IMediaControl interface"),
  dual,
  oleautomation
]
interface IMediaControl : IDispatch
{
  [id(0x60020000)]
  HRESULT Run();

  [id(0x60020001)]
  HRESULT Pause();

  [id(0x60020002)]
  HRESULT Stop();

  [id(0x60020003)]
  HRESULT GetState( [in] long msTimeout, [out] long* pfs);

  [id(0x60020004)]
  HRESULT RenderFile([in] BSTR strFilename);

  [id(0x60020005)]
  HRESULT AddSourceFilter( [in] BSTR strFilename, [out] IDispatch** ppUnk);

  [id(0x60020006), propget]
  HRESULT FilterCollection([out, retval] IDispatch** ppUnk);
```

```
  [id(0x60020007), propget]
  HRESULT RegFilterCollection([out, retval] IDispatch** ppUnk);

  [id(0x60020008)]
  HRESULT StopWhenReady();
};
```

Here is the C# equivalent of this interface:

```
using System.Runtime.InteropServices;

// Declare IMediaControl as a COM interface which
// derives from the IDispatch interface.
[Guid("56A868B1-0AD4-11CE-B03A-0020AF0BA770"),
    InterfaceType(ComInterfaceType.InterfaceIsDual)]
interface IMediaControl // cannot list any base interfaces here
{
    // Note that the members of IUnknown and Interface are NOT
    // listed here
    //
    void Run();

    void Pause();

    void Stop();

    void GetState( [In] int msTimeout, [Out] out int pfs);

    void RenderFile(
    [In, MarshalAs(UnmanagedType.BStr)] string strFilename);

    void AddSourceFilter(
    [In, MarshalAs(UnmanagedType.BStr)] string strFilename,
    [Out, MarshalAs(UnmanagedType.Interface)] out object ppUnk);

    [return : MarshalAs(UnmanagedType.Interface)]
    object FilterCollection();

    [return : MarshalAs(UnmanagedType.Interface)]
    object RegFilterCollection();

    void StopWhenReady();
}
```

Note how the C# interface has mapped the error-handling cases. If the COM method returns an error, an exception will be raised on the C# side.

To prevent the translation of HRESULTs to COMExceptions, attach the **PreserveSig(true)** attribute to the method in the C# declaration. For details, see PreserveSigAttribute Class.

Using Casts Instead of QueryInterface

A C# coclass is not very useful until you can access an interface that it implements. In C++ you would navigate an object's interfaces using the **QueryInterface** method on the **IUnknown** interface. In C# you can do the same thing by explicitly casting the COM object to the desired COM interface. If the cast fails, then an invalid cast exception is thrown:

```
// Create an instance of a COM coclass:
FilgraphManager graphManager = new FilgraphManager();

// See if it supports the IMediaControl COM interface.
// Note that this will throw a System.InvalidCastException if
// the cast fails. This is equivalent to QueryInterface for
// COM objects:
IMediaControl mc = (IMediaControl) graphManager;
```

```
// Now you call a method on a COM interface:
mc.Run();
```

Putting It All Together

Here is a complete example that creates an AVI file viewer using C#. The program creates an instance of a COM coclass, casts it to a COM interface, and then calls methods on the COM interface.

The examples in this section represent two approaches:

- Example 1 Using TlbImp to create the .NET Framework class.
- Example 2 Writing C# code that manually does the COM mapping.

Example 1: Using TlbImp

This example shows you how to create an AVI viewer using TlbImp. The program reads an AVI filename from the command line, creates an instance of the Quartz COM object, then uses the methods **RenderFile** and **Run** to display the AVI file.

These are the steps to build the program:

- Run TlbImp over the TLB. The Media Player used in this example is contained in Quartz.dll, which should be in your Windows system directory. Use the following command to create the .NET Framework DLL:

  ```
  tlbimp c:\winnt\system32\quartz.dll /out:QuartzTypeLib.dll
  ```

  Note that the resulting DLL needs to be named `QuartzTypeLib`, so the .NET Framework can load the containing types correctly when running.

- You can use the Ildasm tool to examine the resulting DLL. For example, to display the contents of the file `QuartzTypeLib.dll`, use the following command:

  ```
  Ildasm QuartzTypeLib.dll
  ```

- Build the program using the C# compiler option /R to include the `QuartzTypeLib.dll` file.

You can then use the program to display a movie (an example movie to try is Clock.avi, which resides in your Windows directory).

```
// interop1.cs
// compile with: /R:QuartzTypeLib.dll
using System;
class MainClass
{
      /*************************************************************
      Abstract: This method collects the file name of an AVI to
      show then creates an instance of the Quartz COM object.
      To show the AVI, the program calls RenderFile and Run on
      IMediaControl. Quartz uses its own thread and window to
      display the AVI.The main thread blocks on a ReadLine until
      the user presses ENTER.
            Input Parameters: the location of the AVI file it is
            going to display
            Returns: void
      *************************************************************/
      public static void Main(string[] args)
      {
            // Check to see if the user passed in a filename
            if (args.Length != 1)
            {
                  DisplayUsage();
                  return;
            }

            if (args[0] == "/?")
            {
                  DisplayUsage();
```

```
                return;
            }

            string filename = args[0];

            // Check to see if the file exists
            if (!System.IO.File.Exists(filename))
            {
                Console.WriteLine("File " + filename + " not found.");
                DisplayUsage();
                return;
            }

            // Create instance of Quartz
            // (Calls CoCreateInstance(E436EBB3-524F-11CE-9F53-0020AF0BA770,
            // NULL, CLSCTX_ALL, IID_IUnknown, &graphManager).):

            try
            {
                QuartzTypeLib.FilgraphManager graphManager =
                    new QuartzTypeLib.FilgraphManager();

                // QueryInterface for the IMediaControl interface:
                QuartzTypeLib.IMediaControl mc =
                    (QuartzTypeLib.IMediaControl)graphManager;

                // Call some methods on a COM interface
                // Pass in file to RenderFile method on COM object.
                mc.RenderFile(filename);

                // Show file.
                mc.Run();
            }
            catch(Exception ex)
            {
                Console.WriteLine("Unexpected COM exception: " + ex.Message);
            }

            // Wait for completion.
            Console.WriteLine("Press Enter to continue.");
            Console.ReadLine();
        }

        private static void DisplayUsage()
        {
            // User did not provide enough parameters.
            // Display usage:
            Console.WriteLine("VideoPlayer: Plays AVI files.");
            Console.WriteLine("Usage: VIDEOPLAYER.EXE filename");
            Console.WriteLine("where filename is the full path and");
            Console.WriteLine("file name of the AVI to display.");
        }
    }
```

Sample Run

To display the example movie, Clock.avi, use the following command:

```
interop1 %windir%\clock.avi
```

This will display the movie on your screen after you press ENTER.

Example 2: The C# Code Approach

This example uses the same **Main** method as Example 1, but instead of running TlbImp, it simply maps the Media Player COM

object using C#.

```
// interop2.cs
using System;
using System.Runtime.InteropServices;

namespace QuartzTypeLib
{
      // Declare IMediaControl as a COM interface which
      // derives from IDispatch interface:
      [Guid("56A868B1-0AD4-11CE-B03A-0020AF0BA770"),
      InterfaceType(ComInterfaceType.InterfaceIsDual)]
      interface IMediaControl   // Cannot list any base interfaces here
      {
            // Note that IUnknown Interface members are NOT listed here:

            void Run();
            void Pause();

            void Stop();

            void GetState( [In] int msTimeout, [Out] out int pfs);

            void RenderFile(
                  [In, MarshalAs(UnmanagedType.BStr)] string strFilename);

            void AddSourceFilter(
                  [In, MarshalAs(UnmanagedType.BStr)] string strFilename,
                  [Out, MarshalAs(UnmanagedType.Interface)]
                  out object ppUnk);

            [return: MarshalAs(UnmanagedType.Interface)]
            object FilterCollection();

            [return: MarshalAs(UnmanagedType.Interface)]
            object RegFilterCollection();

            void StopWhenReady();
      }
      // Declare FilgraphManager as a COM coclass:
      [ComImport, Guid("E436EBB3-524F-11CE-9F53-0020AF0BA770")]
      class FilgraphManager   // Cannot have a base class or
            // interface list here.
      {
            // Cannot have any members here
            // NOTE that the C# compiler will add a default constructor
            // for you (no parameters).
      }
}

class MainClass
{
      /*************************************************************
      Abstract: This method collects the file name of an AVI to
      show then creates an instance of the Quartz COM object.
      To show the AVI, the program calls RenderFile and Run on
      IMediaControl. Quartz uses its own thread and window to
      display the AVI.The main thread blocks on a ReadLine until
      the user presses ENTER.
            Input Parameters: the location of the AVI file it is
            going to display
            Returns: void
      *************************************************************/

      public static void Main(string[] args)
      {
            // Check to see if the user passed in a filename:
```

```
            if (args.Length != 1)
            {
                  DisplayUsage();
                  return;
            }

            if (args[0] == "/?")
            {
                  DisplayUsage();
                  return;
            }

            String filename = args[0];

            // Check to see if the file exists
            if (!System.IO.File.Exists(filename))
            {
                  Console.WriteLine("File " + filename + " not found.");
                  DisplayUsage();
                  return;
            }

            // Create instance of Quartz
            // (Calls CoCreateInstance(E436EBB3-524F-11CE-9F53-0020AF0BA770,
            //  NULL, CLSCTX_ALL, IID_IUnknown,
            //  &graphManager).):
            try
            {
                  QuartzTypeLib.FilgraphManager graphManager =
                        new QuartzTypeLib.FilgraphManager();

                  // QueryInterface for the IMediaControl interface:
                  QuartzTypeLib.IMediaControl mc =
                        (QuartzTypeLib.IMediaControl)graphManager;

                  // Call some methods on a COM interface.
                  // Pass in file to RenderFile method on COM object.
                  mc.RenderFile(filename);

                  // Show file.
                  mc.Run();
            }
            catch(Exception ex)
            {
                  Console.WriteLine("Unexpected COM exception: " + ex.Message);
            }
            // Wait for completion.
            Console.WriteLine("Press Enter to continue.");
            Console.ReadLine();
      }

      private static void DisplayUsage()
      {
            // User did not provide enough parameters.
            // Display usage.
            Console.WriteLine("VideoPlayer: Plays AVI files.");
            Console.WriteLine("Usage: VIDEOPLAYER.EXE filename");
            Console.WriteLine("where filename is the full path and");
            Console.WriteLine("file name of the AVI to display.");
      }
}
```

Sample Run

To display the example movie, Clock.avi, use the following command:

```
interop2 %windir%\clock.avi
```

This will display the movie on your screen after you press ENTER.

COM Interop Part 2: C# Server Tutorial

COM Interop allows COM developers to access managed code as easily as they access other COM objects. This tutorial demonstrates using a C# server with a C++ COM client. It also explains the following activities:

- How to create the C# server
- How to create the COM client

The tutorial also briefly demonstrates the marshaling that is automatically applied between managed and unmanaged components.

COM Interop Part 1: C# Client Tutorial shows the fundamentals of using C# to interoperate with COM objects and is a prerequisite for this tutorial. For an overview of both tutorials, see COM Interop Tutorials.

Sample Files

See COM Interop Part 2 Sample to download and build the sample files discussed in this tutorial.

- Assembly Registration Tool (Regasm.exe)
- Type Library Importer (Tlbimp.exe)
- Interop Marshaling
- COM Interop Part 1: C# Client Tutorial

Tutorial

This tutorial demonstrates the following activities to create the C# server:

- How to use the **Guid** attribute on interfaces and classes to expose them as COM objects and how to generate a globally unique identifier (GUID) for the **Guid** attribute.
- How to use RegAsm to register a .NET Framework program for use by COM clients and create a type library (.tlb file) from a .NET Framework program.

The tutorial also demonstrates the following activities to create the COM client:

- How to export managed servers and how to use them to create COM objects.
- How to import the .tlb file, generated by RegAsm, into the COM client and how to use **CoCreateInstance** to create an instance of a .NET Framework coclass.

> **Note** To create a GUID for interfaces and coclasses that you export to COM clients, use the tool Guidgen.exe, shipped as part of Visual Studio. Guidgen allows you to choose the format in which the GUID is expressed so you don't have to retype it. For more information on Guidgen, see the Knowledge Base article Q168318 "XADM: Guidgen.exe Available Only for Intel Platforms." KB articles are available in the MSDN Library and on the Web at http://support.microsoft.com.

Example

This example consists of two files:

- A C# file, CSharpServer.cs, that creates the CSharpServer.dll file. The .dll is used to create the file CSharpServer.tlb.
- A C++ file, COMClient.cpp, that creates the executable client, COMClient.exe.

File 1: CSharpServer.cs

```
// CSharpServer.cs
// compile with: /target:library
// post-build command: regasm CSharpServer.dll /tlb:CSharpServer.tlb

using System;
using System.Runtime.InteropServices;
namespace CSharpServer
{
   // Since the .NET Framework interface and coclass have to behave as
   // COM objects, we have to give them guids.
   [Guid("DBE0E8C4-1C61-41f3-B6A4-4E2F353D3D05")]
   public interface IManagedInterface
   {
      int PrintHi(string name);
   }

   [Guid("C6659361-1625-4746-931C-36014B146679")]
   public class InterfaceImplementation : IManagedInterface
   {
      public int PrintHi(string name)
      {
         Console.WriteLine("Hello, {0}!", name);
         return 33;
      }
   }
}
```

File 2: COMClient.cpp

```
// COMClient.cpp
// Build with "cl COMClient.cpp"
// arguments: friend

#include <windows.h>
#include <stdio.h>

#pragma warning (disable: 4278)

// To use managed-code servers like the C# server,
// we have to import the common language runtime:
#import <mscorlib.tlb> raw_interfaces_only

// For simplicity, we ignore the server namespace and use named guids:
#if defined (USINGPROJECTSYSTEM)
#import "..\RegisterCSharpServerAndExportTLB\CSharpServer.tlb" no_namespace named_guids
#else  // Compiling from the command line, all files in the same directory
#import "CSharpServer.tlb" no_namespace named_guids
#endif
int main(int argc, char* argv[])
{
   IManagedInterface *cpi = NULL;
   int retval = 1;

   // Initialize COM and create an instance of the InterfaceImplementation class:
   CoInitialize(NULL);
   HRESULT hr = CoCreateInstance(CLSID_InterfaceImplementation,
               NULL, CLSCTX_INPROC_SERVER,
               IID_IManagedInterface, reinterpret_cast<void**>(&cpi));

   if (FAILED(hr))
   {
      printf("Couldn't create the instance!... 0x%x\n", hr);
   }
   else
   {
      if (argc > 1)
```

```
        {
           printf("Calling function.\n");
           fflush(stdout);
           // The variable cpi now holds an interface pointer
           // to the managed interface.
           // If you are on an OS that uses ASCII characters at the
           // command prompt, notice that the ASCII characters are
           // automatically marshaled to Unicode for the C# code.
           if (cpi->PrintHi(argv[1]) == 33)
              retval = 0;
           printf("Returned from function.\n");
        }
        else
           printf ("Usage:  COMClient <name>\n");
        cpi->Release();
        cpi = NULL;
     }

     // Be a good citizen and clean up COM:
     CoUninitialize();
     return retval;
  }
```

Output

The executable client can be invoked with the command line: `COMClient <name>`, where `<name>` is any string you want to use, for example, `COMClient friend`.

```
Calling function.
Hello, friend!
Returned from function.
```

In the sample IDE project, set the **Command Line Arguments** property in the project's Property Pages to the desired string (for example, "friend").

Attributes Tutorial

This tutorial shows how to create custom attribute classes, use them in code, and query them through reflection.

Sample Files

See Attributes Sample to download and build the sample files discussed in this tutorial.

Further Reading

- C# Attributes
- 17. Attributes
- AttributeUsage
- Discovering Type Information at Runtime

Tutorial

Attributes provide a powerful method of associating declarative information with C# code (types, methods, properties, and so forth). Once associated with a program entity, the attribute can be queried at run time and used in any number of ways.

Example usage of attributes includes:

- Associating help documentation with program entities (through a `Help` attribute).
- Associating value editors to a specific type in a GUI framework (through a `ValueEditor` attribute).

In addition to a complete example, this tutorial includes the following topics:

- Declaring an Attribute Class

  The first thing you need to be able to do is declare an attribute.

- Using an Attribute Class

  Once the attribute has been created, you then associate the attribute with a particular program element.

- Accessing Attributes Through Reflection

  Once the attribute has been associated with a program element, you use reflection to query its existence and its value.

Declaring an Attribute Class

Declaring an attribute in C# is simple — it takes the form of a class declaration that inherits from **System.Attribute** and has been marked with the **AttributeUsage** attribute as shown below:

```
using System;
[AttributeUsage(AttributeTargets.All)]
public class HelpAttribute : System.Attribute
{
   public readonly string Url;

   public string Topic               // Topic is a named parameter
   {
      get
      {
         return topic;
      }
      set
      {

        topic = value;
      }
   }

   public HelpAttribute(string url)  // url is a positional parameter
   {
      this.Url = url;
```

```
    }

    private string topic;
  }
```

Code Discussion

- The attribute **AttributeUsage** specifies the language elements to which the attribute can be applied.
- Attributes classes are public classes derived from **System.Attribute** that have at least one public constructor.
- Attribute classes have two types of parameters:
  - *Positional parameters* must be specified every time the attribute is used. Positional parameters are specified as constructor arguments to the attribute class. In the example above, `url` is a positional parameter.
  - *Named parameters* are optional. If they are specified when the attribute is used, the name of the parameter must be used. Named parameters are defined by having a nonstatic field or property. In the example above, `Topic` is a named parameter.
- Attribute parameters are restricted to constant values of the following types:
  - Simple types (bool, byte, char, short, int, long, float, and double)
  - string
  - System.Type
  - enums
  - object (The argument to an attribute parameter of type object must be a constant value of one of the above types.)
  - One-dimensional arrays of any of the above types

Parameters for the AttributeUsage Attribute

The attribute **AttributeUsage** provides the underlying mechanism by which attributes are declared.

AttributeUsage has one positional parameter:

- **AllowOn**, which specifies the program elements that the attribute can be assigned to (class, method, property, parameter, and so on). Valid values for this parameter can be found in the **System.Attributes.AttributeTargets** enumeration in the .NET Framework. The default value for this parameter is all program elements (**AttributeElements.All**).

AttributeUsage has one named parameter:

- **AllowMultiple**, a Boolean value that indicates whether multiple attributes can be specified for one program element. The default value for this parameter is **False**.

Using an Attribute Class

Here's a simple example of using the attribute declared in the previous section:

```
[HelpAttribute("http://localhost/MyClassInfo")]
class MyClass
{
}
```

In this example, the `HelpAttribute` attribute is associated with `MyClass`.

> **Note** By convention, all attribute names end with the word "Attribute" to distinguish them from other items in the .NET Framework. However, you do not need to specify the attribute suffix when using attributes in code. For example, you can specify `HelpAttribute` as follows:
>
> ```
> [Help("http://localhost/MyClassInfo")] // [Help] == [HelpAttribute]
>
> class MyClass
>
> {
>
> }
> ```

Accessing Attributes Through Reflection

Once attributes have been associated with program elements, reflection can be used to query their existence and values. The main reflection methods to query attributes are contained in the **System.Reflection.MemberInfo** class (**GetCustomAttributes** family of methods). The following example demonstrates the basic way of using reflection to get access to attributes:

```
class MainClass
{
   public static void Main()
   {
      System.Reflection.MemberInfo info = typeof(MyClass);
      object[] attributes = info.GetCustomAttributes(true);
      for (int i = 0; i < attributes.Length; i ++)
      {
         System.Console.WriteLine(attributes[i]);
      }
   }
}
```

Example

The following is a complete example where all pieces are brought together.

```
// AttributesTutorial.cs
// This example shows the use of class and method attributes.

using System;
using System.Reflection;
using System.Collections;

// The IsTested class is a user-defined custom attribute class.
// It can be applied to any declaration including
//  - types (struct, class, enum, delegate)
//  - members (methods, fields, events, properties, indexers)
// It is used with no arguments.
public class IsTestedAttribute : Attribute
{
    public override string ToString()
    {
        return "Is Tested";
    }
}

// The AuthorAttribute class is a user-defined attribute class.
// It can be applied to classes and struct declarations only.
// It takes one unnamed string argument (the author's name).
// It has one optional named argument Version, which is of type int.
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Struct)]
public class AuthorAttribute : Attribute
{
    // This constructor specifies the unnamed arguments to the attribute class.
    public AuthorAttribute(string name)
    {
        this.name = name;
        this.version = 0;
    }

    // This property is readonly (it has no set accessor)
    // so it cannot be used as a named argument to this attribute.
    public string Name
    {
        get
        {
            return name;
        }
    }

    // This property is read-write (it has a set accessor)
```

```
    // so it can be used as a named argument when using this
    // class as an attribute class.
    public int Version
    {
        get
        {
            return version;
        }
        set
        {
            version = value;
        }
    }

    public override string ToString()
    {
        string value = "Author : " + Name;
        if (version != 0)
        {
            value += " Version : " + Version.ToString();
        }
        return value;
    }

    private string name;
    private int version;
}

// Here you attach the AuthorAttribute user-defined custom attribute to
// the Account class. The unnamed string argument is passed to the
// AuthorAttribute class's constructor when creating the attributes.
[Author("Joe Programmer")]
class Account
{
    // Attach the IsTestedAttribute custom attribute to this method.
    [IsTested]
    public void AddOrder(Order orderToAdd)
    {
        orders.Add(orderToAdd);
    }

    private ArrayList orders = new ArrayList();
}

// Attach the AuthorAttribute and IsTestedAttribute custom attributes
// to this class.
// Note the use of the 'Version' named argument to the AuthorAttribute.
[Author("Jane Programmer", Version = 2), IsTested()]
class Order
{
    // add stuff here ...
}

class MainClass
{
   private static bool IsMemberTested(MemberInfo member)
   {
        foreach (object attribute in member.GetCustomAttributes(true))
        {
            if (attribute is IsTestedAttribute)
            {
               return true;
            }
        }
      return false;
   }

    private static void DumpAttributes(MemberInfo member)
```

```
    {
        Console.WriteLine("Attributes for : " + member.Name);
        foreach (object attribute in member.GetCustomAttributes(true))
        {
            Console.WriteLine(attribute);
        }
    }

    public static void Main()
    {
        // display attributes for Account class
        DumpAttributes(typeof(Account));

        // display list of tested members
        foreach (MethodInfo method in (typeof(Account)).GetMethods())
        {
            if (IsMemberTested(method))
            {
               Console.WriteLine("Member {0} is tested!", method.Name);
            }
            else
            {
               Console.WriteLine("Member {0} is NOT tested!", method.Name);
            }
        }
        Console.WriteLine();

        // display attributes for Order class
        DumpAttributes(typeof(Order));

        // display attributes for methods on the Order class
        foreach (MethodInfo method in (typeof(Order)).GetMethods())
        {
           if (IsMemberTested(method))
           {
               Console.WriteLine("Member {0} is tested!", method.Name);
           }
           else
           {
               Console.WriteLine("Member {0} is NOT tested!", method.Name);
           }
        }
        Console.WriteLine();
    }
}
```

Output

```
Attributes for : Account
Author : Joe Programmer
Member GetHashCode is NOT tested!
Member Equals is NOT tested!
Member ToString is NOT tested!
Member AddOrder is tested!
Member GetType is NOT tested!

Attributes for : Order

Tutorial

Most application and component developers should not need to do anything special in order to work with the .NET Framework security system and benefit from the safety protection it provides.

One exception that requires more in-depth knowledge and special consideration of the security system is *secure libraries*. This code represents the boundary between secure managed code and unrestricted code, such as native code (that is outside the ability of the .NET Framework security infrastructure to enforce). These libraries typically must be highly trusted to work, and are the one place in managed code where a programming error can potentially expose a security vulnerability. Code access security can't eliminate the potential for human error, but compared to the much larger volume of application code that uses a few secure libraries, the amount of code that requires close scrutiny is dramatically reduced.

Examples

The tutorial includes the following examples:

- Example 1: Imperative Security
- Example 2: Declarative Security
- Example 3: Suppressing Security

Security

The .NET Framework security protects your code and data from being misused or damaged by other code by enforcing security restrictions on managed code. When a .NET Framework application requests permission, the security policy established by the administrator grants the permission or refuses to run the code. Trust is based on evidence about the code such as a digital signature, where the code comes from, and so forth. Once granted, security enforces permissions that control what code is (and by not being granted, what code is not) allowed to do.

Permissions

The .NET Framework security allows code to use protected resources only if it has "permission" to do so. To express this, the .NET Framework uses the concept of *permissions*, which represent the right for code to access protected resources. Code requests the permissions it needs, and the security policy applied by the .NET Framework determines which permissions the code is actually granted.

The .NET Framework provides code access permission classes, each of which encapsulates the ability to access a particular resource. You use these permissions to indicate to the .NET Framework what your code needs to be allowed to do and to indicate what your code's callers must be authorized to do. Policy also uses these objects to determine what permissions to grant to code.

Policy

Enforcement of security policy is what makes .NET Framework managed code safe. Every assembly that loads is subject to security policy that grants code permissions based on trust, with trust based on evidence about the code. See the .NET Framework documentation in the Reading List for information on administering security policy.

Demanding Security Permissions in C#

There are two ways to demand security permissions in C#:

- Imperatively: Using calls to permission classes in the .NET Framework
- Declaratively: Using security permission attributes

The following two examples demonstrate these two approaches. For more information on demanding security permissions, see Demands.

Example 1: Imperative Security

The following is an example of using .NET Framework calls to deny the **UnmanagedCode** permission.

```
// ImperativeSecurity.cs
using System;
using System.Security;
using System.Security.Permissions;
using System.Runtime.InteropServices;

class NativeMethods
{
    // This is a call to unmanaged code. Executing this method requires
    // the UnmanagedCode security permission. Without this permission
    // an attempt to call this method will throw a SecurityException:
    [DllImport("msvcrt.dll")]
    public static extern int puts(string str);
    [DllImport("msvcrt.dll")]
    internal static extern int _flushall();
}

class MainClass
{
    private static void CallUnmanagedCodeWithoutPermission()
    {
        // Create a security permission object to describe the
        // UnmanagedCode permission:
        SecurityPermission perm =
           new SecurityPermission(SecurityPermissionFlag.UnmanagedCode);

        // Deny the UnmanagedCode from our current set of permissions.
        // Any method that is called on this thread until this method
        // returns will be denied access to unmanaged code.
        // Even though the CallUnmanagedCodeWithPermission method
        // is called from a stack frame that already
        // calls Assert for unmanaged code, you still cannot call native
        // code. Because you use Deny here, the permission gets
        // overwritten.
        perm.Deny();

        try
        {
            Console.WriteLine("Attempting to call unmanaged code without permission.");
            NativeMethods.puts("Hello World!");
            NativeMethods._flushall();
            Console.WriteLine("Called unmanaged code without permission. Whoops!");
        }
        catch (SecurityException)
        {
            Console.WriteLine("Caught Security Exception attempting to call unmanaged code.")
;
        }
    }

    private static void CallUnmanagedCodeWithPermission()
    {
        // Create a security permission object to describe the
```

```
        // UnmanagedCode permission:
        SecurityPermission perm =
           new SecurityPermission(SecurityPermissionFlag.UnmanagedCode);

        // Check that you have permission to access unmanaged code.
        // If you don't have permission to access unmanaged code, then
        // this call will throw a SecurityException.
        // Even though the CallUnmanagedCodeWithPermission method
        // is called from a stack frame that already
        // calls Assert for unmanaged code, you still cannot call native
        // code. Because you use Deny here, the permission gets
        // overwritten.
        perm.Assert();

        try
        {
            Console.WriteLine("Attempting to call unmanaged code with permission.");
            NativeMethods.puts("Hello World!");
            NativeMethods._flushall();
            Console.WriteLine("Called unmanaged code with permission.");
        }
        catch (SecurityException)
        {
            Console.WriteLine("Caught Security Exception attempting to call unmanaged code. W
hoops!");
        }
    }

    public static void Main()
    {
        // The method itself will call the security permission Deny
        // for unmanaged code, which will override the Assert permission
        // in this stack frame.
        SecurityPermission perm = new
            SecurityPermission(SecurityPermissionFlag.UnmanagedCode);
        perm.Assert();
        CallUnmanagedCodeWithoutPermission();

        // The method itself will call the security permission Assert
        // for unmanaged code, which will override the Deny permission in
        // this stack frame.
        perm.Deny();
        CallUnmanagedCodeWithPermission();
    }
}
```

Output

```
Attempting to call unmanaged code without permission.
Caught Security Exception attempting to call unmanaged code.
Attempting to call unmanaged code with permission.
Hello World!
Called unmanaged code with permission.
```

Example 2: Declarative Security

This is the same example using attributes for the security permissions.

```
// DeclarativeSecurity.cs
using System;
using System.Security;
using System.Security.Permissions;
using System.Runtime.InteropServices;

class NativeMethods
```

```
{
    // This is a call to unmanaged code. Executing this method requires
    // the UnmanagedCode security permission. Without this permission,
    // an attempt to call this method will throw a SecurityException:
    [DllImport("msvcrt.dll")]
    public static extern int puts(string str);
    [DllImport("msvcrt.dll")]
    internal static extern int _flushall();
}

class MainClass
{
    // The security permission attached to this method will deny the
    // UnmanagedCode permission from the current set of permissions for
    // the duration of the call to this method:
    // Even though the CallUnmanagedCodeWithoutPermission method is
    // called from a stack frame that already calls
    // Assert for unmanaged code, you still cannot call native code.
    // Because this function is attached with the Deny permission for
    // unmanaged code, the permission gets overwritten.
    [SecurityPermission(SecurityAction.Deny, Flags =
       SecurityPermissionFlag.UnmanagedCode)]
    private static void CallUnmanagedCodeWithoutPermission()
    {
        try
        {
            Console.WriteLine("Attempting to call unmanaged code without permission.");
            NativeMethods.puts("Hello World!");
            NativeMethods._flushall();
            Console.WriteLine("Called unmanaged code without permission. Whoops!");
        }
        catch (SecurityException)
        {
            Console.WriteLine("Caught Security Exception attempting to call unmanaged code.")
;
        }
    }

    // The security permission attached to this method will force a
    // runtime check for the unmanaged code permission whenever
    // this method is called. If the caller does not have unmanaged code
    // permission, then the call will generate a Security Exception.
    // Even though the CallUnmanagedCodeWithPermission method is called
    // from a stack frame that already calls
    // Deny for unmanaged code, it will not prevent you from calling
    // native code. Because this method is attached with the Assert
    // permission for unmanaged code, the permission gets overwritten.
    [SecurityPermission(SecurityAction.Assert, Flags =
       SecurityPermissionFlag.UnmanagedCode)]
    private static void CallUnmanagedCodeWithPermission()
    {
        try
        {
            Console.WriteLine("Attempting to call unmanaged code with permission.");
            NativeMethods.puts("Hello World!");
            NativeMethods._flushall();
            Console.WriteLine("Called unmanaged code with permission.");
        }
        catch (SecurityException)
        {
            Console.WriteLine("Caught Security Exception attempting to call unmanaged code. W
hoops!");
        }
    }

    public static void Main()
    {
        SecurityPermission perm = new
```

```
            SecurityPermission(SecurityPermissionFlag.UnmanagedCode);

        // The method itself is attached with the security permission
        // Deny for unmanaged code, which will override
        // the Assert permission in this stack frame.
        perm.Assert();
        CallUnmanagedCodeWithoutPermission();

        // The method itself is attached with the security permission
        // Assert for unmanaged code, which will override the Deny
        // permission in this stack frame.
        perm.Deny();

    }
}
```

Output

```
Attempting to call unmanaged code without permission.
Caught Security Exception attempting to call unmanaged code.
Attempting to call unmanaged code with permission.
Hello World!
Called unmanaged code with permission.
```

Security and Performance

The .NET Framework security system prevents malicious code downloaded from the network from damaging your computer system. However, these security checks are not without cost, even if your code never throws a **SecurityException**.

Normally the common language runtime verifies that the caller of an unmanaged method has unmanaged code access permission at run time for every call to the unmanaged method. This can be very expensive for applications that make many calls to unmanaged code. The **SuppressUnmanagedCodeSecurityAttribute** changes this default behavior. When an unmanaged method is declared with this attribute, the security demand is checked when code that calls the method is loaded into the common language runtime.

> **Security Note** When using the SuppressUnmanagedCodeSecurityAttribute, you should take extra care to ensure that you are not introducing a security hole. For example, the developer needs to verify that he/she is using the unmanaged API safely and that callers cannot influence or abuse the call. Alternatively, the developer can add an appropriate demand to ensure that all callers have the appropriate permissions. For example, if a call was made into native code to access a file (to take advantage of structured storage such as extended file properties, and so forth) and the unmanaged code demand was suppressed, then a file IO demand should be made explicitly to ensure that the code cannot be misused.

Example 3: Optimizing Unmanaged Calls

In this example, the check for the unmanaged code permission is executed once at load time, rather than upon every call to the unmanaged method. If the unmanaged method is called multiple times, this could yield a significant performance gain.

```
// SuppressSecurity.cs
using System;
using System.Security;
using System.Security.Permissions;
using System.Runtime.InteropServices;

class NativeMethods
{
    // This is a call to unmanaged code. Executing this method requires
    // the UnmanagedCode security permission. Without this permission,
    // an attempt to call this method will throw a SecurityException:
    /* NOTE: The SuppressUnmanagedCodeSecurityAttribute disables the
       check for the UnmanagedCode permission at runtime. Be Careful! */
    [SuppressUnmanagedCodeSecurityAttribute()]
    [DllImport("msvcrt.dll")]
```

```
    internal static extern int puts(string str);
    [SuppressUnmanagedCodeSecurityAttribute()]
    [DllImport("msvcrt.dll")]
    internal static extern int _flushall();
}

class MainClass
{
    // The security permission attached to this method will remove the
    // UnmanagedCode permission from the current set of permissions for
    // the duration of the call to this method.
    // Even though the CallUnmanagedCodeWithoutPermission method is
    // called from a stack frame that already calls
    // Assert for unmanaged code, you still cannot call native code.
    // Because this method is attached with the Deny permission for
    // unmanaged code, the permission gets overwritten. However, because
    // you are using SuppressUnmanagedCodeSecurityAttribute here, you can
    // still call the unmanaged methods successfully.
    // The code should use other security checks to ensure that you don't
    // incur a security hole.
    [SecurityPermission(SecurityAction.Deny, Flags =
       SecurityPermissionFlag.UnmanagedCode)]
    private static void CallUnmanagedCodeWithoutPermission()
    {
        try
        {
            // The UnmanagedCode security check is disbled on the call
            // below. However, the unmanaged call only displays UI. The
            // security will be ensured by only allowing the unmanaged
            // call if there is a UI permission.
            UIPermission uiPermission =
               new UIPermission(PermissionState.Unrestricted);
            uiPermission.Demand();

            Console.WriteLine("Attempting to call unmanaged code without UnmanagedCode permis
sion.");
            NativeMethods.puts("Hello World!");
            NativeMethods._flushall();
            Console.WriteLine("Called unmanaged code without UnmanagedCode permission.");
        }
        catch (SecurityException)
        {
            Console.WriteLine("Caught Security Exception attempting to call unmanaged code.")
;
        }
    }

    // The security permission attached to this method will add the
    // UnmanagedCode permission to the current set of permissions for the
    // duration of the call to this method.
    // Even though the CallUnmanagedCodeWithPermission method is called
    // from a stack frame that already calls
    // Deny for unmanaged code, it will not prevent you from calling
    // native code. Because this method is attached with the Assert
    // permission for unmanaged code, the permission gets overwritten.
    // Because you are using SuppressUnmanagedCodeSecurityAttribute here,
    // you can call the unmanaged methods successfully.
    // The SuppressUnmanagedCodeSecurityAttribute will let you succeed,
    // even if you don't have a permission.
    [SecurityPermission(SecurityAction.Assert, Flags =
       SecurityPermissionFlag.UnmanagedCode)]
    private static void CallUnmanagedCodeWithPermission()
    {
        try
        {
            Console.WriteLine("Attempting to call unmanaged code with permission.");
            NativeMethods.puts("Hello World!");
            NativeMethods._flushall();
```

```
            Console.WriteLine("Called unmanaged code with permission.");
        }
        catch (SecurityException)
        {
            Console.WriteLine("Caught Security Exception attempting to call unmanaged code. W
hoops!");
        }
    }

    public static void Main()
    {
        SecurityPermission perm = new
            SecurityPermission(SecurityPermissionFlag.UnmanagedCode);

       // The method itself is attached with the security permission Deny
       // for unmanaged code, which will override the Assert permission in
       // this stack frame. However, because you are using
       // SuppressUnmanagedCodeSecurityAttribute, you can still call the
       // unmanaged methods successfully.
       // The code should use other security checks to ensure that you
       // don't incur a security hole.
       perm.Assert();
       CallUnmanagedCodeWithoutPermission();

       // The method itself is attached with the security permission
       // Assert for unmanaged code, which will override the Deny
       // permission in this stack frame. Because you are using
       // SuppressUnmanagedCodeSecurityAttribute, you can call the
       // unmanaged methods successfully.
       // The SuppressUnmanagedCodeSecurityAttribute will let you succeed,
       // even if you don't have a permission.
       perm.Deny();
       CallUnmanagedCodeWithPermission();
    }
}
```

Output

```
Attempting to call unmanaged code without UnmanagedCode permission.
Hello World!
Called unmanaged code without UnmanagedCode permission.
Attempting to call unmanaged code with permission.
Hello World!
Called unmanaged code with permission.
```

Code Discussion

Note that the above example allows both unmanaged calls to succeed even though the first call doesn't have **UnmanagedCode** permission. When using the **SuppressUnmanagedCodeSecurityAttribute**, you should use other security checks to ensure that you don't incur a security hole. In the above example, this is done by adding the **Demand** for the **UIPermission**:

```
uiPermission.Demand();
```

before the unmanaged call, which ensures that the caller has permission to display UI.

Threading Tutorial

The advantage of threading is the ability to create applications that use more than one thread of execution. For example, a process can have a user interface thread that manages interactions with the user and worker threads that perform other tasks while the user interface thread waits for user input.

This tutorial demonstrates various thread activities:

- Creating and executing a thread
- Synchronization of threads
- Interaction between threads
- Using a thread pool
- Using a mutex object to protect a shared resource

Sample Files

See Threading Sample to download and build the sample files discussed in this tutorial.

Tutorial

This tutorial contains the following examples:

- Example 1: Creating, starting, and interacting between threads
- Example 2: Synchronizing two threads: a producer and a consumer
- Example 3: Using a thread pool
- Example 4: Using the Mutex object

Example 1: Creating, starting, and interacting between threads

This example demonstrates how to create and start a thread, and shows the interaction between two threads running simultaneously within the same process. Note that you don't have to stop or free the thread. This is done automatically by the .NET Framework common language runtime.

The program begins by creating an object of type `Alpha` (`oAlpha`) and a thread (`oThread`) that references the `Beta` method of the `Alpha` class. The thread is then started. The `IsAlive` property of the thread allows the program to wait until the thread is initialized (created, allocated, and so on). The main thread is accessed through `Thread`, and the `Sleep` method tells the thread to give up its time slice and stop executing for a certain amount of milliseconds. The `oThread` is then stopped and joined. Joining a thread makes the main thread wait for it to die or for a specified time to expire (for more details, see Thread.Join Method). Finally, the program attempts to restart `oThread`, but fails because a thread cannot be restarted after it is stopped (aborted). For information on temporary cessation of execution, see Suspending Thread Execution.

```
// StopJoin.cs
using System;
using System.Threading;

public class Alpha
{

   // This method that will be called when the thread is started
   public void Beta()
   {
      while (true)
      {
         Console.WriteLine("Alpha.Beta is running in its own thread.");
```

```
        }
    }
};

public class Simple
{
    public static int Main()
    {
        Console.WriteLine("Thread Start/Stop/Join Sample");

        Alpha oAlpha = new Alpha();

        // Create the thread object, passing in the Alpha.Beta method
        // via a ThreadStart delegate. This does not start the thread.
        Thread oThread = new Thread(new ThreadStart(oAlpha.Beta));

        // Start the thread
        oThread.Start();

        // Spin for a while waiting for the started thread to become
        // alive:
        while (!oThread.IsAlive);

        // Put the Main thread to sleep for 1 millisecond to allow oThread
        // to do some work:
        Thread.Sleep(1);

        // Request that oThread be stopped
        oThread.Abort();

        // Wait until oThread finishes. Join also has overloads
        // that take a millisecond interval or a TimeSpan object.
        oThread.Join();

        Console.WriteLine();
        Console.WriteLine("Alpha.Beta has finished");

        try
        {
            Console.WriteLine("Try to restart the Alpha.Beta thread");
            oThread.Start();
        }
        catch (ThreadStateException)
        {
            Console.Write("ThreadStateException trying to restart Alpha.Beta. ");
            Console.WriteLine("Expected since aborted threads cannot be restarted.");
        }
        return 0;
    }
}
```

Example Output

```
Thread Start/Stop/Join Sample
Alpha.Beta is running in its own thread.
Alpha.Beta is running in its own thread.
Alpha.Beta is running in its own thread.
...
...
Alpha.Beta has finished
Try to restart the Alpha.Beta thread
ThreadStateException trying to restart Alpha.Beta. Expected since aborted threads cannot be r
estarted.
```

Example 2: Synchronizing two threads: a producer and a consumer

The following example shows how synchronization can be accomplished using the C# **lock** keyword and the **Pulse** method of the **Monitor** object. The **Pulse** method notifies a thread in the waiting queue of a change in the object's state (for more details on pulses, see the Monitor.Pulse Method).

The example creates a `Cell` object that has two methods: `ReadFromCell` and `WriteToCell`. Two other objects are created from classes `CellProd` and `CellCons`; these objects both have a method `ThreadRun` whose job is to call `ReadFromCell` and `WriteToCell`. Synchronization is accomplished by waiting for "pulses" from the **Monitor** object, which come in order. That is, first an item is produced (the consumer at this point is waiting for a pulse), then a pulse occurs, then the consumer consumes the production (while the producer is waiting for a pulse), and so on.

```
// MonitorSample.cs
// This example shows use of the following methods of the C# lock keyword
// and the Monitor class
// in threads:
//      Monitor.Pulse(Object)
//      Monitor.Wait(Object)
using System;
using System.Threading;

public class MonitorSample
{
   public static void Main(String[] args)
   {
      int result = 0;   // Result initialized to say there is no error
      Cell cell = new Cell( );

      CellProd prod = new CellProd(cell, 20);  // Use cell for storage,
                                               // produce 20 items
      CellCons cons = new CellCons(cell, 20);  // Use cell for storage,
                                               // consume 20 items

      Thread producer = new Thread(new ThreadStart(prod.ThreadRun));
      Thread consumer = new Thread(new ThreadStart(cons.ThreadRun));
      // Threads producer and consumer have been created,
      // but not started at this point.

      try
      {
         producer.Start( );
         consumer.Start( );

         producer.Join( );   // Join both threads with no timeout
                             // Run both until done.
         consumer.Join( );
      // threads producer and consumer have finished at this point.
      }
      catch (ThreadStateException e)
      {
         Console.WriteLine(e);  // Display text of exception
         result = 1;            // Result says there was an error
      }
      catch (ThreadInterruptedException e)
      {
         Console.WriteLine(e);  // This exception means that the thread
                                // was interrupted during a Wait
         result = 1;            // Result says there was an error
      }
      // Even though Main returns void, this provides a return code to
      // the parent process.
      Environment.ExitCode = result;
   }
}

public class CellProd
{
   Cell cell;         // Field to hold cell object to be used
   int quantity = 1;  // Field for how many items to produce in cell
```

```
   public CellProd(Cell box, int request)
   {
      cell = box;          // Pass in what cell object to be used
      quantity = request;  // Pass in how many items to produce in cell
   }
   public void ThreadRun( )
   {
      for(int looper=1; looper<=quantity; looper++)
         cell.WriteToCell(looper);  // "producing"
   }
}

public class CellCons
{
   Cell cell;         // Field to hold cell object to be used
   int quantity = 1;  // Field for how many items to consume from cell

   public CellCons(Cell box, int request)
   {
      cell = box;          // Pass in what cell object to be used
      quantity = request;  // Pass in how many items to consume from cell
   }
   public void ThreadRun( )
   {
      int valReturned;
      for(int looper=1; looper<=quantity; looper++)
      // Consume the result by placing it in valReturned.
         valReturned=cell.ReadFromCell( );
   }
}

public class Cell
{
   int cellContents;         // Cell contents
   bool readerFlag = false;  // State flag
   public int ReadFromCell( )
   {
      lock(this)   // Enter synchronization block
      {
         if (!readerFlag)
         {            // Wait until Cell.WriteToCell is done producing
            try
            {
               // Waits for the Monitor.Pulse in WriteToCell
               Monitor.Wait(this);
            }
            catch (SynchronizationLockException e)
            {
               Console.WriteLine(e);
            }
            catch (ThreadInterruptedException e)
            {
               Console.WriteLine(e);
            }
         }
         Console.WriteLine("Consume: {0}",cellContents);
         readerFlag = false;    // Reset the state flag to say consuming
                                // is done.
         Monitor.Pulse(this);   // Pulse tells Cell.WriteToCell that
                                // Cell.ReadFromCell is done.
      }   // Exit synchronization block
      return cellContents;
   }

   public void WriteToCell(int n)
   {
      lock(this)  // Enter synchronization block
```

```
      {
         if (readerFlag)
         {      // Wait until Cell.ReadFromCell is done consuming.
            try
            {
               Monitor.Wait(this);   // Wait for the Monitor.Pulse in
                                     // ReadFromCell
            }
            catch (SynchronizationLockException e)
            {
               Console.WriteLine(e);
            }
            catch (ThreadInterruptedException e)
            {
               Console.WriteLine(e);
            }
         }
         cellContents = n;
         Console.WriteLine("Produce: {0}",cellContents);
         readerFlag = true;    // Reset the state flag to say producing
                               // is done
         Monitor.Pulse(this);  // Pulse tells Cell.ReadFromCell that
                               // Cell.WriteToCell is done.
      }   // Exit synchronization block
   }
}
```

Example Output

```
Produce: 1
Consume: 1
Produce: 2
Consume: 2
Produce: 3
Consume: 3
...
...
Produce: 20
Consume: 20
```

Example 3: Using a thread pool

The following example shows how to use a thread pool. It first creates a **ManualResetEvent** object, which enables the program to know when the thread pool has finished running all of the work items. Next, it attempts to add one thread to the thread pool. If this succeeds, it adds the rest (four in this example). The thread pool will then put work items into available threads. The **WaitOne** method on `eventX` is called, which causes the rest of the program to wait until the event is triggered (with the `eventX.Set` method). Finally, the program prints out the load (the thread that actually executes a particular work item) on the threads.

```
// SimplePool.cs
// Simple thread pool example
using System;
using System.Collections;
using System.Threading;

// Useful way to store info that can be passed as a state on a work item
public class SomeState
{
   public int Cookie;
   public SomeState(int iCookie)
   {
      Cookie = iCookie;
   }
}
```

```
public class Alpha
{
   public Hashtable HashCount;
   public ManualResetEvent eventX;
   public static int iCount = 0;
   public static int iMaxCount = 0;
   public Alpha(int MaxCount)
   {
      HashCount = new Hashtable(MaxCount);
      iMaxCount = MaxCount;
   }

   // Beta is the method that will be called when the work item is
   // serviced on the thread pool.
   // That means this method will be called when the thread pool has
   // an available thread for the work item.
   public void Beta(Object state)
   {
      // Write out the hashcode and cookie for the current thread
      Console.WriteLine(" {0} {1} :", Thread.CurrentThread.GetHashCode(),
         ((SomeState)state).Cookie);
      // The lock keyword allows thread-safe modification
      // of variables accessible across multiple threads.
      Console.WriteLine(
         "HashCount.Count={{0}, Thread.CurrentThread.GetHashCode()={{1}",
         HashCount.Count,
         Thread.CurrentThread.GetHashCode());
      lock (HashCount)
      {
         if (!HashCount.ContainsKey(Thread.CurrentThread.GetHashCode()))
            HashCount.Add (Thread.CurrentThread.GetHashCode(), 0);
         HashCount[Thread.CurrentThread.GetHashCode()] =
            ((int)HashCount[Thread.CurrentThread.GetHashCode()])+1;
      }

      // Do some busy work.
      // Note: Depending on the speed of your machine, if you
      // increase this number, the dispersement of the thread
      // loads should be wider.
      int iX  = 2000;
      Thread.Sleep(iX);
      // The Interlocked.Increment method allows thread-safe modification
      // of variables accessible across multiple threads.
      Interlocked.Increment(ref iCount);
      if (iCount == iMaxCount)
      {
         Console.WriteLine();
         Console.WriteLine("Setting eventX ");
         eventX.Set();
      }
   }
}

public class SimplePool
{
   public static int Main(string[] args)
   {
      Console.WriteLine("Thread Pool Sample:");
      bool W2K = false;
      int MaxCount = 10;  // Allow a total of 10 threads in the pool
      // Mark the event as unsignaled.
      ManualResetEvent eventX = new ManualResetEvent(false);
      Console.WriteLine("Queuing {0} items to Thread Pool", MaxCount);
      Alpha oAlpha = new Alpha(MaxCount);  // Create the work items.
      // Make sure the work items have a reference to the signaling event.
      oAlpha.eventX = eventX;
      Console.WriteLine("Queue to Thread Pool 0");
      try
```

```
        {
           // Queue the work items, which has the added effect of checking
           // which OS is running.
           ThreadPool.QueueUserWorkItem(new WaitCallback(oAlpha.Beta),
              new SomeState(0));
           W2K = true;
        }
        catch (NotSupportedException)
        {
           Console.WriteLine("These API's may fail when called on a non-Windows 2000 system.");
           W2K = false;
        }
        if (W2K)  // If running on an OS which supports the ThreadPool methods.
        {
           for (int iItem=1;iItem < MaxCount;iItem++)
           {
              // Queue the work items:
              Console.WriteLine("Queue to Thread Pool {0}", iItem);
              ThreadPool.QueueUserWorkItem(new WaitCallback(oAlpha.Beta),new SomeState(iItem));
           }
           Console.WriteLine("Waiting for Thread Pool to drain");
           // The call to exventX.WaitOne sets the event to wait until
           // eventX.Set() occurs.
           // (See oAlpha.Beta).
           // Wait until event is fired, meaning eventX.Set() was called:
           eventX.WaitOne(Timeout.Infinite,true);
           // The WaitOne won't return until the event has been signaled.
           Console.WriteLine("Thread Pool has been drained (Event fired)");
           Console.WriteLine();
           Console.WriteLine("Load across threads");
           foreach(object o in oAlpha.HashCount.Keys)
              Console.WriteLine("{0} {1}", o, oAlpha.HashCount[o]);
        }
        return 0;
     }
  }
```

Example Output

Note The following output will vary from one computer to another.

```
Thread Pool Sample:
Queuing 10 items to Thread Pool
Queue to Thread Pool 0
Queue to Thread Pool 1
...
...
Queue to Thread Pool 9
Waiting for Thread Pool to drain
 98 0 :
HashCount.Count==0, Thread.CurrentThread.GetHashCode()==98
 100 1 :
HashCount.Count==1, Thread.CurrentThread.GetHashCode()==100
 98 2 :
...
...
Setting eventX
Thread Pool has been drained (Event fired)

Load across threads
101 2
100 3
98 4
102 1
```

Example 4: Using the Mutex object

You can use a mutex object to protect a shared resource from simultaneous access by multiple threads or processes. The state of a mutex object is either set to signaled, when it is not owned by any thread, or nonsignaled, when it is owned. Only one thread at a time can own a mutex object. For example, to prevent two threads from writing to shared memory at the same time, each thread waits for ownership of a mutex object before executing the code that accesses the memory. After writing to the shared memory, the thread releases the mutex object.

This example demonstrates how to use the classes **Mutex**, **AutoResetEvent**, and **WaitHandle** in processing threads. It also demonstrates the methods used in processing the mutex object.

```
// Mutex.cs
// Mutex object example
using System;
using System.Threading;

public class MutexSample
{
   static Mutex gM1;
   static Mutex gM2;
   const int ITERS = 100;
   static AutoResetEvent Event1 = new AutoResetEvent(false);
   static AutoResetEvent Event2 = new AutoResetEvent(false);
   static AutoResetEvent Event3 = new AutoResetEvent(false);
   static AutoResetEvent Event4 = new AutoResetEvent(false);

   public static void Main(String[] args)
   {
      Console.WriteLine("Mutex Sample ...");
      // Create Mutex initialOwned, with name of "MyMutex".
      gM1 = new Mutex(true,"MyMutex");
      // Create Mutex initialOwned, with no name.
      gM2 = new Mutex(true);
      Console.WriteLine(" - Main Owns gM1 and gM2");

      AutoResetEvent[] evs = new AutoResetEvent[4];
      evs[0] = Event1;    // Event for t1
      evs[1] = Event2;    // Event for t2
      evs[2] = Event3;    // Event for t3
      evs[3] = Event4;    // Event for t4

      MutexSample tm = new MutexSample( );
      Thread t1 = new Thread(new ThreadStart(tm.t1Start));
      Thread t2 = new Thread(new ThreadStart(tm.t2Start));
      Thread t3 = new Thread(new ThreadStart(tm.t3Start));
      Thread t4 = new Thread(new ThreadStart(tm.t4Start));
      t1.Start( );   // Does Mutex.WaitAll(Mutex[] of gM1 and gM2)
      t2.Start( );   // Does Mutex.WaitOne(Mutex gM1)
      t3.Start( );   // Does Mutex.WaitAny(Mutex[] of gM1 and gM2)
      t4.Start( );   // Does Mutex.WaitOne(Mutex gM2)

      Thread.Sleep(2000);
      Console.WriteLine(" - Main releases gM1");
      gM1.ReleaseMutex( );  // t2 and t3 will end and signal

      Thread.Sleep(1000);
      Console.WriteLine(" - Main releases gM2");
      gM2.ReleaseMutex( );  // t1 and t4 will end and signal

      // Waiting until all four threads signal that they are done.
      WaitHandle.WaitAll(evs);
      Console.WriteLine("... Mutex Sample");
   }

   public void t1Start( )
   {
      Console.WriteLine("t1Start started,  Mutex.WaitAll(Mutex[])");
```

```
        Mutex[] gMs = new Mutex[2];
        gMs[0] = gM1;  // Create and load an array of Mutex for WaitAll call
        gMs[1] = gM2;
        Mutex.WaitAll(gMs);  // Waits until both gM1 and gM2 are released
        Thread.Sleep(2000);
        Console.WriteLine("t1Start finished, Mutex.WaitAll(Mutex[]) satisfied");
        Event1.Set( );      // AutoResetEvent.Set() flagging method is done
    }

    public void t2Start( )
    {
        Console.WriteLine("t2Start started,  gM1.WaitOne( )");
        gM1.WaitOne( );    // Waits until Mutex gM1 is released
        Console.WriteLine("t2Start finished, gM1.WaitOne( ) satisfied");
        Event2.Set( );     // AutoResetEvent.Set() flagging method is done
    }

    public void t3Start( )
    {
        Console.WriteLine("t3Start started,  Mutex.WaitAny(Mutex[])");
        Mutex[] gMs = new Mutex[2];
        gMs[0] = gM1;  // Create and load an array of Mutex for WaitAny call
        gMs[1] = gM2;
        Mutex.WaitAny(gMs);  // Waits until either Mutex is released
        Console.WriteLine("t3Start finished, Mutex.WaitAny(Mutex[])");
        Event3.Set( );       // AutoResetEvent.Set() flagging method is done
    }

    public void t4Start( )
    {
        Console.WriteLine("t4Start started,  gM2.WaitOne( )");
        gM2.WaitOne( );   // Waits until Mutex gM2 is released
        Console.WriteLine("t4Start finished, gM2.WaitOne( )");
        Event4.Set( );    // AutoResetEvent.Set() flagging method is done
    }
}
```

Sample Output

```
Mutex Sample ...
 - Main Owns gM1 and gM2
t1Start started,  Mutex.WaitAll(Mutex[])
t2Start started,  gM1.WaitOne( )
t3Start started,  Mutex.WaitAny(Mutex[])
t4Start started,  gM2.WaitOne( )
 - Main releases gM1
t2Start finished, gM1.WaitOne( ) satisfied
t3Start finished, Mutex.WaitAny(Mutex[])
 - Main releases gM2
t1Start finished, Mutex.WaitAll(Mutex[]) satisfied
t4Start finished, gM2.WaitOne( )
... Mutex Sample
```

Note The output of the example may vary from one machine to another and from one run to another. The speed and operating system of the machine running the sample can affect the output order. In multithread environments, events may not occur in the order that you expect.

Unsafe Code Tutorial

This tutorial demonstrates how to use unsafe code (code using pointers) in C#.

Sample Files

See Unsafe Code Sample to download and build the sample files discussed in this tutorial.

Further Reading

- A. Unsafe code
- unsafe
- fixed Statement

Tutorial

The use of pointers is rarely required in C#, but there are some situations that require them. As examples, using an unsafe context to allow pointers is warranted by the following cases:

- Dealing with existing structures on disk
- Advanced COM or Platform Invoke scenarios that involve structures with pointers in them
- Performance-critical code

The use of unsafe context in other situations is discouraged. Specifically, an unsafe context should not be used to attempt to write C code in C#.

> **Caution** Code written using an unsafe context cannot be verified to be safe, so it will be executed only when the code is fully trusted. In other words, unsafe code cannot be executed in an untrusted environment. For example, you cannot run unsafe code directly from the Internet.

This tutorial includes the following examples:

- Example 1 Uses pointers to copy an array of bytes.
- Example 2 Shows how to call the Windows **ReadFile** function.
- Example 3 Shows how to print the Win32 version of the executable file.

Example 1

The following example uses pointers to copy an array of bytes from `src` to `dst`. Compile the example with the /unsafe option.

```
// fastcopy.cs
// compile with: /unsafe
using System;

class Test
{
    // The unsafe keyword allows pointers to be used within
    // the following method:
    static unsafe void Copy(byte[] src, int srcIndex,
        byte[] dst, int dstIndex, int count)
    {
        if (src == null || srcIndex < 0 ||
            dst == null || dstIndex < 0 || count < 0)
        {
            throw new ArgumentException();
        }
        int srcLen = src.Length;
        int dstLen = dst.Length;
        if (srcLen - srcIndex < count ||
            dstLen - dstIndex < count)
        {
            throw new ArgumentException();
        }
```

```
            // The following fixed statement pins the location of
            // the src and dst objects in memory so that they will
            // not be moved by garbage collection.
            fixed (byte* pSrc = src, pDst = dst)
            {
                  byte* ps = pSrc;
                  byte* pd = pDst;

            // Loop over the count in blocks of 4 bytes, copying an
            // integer (4 bytes) at a time:
            for (int n =0 ; n < count/4 ; n++)
            {
                *((int*)pd) = *((int*)ps);
                pd += 4;
                ps += 4;
            }

            // Complete the copy by moving any bytes that weren't
            // moved in blocks of 4:
            for (int n =0; n < count%4; n++)
            {
                *pd = *ps;
                pd++;
                ps++;
            }
            }
    }

    static void Main(string[] args)
    {
        byte[] a = new byte[100];
        byte[] b = new byte[100];
        for(int i=0; i<100; ++i)
           a[i] = (byte)i;
        Copy(a, 0, b, 0, 100);
        Console.WriteLine("The first 10 elements are:");
        for(int i=0; i<10; ++i)
           Console.Write(b[i] + " ");
        Console.WriteLine("\n");
    }
}
```

Example Output

```
The first 10 elements are:
0 1 2 3 4 5 6 7 8 9
```

Code Discussion

- Notice the use of the **unsafe** keyword, which allows pointers to be used within the `Copy` method.
- The **fixed** statement is used to declare pointers to the source and destination arrays. It pins the location of the `src` and `dst` objects in memory so that they will not be moved by garbage collection. The objects will be unpinned when the **fixed** block completes
- Unsafe code increases the performance by getting rid of array bounds checks.

Example 2

This example shows how to call the Windows **ReadFile** function from the *Platform SDK*, which requires the use of an unsafe context because the read buffer requires a pointer as a parameter.

```
// readfile.cs
```

```
// compile with: /unsafe
// arguments: readfile.cs

// Use the program to read and display a text file.
using System;
using System.Runtime.InteropServices;
using System.Text;

class FileReader
{
      const uint GENERIC_READ = 0x80000000;
      const uint OPEN_EXISTING = 3;
      IntPtr handle;

      [DllImport("kernel32", SetLastError=true)]
      static extern unsafe IntPtr CreateFile(
            string FileName,                    // file name
            uint DesiredAccess,                 // access mode
            uint ShareMode,                     // share mode
            uint SecurityAttributes,            // Security Attributes
            uint CreationDisposition,           // how to create
            uint FlagsAndAttributes,            // file attributes
            int hTemplateFile                   // handle to template file
            );

       [DllImport("kernel32", SetLastError=true)]
      static extern unsafe bool ReadFile(
            IntPtr hFile,                       // handle to file
            void* pBuffer,                      // data buffer
            int NumberOfBytesToRead,            // number of bytes to read
            int* pNumberOfBytesRead,            // number of bytes read
            int Overlapped                      // overlapped buffer
            );

      [DllImport("kernel32", SetLastError=true)]
      static extern unsafe bool CloseHandle(
            IntPtr hObject   // handle to object
            );

      public bool Open(string FileName)
      {
            // open the existing file for reading
            handle = CreateFile(
                  FileName,
                  GENERIC_READ,
                  0,
                  0,
                  OPEN_EXISTING,
                  0,
                  0);

            if (handle != IntPtr.Zero)
                  return true;
            else
                  return false;
      }

      public unsafe int Read(byte[] buffer, int index, int count)
      {
            int n = 0;
            fixed (byte* p = buffer)
            {
                  if (!ReadFile(handle, p + index, count, &n, 0))
                        return 0;
            }
            return n;
      }
```

```
        public bool Close()
        {
                // close file handle
                return CloseHandle(handle);
        }
}

class Test
{
        public static int Main(string[] args)
        {
                if (args.Length != 1)
                {
                        Console.WriteLine("Usage : ReadFile <FileName>");
                        return 1;
                }

                if (! System.IO.File.Exists(args[0]))
                {
                        Console.WriteLine("File " + args[0] + " not found.");
                        return 1;
                }

                byte[] buffer = new byte[128];
                FileReader fr = new FileReader();

                if (fr.Open(args[0]))
                {

                        // Assume that an ASCII file is being read
                        ASCIIEncoding Encoding = new ASCIIEncoding();

                        int bytesRead;
                        do
                        {
                                bytesRead = fr.Read(buffer, 0, buffer.Length);
                                string content = Encoding.GetString(buffer,0,bytesRead);
                                Console.Write("{0}", content);
                        }
                        while ( bytesRead > 0);

                        fr.Close();
                        return 0;
                }
                else
                {
                        Console.WriteLine("Failed to open requested file");
                        return 1;
                }
        }
}
```

Example Input

The following input from readfile.txt produces the output shown in Example Output when you compile and run this sample.

```
line 1
line 2
```

Example Output

```
line 1
line 2
```

Code Discussion

The byte array passed into the **Read** function is a managed type. This means that the common language runtime garbage collector could relocate the memory used by the array at will. The **fixed** statement allows you to both get a pointer to the memory used by the byte array and to mark the instance so that the garbage collector won't move it.

At the end of the **fixed** block, the instance will be marked so that it can be moved. This capability is known as declarative pinning. The nice part about pinning is that there is very little overhead unless a garbage collection occurs in the **fixed** block, which is an unlikely occurrence.

Example 3

This example reads and displays the Win32 version number of the executable file, which is the same as the assembly version number in this example. The executable file, in this example, is printversion.exe. The example uses the *Platform SDK* functions VerQueryValue, GetFileVersionInfoSize, and GetFileVersionInfo to retrieve specified version information from the specified version-information resource.

This example uses pointers because it simplifies the use of methods whose signatures use pointers to pointers, which are common in the Win32 APIs.

```
// printversion.cs
// compile with: /unsafe
using System;
using System.Reflection;
using System.Runtime.InteropServices;

// Give this assembly a version number:
[assembly:AssemblyVersion("4.3.2.1")]

public class Win32Imports
{
      [DllImport("version.dll")]
      public static extern bool GetFileVersionInfo (string sFileName,
            int handle, int size, byte[] infoBuffer);
      [DllImport("version.dll")]
      public static extern int GetFileVersionInfoSize (string sFileName,
            out int handle);

      // The third parameter - "out string pValue" - is automatically
      // marshaled from ANSI to Unicode:
      [DllImport("version.dll")]
      unsafe public static extern bool VerQueryValue (byte[] pBlock,
            string pSubBlock, out string pValue, out uint len);
      // This VerQueryValue overload is marked with 'unsafe' because
      // it uses a short*:
      [DllImport("version.dll")]
      unsafe public static extern bool VerQueryValue (byte[] pBlock,
            string pSubBlock, out short *pValue, out uint len);
}

public class C
{
      // Main is marked with 'unsafe' because it uses pointers:
      unsafe public static int Main ()
      {
            try
            {
                  int handle = 0;
                  // Figure out how much version info there is:
                  int size =
                        Win32Imports.GetFileVersionInfoSize("printversion.exe",
                        out handle);

                  if (size == 0) return -1;

                  byte[] buffer = new byte[size];
```

```
                    if (!Win32Imports.GetFileVersionInfo("printversion.exe", handle, size, buff
er))
                    {
                          Console.WriteLine("Failed to query file version information.");
                          return 1;
                    }

                    short *subBlock = null;
                    uint len = 0;
                    // Get the locale info from the version info:
                    if (!Win32Imports.VerQueryValue (buffer, @"\VarFileInfo\Translation", out s
ubBlock, out len))
                    {
                          Console.WriteLine("Failed to query version information.");
                          return 1;
                    }

                    string spv = @"\StringFileInfo\" + subBlock[0].ToString("X4") + subBlock[1]
.ToString("X4") + @"\ProductVersion";

                    byte *pVersion = null;
                    // Get the ProductVersion value for this program:
                    string versionInfo;

                    if (!Win32Imports.VerQueryValue (buffer, spv, out versionInfo, out len))
                    {
                          Console.WriteLine("Failed to query version information.");
                          return 1;
                    }

                   Console.WriteLine ("ProductVersion == {0}", versionInfo);
              }
              catch (Exception e)
              {
                    Console.WriteLine ("Caught unexpected exception " + e.Message);
              }

              return 0;
        }
}
```

Example Output

```
ProductVersion == 4.3.2.1
```

OLE DB Tutorial

OLE DB is a COM-based application programming interface (API) for accessing data. OLE DB supports accessing data stored in any format (databases, spreadsheets, text files, and so on) for which an OLE DB provider is available. Each OLE DB provider exposes data from a particular type of data source (for example SQL Server databases, Microsoft Access databases, or Microsoft Excel spreadsheets).

This tutorial demonstrates using a Microsoft Access database from a C# application.

Sample Files

See OLE DB Sample to download and build the sample files discussed in this tutorial.

- Choosing Tools and Technologies

Tutorial

This tutorial demonstrates how to use a Microsoft Access database from C#. It shows how you can create a dataset and add tables to it from a database. The BugTypes.mdb database used in the sample program is a Microsoft Access 2000 .MDB file.

Example

This program accesses the BugTypes.mdb database, creates a dataset, adds the tables to it, and displays the number of tables, columns, and rows. It also displays the titles of each row.

```
// OleDbSample.cs
using System;
using System.Data;
using System.Data.OleDb;
using System.Xml.Serialization;

public class MainClass {
    public static void Main ()
    {
            // Set Access connection and select strings.
            // The path to BugTypes.MDB must be changed if you build
            // the sample from the command line:
#if USINGPROJECTSYSTEM
            string strAccessConn = "Provider=Microsoft.Jet.OLEDB.4.0;Data Source=..\\..\\BugT
ypes.MDB";
#else
            string strAccessConn = "Provider=Microsoft.Jet.OLEDB.4.0;Data Source=BugTypes.MDB
";
#endif
            string strAccessSelect = "SELECT * FROM Categories";

            // Create the dataset and add the Categories table to it:
            DataSet myDataSet = new DataSet();
            OleDbConnection myAccessConn = null;
            try
            {
                  myAccessConn = new OleDbConnection(strAccessConn);
            }
            catch(Exception ex)
            {
                  Console.WriteLine("Error: Failed to create a database connection. \n{0}", e
```

```
x.Message);
                return;
            }

            try
            {

                OleDbCommand myAccessCommand = new OleDbCommand(strAccessSelect,myAccessCon
n);
                OleDbDataAdapter myDataAdapter = new OleDbDataAdapter(myAccessCommand);

                myAccessConn.Open();
                myDataAdapter.Fill(myDataSet,"Categories");

            }
            catch (Exception ex)
            {
                Console.WriteLine("Error: Failed to retrieve the required data from the Dat
aBase.\n{0}", ex.Message);
                return;
            }
            finally
            {
                myAccessConn.Close();
            }

            // A dataset can contain multiple tables, so let's get them
            // all into an array:
            DataTableCollection dta = myDataSet.Tables;
            foreach (DataTable dt in dta)
            {
            Console.WriteLine("Found data table {0}", dt.TableName);
            }

            // The next two lines show two different ways you can get the
            // count of tables in a dataset:
            Console.WriteLine("{0} tables in data set", myDataSet.Tables.Count);
            Console.WriteLine("{0} tables in data set", dta.Count);
            // The next several lines show how to get information on
            // a specific table by name from the dataset:
            Console.WriteLine("{0} rows in Categories table", myDataSet.Tables["Categories"].
Rows.Count);
            // The column info is automatically fetched from the database,
            // so we can read it here:
            Console.WriteLine("{0} columns in Categories table", myDataSet.Tables["Categories
"].Columns.Count);
            DataColumnCollection drc = myDataSet.Tables["Categories"].Columns;
            int i = 0;
            foreach (DataColumn dc in drc)
            {
                // Print the column subscript, then the column's name
                // and its data type:
                Console.WriteLine("Column name[{0}] is {1}, of type {2}",i++ , dc.ColumnNam
e, dc.DataType);
            }
            DataRowCollection dra = myDataSet.Tables["Categories"].Rows;
            foreach (DataRow dr in dra)
            {
                // Print the CategoryID as a subscript, then the CategoryName:
                Console.WriteLine("CategoryName[{0}] is {1}", dr[0], dr[1]);
            }

    }
}
```

Output

The `Categories` table of the BugTypes.mdb database contains the following information.

Category ID	Category Name
1	Bugbash Stuff
2	Appweek Bugs
3	.NET Framework Reports
4	Internal Support

When you run the sample, the following output will be displayed on the screen:

```
Found data table Categories
1 tables in data set
1 tables in data set
4 rows in Categories table
2 columns in Categories table
Column name[0] is CategoryID, of type System.Int32
Column name[1] is CategoryName, of type System.String
CategoryName[1] is Bugbash Stuff
CategoryName[2] is Appweek Bugs
CategoryName[3] is .NET Framework Reports
CategoryName[4] is Internal Support
```

C# Keywords

Keywords are predefined reserved identifiers that have special meanings to the compiler. They cannot be used as identifiers in your program unless they include `@` as a prefix. For example, `@if` is a legal identifier but `if` is not because it is a keyword.

abstract	event	new	struct
as	explicit	null	switch
base	extern	object	this
bool	false	operator	throw
break	finally	out	true
byte	fixed	override	try
case	float	params	typeof
catch	for	private	uint
char	foreach	protected	ulong
checked	goto	public	unchecked
class	if	readonly	unsafe
const	implicit	ref	ushort
continue	in	return	using
decimal	int	sbyte	virtual
default	interface	sealed	volatile
delegate	internal	short	void
do	is	sizeof	while
double	lock	stackalloc	
else	long	static	
enum	namespace	string

Types

The C# typing system contains the following categories:

- Value types
- Reference types
- A.2 Pointer types

Variables of the value types store data, while those of the reference types store references to the actual data. Reference types are also referred to as objects. Pointer types can be used only in unsafe mode.

It is possible to convert a value type to a reference type and vice versa, by using boxing and unboxing.

This section also introduces the void type.

See Also

C# Keywords | Types Reference Tables

Value Types

The value types consist of two main categories:

- Struct type
- Enumeration type

The struct types contain the user-defined struct types and the following built-in simple types:

- Numeric types
    - Integral types
    - Floating-point types
    - decimal
- bool

In addition to explaining each category of the value types, the following topics are discussed in this section:

- Main Features of Value Types
- Main Features of Simple Types
- Initializing Value Types

Main Features of Value Types

A variable of a value type always contains a value of that type. The assignment to a variable of a value type creates a copy of the assigned value, while the assignment to a variable of a reference type creates a copy of the reference but not of the referenced object.

All value types are derived implicitly from the Object class.

Unlike reference types, it is not possible to derive a new type from a value type. However, like reference types, structs can implement interfaces.

Unlike reference types, it is not possible for a value type to contain the **null** value.

Each value type has an implicit default constructor that initializes the default value of that type. For information on default values of value types, see Default Values Table.

Main Features of Simple Types

All of the simple types are aliases of the .NET Framework System types. For example, **int** is an alias of **System.Int32**. For a complete list of aliases, see Built-in Types Table.

Constant expressions, whose operands are all simple type constants, are evaluated at compilation time. For more information, see 7.15 Constant expressions.

Simple types can be initialized using literals. For example, 'A' is a literal of the type **char** and 2001 is a literal of the type **int**.

Initializing Value Types

Local variables in C# must be initialized before being used. Therefore, if you declare a local variable without initialization like this:

```
int myInt;
```

you cannot use it before you initialize it. You can initialize it using the following statement:

```
myInt = new int();  // Invoke the default constructor for the type int
```

which is equivalent to:

```
myInt = 0;          // Assign an initial value, 0 in this example
```

You can, of course, have the declaration and the initialization in the same statement like this:

```
int myInt = new int();
```

–or–

```
int myInt = 0;
```

Using the **new** operator calls the default constructor of the specific type and assigns the default value to the variable. In the preceding example, the default constructor assigned the value `0` to `myInt`. For more information on values assigned by calling default constructors, see Default Values Table.

With user-defined types, use **new** to invoke the default constructor. For example, the following statement invokes the default constructor of the `Point` struct:

```
Point p = new Point();   // Invoke the default constructor for the struct
```

After this call, the struct is considered to be definitely assigned; that is, all of its members are initialized to their default values. For more information, see 5.3 Definite assignment.

For more information on the new operator, see new.

For information on formatting the output of numeric types, see Formatting Numeric Results Table.

C# Keywords | Types | Types Reference Tables | Reference Types

bool

The **bool** keyword is an alias of **System.Boolean**. It is used to declare variables to store the Boolean values, true and false.

Literals

You can assign a Boolean value to a **bool** variable, for example:

```
bool MyVar = true;
```

You can also assign an expression that evaluates to **bool** to a **bool** variable, for example:

```
bool Alphabetic = (c > 64 && c < 123);
```

Conversions

In C++, a value of type **bool** can be converted to a value of type **int**; in other words, **false** is equivalent to zero and **true** is equivalent to nonzero values. In C#, there is no conversion between the **bool** type and other types. For example, the following **if** statement is invalid in C#, while it is legal in C++:

```
int x = 123;
if (x)   // Invalid in C#
{
   printf("The value of x is nonzero.");
}
```

To test a variable of the type **int**, you have to explicitly compare it to a value (for example, zero), that is:

```
int x = 123;
if (x != 0)   // The C# way
{
   Console.Write("The value of x is nonzero.");
}
```

Example

In this example, you enter a character from the keyboard and the program checks if the input character is a letter. If so, it checks if it is lowercase or uppercase. In each case, the proper message is displayed.

```
// keyword_bool.cs
// Character Tester
using System;
public class BoolTest
{
   public static void Main()
   {
      Console.Write("Enter a character: ");
      char c = (char) Console.Read();

      if (Char.IsLetter(c))
         if (Char.IsLower(c))
            Console.WriteLine("The character is lowercase.");
         else
            Console.WriteLine("The character is uppercase.");
      else
         Console.WriteLine("The character is not an alphabetic character.");
   }
}
```

Input

```
X
```

Sample Output

```
Enter a character: X
The character is uppercase.
```

Additional sample runs might look as follow:

```
Enter a character: x
The character is lowercase.

Enter a character: 2
The character is not an alphabetic character.
```

C# Keywords | Default Values Table | Built-in Types Table | Operator Overloading Tutorial

byte

The **byte** keyword denotes an integral type that stores values as indicated in the following table.

Type	Range	Size	.NET Framework type
byte	0 to 255	Unsigned 8-bit integer	**System.Byte**

Literals

You can declare and initialize a **byte** variable like this example:

```
byte myByte = 255;
```

In the preceding declaration, the integer literal `255` is implicitly converted from **int** to **byte**. If the integer literal exceeds the range of **byte**, a compilation error will occur.

Conversions

There is a predefined implicit conversion from **byte** to **short**, **ushort**, **int**, **uint**, **long**, **ulong**, **float**, **double**, or **decimal**.

You cannot implicitly convert nonliteral numeric types of larger storage size to **byte** (see Integral Types Table for the storage sizes of integral types). Consider, for example, the following two **byte** variables `x` and `y`:

```
byte x = 10, y = 20;
```

The following assignment statement will produce a compilation error, because the arithmetic expression on the right-hand side of the assignment operator evaluates to **int** by default.

```
byte z = x + y;   // Error: conversion from int to byte
```

To fix this problem, use a cast:

```
byte z = (byte)(x + y);   // OK: explicit conversion
```

It is possible though to use the following statements, where the destination variable has the same storage size or a larger storage size:

```
int x = 10, y = 20;
int m = x + y;
long n = x + y;
```

Also, there is no implicit conversion from floating-point types to **byte**. For example, the following statement generates a compiler error unless an explicit cast is used:

```
byte x = 3.0;         // Error: no implicit conversion from double
byte y = (byte)3.0;   // OK: explicit conversion
```

When calling overloaded methods, a cast must be used. Consider, for example, the following overloaded methods that use **byte** and **int** parameters:

```
public static void MyMethod(int i) {}
public static void MyMethod(byte b) {}
```

Using the **byte** cast guarantees that the correct type is called, for example:

```
MyMethod(5);        // Calling the method with the int parameter
```

```
MyMethod((byte)5);  // Calling the method with the byte parameter
```

For information on arithmetic expressions with mixed floating-point types and integral types, see float and double.

For more information on implicit numeric conversion rules, see the Implicit Numeric Conversions Table.

C# Keywords | Integral Types Table | Built-in Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | Byte Structure

char

The **char** keyword is used to declare a Unicode character in the range indicated in the following table. Unicode characters are 16-bit characters used to represent most of the known written languages throughout the world.

Type	Range	Size	.NET Framework type
char	U+0000 to U+ffff	Unicode 16-bit character	**System.Char**

Literals

Constants of the **char** type can be written as character literals, hexadecimal escape sequence, or Unicode representation. You can also cast the integral character codes. All of the following statements declare a **char** variable and initialize it with the character `X`:

```
char MyChar = 'X';        // Character literal
char MyChar = '\x0058';   // Hexadecimal
char MyChar = (char)88;   // Cast from integral type
char MyChar = '\u0058';   // Unicode
```

Conversions

A **char** can be implicitly converted to **ushort**, **int**, **uint**, **long**, **ulong**, **float**, **double**, or **decimal**. However, there are no implicit conversions from other types to the **char** type.

See Also

C# Keywords | Integral Types Table | Built-in Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | Char Structure

decimal

The **decimal** keyword denotes a 128-bit data type. Compared to floating-point types, the **decimal** type has a greater precision and a smaller range, which makes it suitable for financial and monetary calculations. The approximate range and precision for the **decimal** type are shown in the following table.

Type	Approximate Range	Precision	.NET Framework type
decimal	$\pm 1.0 \times 10^{-28}$ to $\pm 7.9 \times 10^{28}$	28-29 significant digits	**System.Decimal**

Literals

If you want a numeric real literal to be treated as **decimal**, use the suffix m or M, for example:

```
decimal myMoney = 300.5m;
```

Without the suffix m, the number is treated as a **double**, thus generating a compiler error.

Conversions

The integral types are implicitly converted to **decimal** and the result evaluates to **decimal**. Therefore you can initialize a decimal variable using an integer literal, without the suffix, for example:

```
decimal myMoney = 300;
```

There is no implicit conversion between floating-point types and the **decimal** type; therefore, a cast must be used to convert between these two types. For example:

```
decimal myMoney = 99.9m;
double x = (double) myMoney;
myMoney = (decimal) x;
```

You can also mix **decimal** and numeric integral types in the same expression. However, mixing **decimal** and floating-point types without a cast results in a compilation error.

For more information on implicit numeric conversions, see the Implicit Numeric Conversions Table.

For more information on explicit numeric conversions, see the Explicit Numeric Conversions Table.

Example 1

In this example, a **decimal** and an **int** are mixed in the same expression. The result evaluates to the **decimal** type.

```
// keyword_decimal.cs
// decimal conversion
using System;
public class TestDecimal {
   public static void Main ()
   {
      decimal d = 9.1m;
      int y = 3;
      Console.WriteLine(d + y);   // Result converted to decimal
   }
}
```

Output

```
12.1
```

In the preceding example, if you attempt to add the **double** and **decimal** variables by using a statement like this:

```
Console.WriteLine(d + x);   // error
```

you will get the following error:

```
Operator '+' cannot be applied to operands of type 'double' and 'decimal'
```

Formatting Decimal Output

You can format the results by using the **String.Format** method, or through the **Console.Write** method, which calls **String.Format()**. The currency format is specified using the standard currency format string "C" or "c," as shown in Example 2.

Example 2

In this example, the output is formatted using the currency format string. Notice that `x` is rounded because the decimal places exceed $0.99. The variable `y`, which represents the maximum exact digits, is displayed exactly in the proper format.

```
// keyword_decimal2.cs
// Decimal type formatting
using System;
public class TestDecimalFormat
{
   public static void Main ()
   {
      decimal x = 0.999m;
      decimal y = 9999999999999999999999999999m;
      Console.WriteLine("My amount = {0:C}", x);
      Console.WriteLine("Your amount = {0:C}", y);
   }
}
```

Output

```
My amount = $1.00
Your amount = $9,999,999,999,999,999,999,999,999,999.00
```

For more information on the **String.Format** method, see String.Format Method. For more information on the decimal type precision, see 4.1.6 The decimal type.

C# Keywords | Default Values Table | Built-in Types Table | Floating-Point Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | Decimal Structure

double

The **double** keyword denotes a simple type that stores 64-bit floating-point values. The following table shows the precision and approximate range for the **double** type.

Type	Approximate range	Precision	.NET Framework type
double	$\pm 5.0 \times 10^{-324}$ to $\pm 1.7 \times 10^{308}$	15-16 digits	**System.Double**

Literals

By default, a real numeric literal on the right-hand side of the assignment operator is treated as **double**. However, if you want an integer number to be treated as **double**, use the suffix d or D, for example:

```
double x = 3D;
```

Conversions

You can mix numeric integral types and floating-point types in an expression. In this case, the integral types are converted to floating-point types. The evaluation of the expression is performed according to the following rules:

- If one of the floating-point types is **double**, the expression evaluates to **double** (or **bool** in the case of relational or Boolean expressions).
- If there is no **double** type in the expression, it evaluates to **float** (or **bool** in the case of relational or Boolean expressions).

A floating-point expression can contain the following sets of values:

- Positive and negative zero
- Positive and negative infinity
- Not-a-Number value (NaN)
- The finite set of nonzero values

For more information on these values, refer to IEEE Standard for Binary Floating-Point Arithmetic, available on the Web site http://www.ieee.org/.

For more information on floating-point value sets, see 4.1.5 Floating point types.

Example

In the following example, an **int**, a **short**, a **float**, and a **double** are added together giving a **double** result.

```
// keyword_double.cs
// Mixing types in expressions
using System;
class MixedTypes
{
   public static void Main()
   {
      int x = 3;
      float y = 4.5f;
      short z = 5;
      double w = 1.7E+3;
      Console.WriteLine("The sum is {0}", x + y + z + w);   // double result
   }
}
```

Output

```
The sum is 1712.5
```

See Also

C# Keywords | Default Values Table | Built-in Types Table | Floating-Point Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | Double Structure

enum

The **enum** keyword is used to declare an enumeration, a distinct type consisting of a set of named constants called the enumerator list. Every enumeration type has an underlying type, which can be any integral type except **char**. This declaration takes the following form::

```
[attributes] [modifiers] enum identifier [:base-type] {enumerator-list} [;]
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see 17. Attributes.
modifiers (Optional)
The allowed modifiers are new and the four access modifiers.
identifier
The **enum** name.
base-type (Optional)
The underlying type that specifies the storage allocated for each enumerator. It can be one of the integral types except **char**. The default is **int**.
enumerator-list
The enumerators' identifiers separated by commas, optionally including a value assignment.

Remarks

The default underlying type of the enumeration elements is **int**. By default, the first enumerator has the value 0, and the value of each successive enumerator is increased by 1. For example:

```
enum Days {Sat, Sun, Mon, Tue, Wed, Thu, Fri};
```

In this enumeration, `Sat` is `0`, `Sun` is `1`, `Mon` is `2`, and so forth. Enumerators can have initializers to override the default values. For example:

```
enum Days {Sat=1, Sun, Mon, Tue, Wed, Thu, Fri};
```

In this enumeration, the sequence of elements is forced to start from `1` instead of `0`.

The default value of an **enum** E is the value produced by the expression `(E)0`.

The underlying type specifies how much storage is allocated for each enumerator. However, an explicit cast is needed to convert from **enum** type to an integral type. For example, the following statement assigns the enumerator `Sun` to a variable of the type **int** using a cast to convert from **enum** to **int**:

```
int x = (int) Days.Sun;
```

For more information on enumeration types, see 14. Enums.

Example 1

In this example, an enumeration, `Days`, is declared. Two enumerators are explicitly converted to **int** and assigned to **int** variables.

```
// keyword_enum.cs
// enum initialization:
using System;
public class EnumTest
{
   enum Days {Sat=1, Sun, Mon, Tue, Wed, Thu, Fri};

   public static void Main()
   {
      int x = (int) Days.Sun;
```

```
        int y = (int) Days.Fri;
        Console.WriteLine("Sun = {0}", x);
        Console.WriteLine("Fri = {0}", y);
    }
}
```

Output

```
Sun = 2
Fri = 7
```

Notice that if you remove the initializer from `Sat=1`, the result will be:

```
Sun = 1
Fri = 6
```

Example 2

In this example, the *base-type* option is used to declare an **enum** whose members are of the type **long**. Notice that even though the underlying type of the enumeration is **long**, the enumeration members must still be explicitly converted to type **long** using a cast.

```
// keyword_enum2.cs
// Using long enumerators
using System;
public class EnumTest
{
    enum Range :long {Max = 2147483648L, Min = 255L};
    public static void Main()
    {
        long x = (long) Range.Max;
        long y = (long) Range.Min;
        Console.WriteLine("Max = {0}", x);
        Console.WriteLine("Min = {0}", y);
    }
}
```

Output

```
Max = 2147483648
Min = 255
```

See Also

C# Keywords | Default Values Table | Built-in Types Table | Types | Value Types

float

The **float** keyword denotes a simple type that stores 32-bit floating-point values. The following table shows the precision and approximate range for the **float** type.

Type	Approximate range	Precision	.NET Framework type
float	$\pm 1.5 \times 10^{-45}$ to $\pm 3.4 \times 10^{38}$	7 digits	**System.Single**

Literals

By default, a real numeric literal on the right-hand side of the assignment operator is treated as **double**. Therefore, to initialize a float variable use the suffix `f` or `F`, for example:

```
float x = 3.5F;
```

If you don't use the suffix in the previous declaration, you will get a compilation error because you are attempting to store a **double** value into a **float** variable.

Conversions

You can mix numeric integral types and floating-point types in an expression. In this case, the integral types are converted to floating-point types. The evaluation of the expression is performed according to the following rules:

- If one of the floating-point types is **double**, the expression evaluates to **double** (or **bool** in the case of relational or Boolean expressions).
- If there is no **double** type in the expression, the expression evaluates to **float** (or **bool** in the case of relational or Boolean expressions).

A floating-point expression can contain the following sets of values:

- Positive and negative zero
- Positive and negative infinity
- Not-a-Number value (NaN)
- The finite set of nonzero values

For more information on these values, refer to IEEE Standard for Binary Floating-Point Arithmetic, available on the Web site http://www.ieee.org/.

For more information on floating-point value sets, see 4.1.5 Floating point types.

Example

In the following example, an **int**, a **short**, and a **float** are included in a mathematical expression giving a **float** result (notice that there is no **double** in the expression).

```
// keyword_float.cs
// Mixing types in expressions
using System;
class MixedTypes
{
   public static void Main()
   {
      int x = 3;
      float y = 4.5f;
      short z = 5;
      Console.WriteLine("The result is {0}", x*y/z);
   }
}
```

Output

```
The result is 2.7
```

See Also

C# Keywords | Default Values Table | Built-in Types Table | Floating-Point Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | Single Structure

int

The **int** keyword denotes an integral type that stores values according to the size and range shown in the following table.

Type	Range	Size	.NET Framework type
int	-2,147,483,648 to 2,147,483,647	Signed 32-bit integer	**System.Int32**

Literals

You can declare and initialize a variable of the type **int** like this example:

```
int myInt = 123;
```

When an integer literal has no suffix, its type is the first of these types in which its value can be represented: **int**, **uint**, **long**, **ulong**. In this example, it is of the type **int**.

Conversions

There is a predefined implicit conversion from **int** to **long**, **float**, **double**, or **decimal**. For example:

```
float myFloat = 123;   // OK: implicit conversion to float
```

There is a predefined implicit conversion from **sbyte**, **byte**, **short**, **ushort**, or **char** to **int**. For example, if you have a **long** variable, `myLong`, the following assignment statement will produce a compilation error without a cast:

```
long myLong = 22;
int myInt = myLong;       // Error: no implicit conversion from long
int myInt = (int)myLong;  // OK: explicit conversion
```

Notice also that there is no implicit conversion from floating-point types to **int**. For example, the following statement generates a compiler error unless an explicit cast is used:

```
int x = 3.0;         // Error: no implicit conversion from double
int y = (int)3.0;    // OK: explicit conversion
```

For information on arithmetic expressions with mixed floating-point types and integral types, see float and double.

See Also

C# Keywords | Integral Types Table | Built-in Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | Int32 Structure

long

The **long** keyword denotes an integral type that stores values according to the size and range shown in the following table.

Type	Range	Size	.NET Framework type
long	–9,223,372,036,854,775,808 to 9,223,372,036,854,775,807	Signed 64-bit integer	**System.Int64**

Literals

You can declare and initialize a **long** variable like this example:

```
long myLong = 4294967296;
```

When an integer literal has no suffix, its type is the first of these types in which its value can be represented: **int**, **uint**, **long**, **ulong**. In the preceding example, it is of the type **long** because it exceeds the range of **uint** (see Integral Types Table for the storage sizes of integral types).

You can also use the suffix L with the **long** type like this:

```
long myLong = 4294967296L;
```

When you use the suffix L, the type of the literal integer is determined to be either **long** or **ulong** according to its size. In the case it is **long** because it less than the range of **ulong**.

A common use of the suffix is with calling overloaded methods. Consider, for example, the following overloaded methods that use **long** and **int** parameters:

```
public static void MyMethod(int i) {}
public static void MyMethod(long l) {}
```

Using the suffix L guarantees that the correct type is called, for example:

```
MyMethod(5);    // Calling the method with the int parameter
MyMethod(5L);   // Calling the method with the long parameter
```

You can use the **long** type with other numeric integral types in the same expression, in which case the expression is evaluated as **long** (or **bool** in the case of relational or Boolean expressions). For example, the following expression evaluates as **long**:

```
898L + 88
```

> **Note** You can also use the lowercase letter "l" as a suffix. However, this generates a compiler warning because the letter "l" is easily confused with the digit "1." Use "L" for clarity.

For information on arithmetic expressions with mixed floating-point types and integral types, see float and double.

Conversions

There is a predefined implicit conversion from **long** to **float**, **double**, or **decimal**. Otherwise a cast must be used. For example, the following statement will produce a compilation error without an explicit cast:

```
int x = 8L;        // Error: no implicit conversion from long to int
int x = (int)8L;   // OK: explicit conversion to int
```

There is a predefined implicit conversion from **sbyte**, **byte**, **short**, **ushort**, **int**, **uint**, or **char** to **long**.

Notice also that there is no implicit conversion from floating-point types to **long**. For example, the following statement generates a compiler error unless an explicit cast is used:

```
long x = 3.0;         // Error: no implicit conversion from double
long y = (long)3.0;   // OK: explicit conversion
```

See Also

C# Keywords | Integral Types Table | Built-in Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | Int64 Structure

sbyte

The **sbyte** keyword denotes an integral type that stores values according to the size and range shown in the following table.

Type	Range	Size	.NET Framework type
sbyte	-128 to 127	Signed 8-bit integer	**System.SByte**

Literals

You can declare and initialize an **sbyte** variable like this example:

```
sbyte mySbyte = 127;
```

In the preceding declaration, the integer literal 127 is implicitly converted from **int** to **sbyte**. If the integer literal exceeds the range of **sbyte**, a compilation error will occur.

A cast must be used when calling overloaded methods. Consider, for example, the following overloaded methods that use **sbyte** and **int** parameters:

```
public static void MyMethod(int i) {}
public static void MyMethod(sbyte b) {}
```

Using the **sbyte** cast guarantees that the correct type is called, for example:

```
MyMethod(5);         // Calling the method with the int parameter
MyMethod((sbyte)5);  // Calling the method with the sbyte parameter
```

Conversions

There is a predefined implicit conversion from **sbyte** to **short**, **int**, **long**, **float**, **double**, or **decimal**.

You cannot implicitly convert nonliteral numeric types of larger storage size to **sbyte** (see Integral Types Table for the storage sizes of integral types). Consider, for example, the following two **sbyte** variables `x` and `y`:

```
sbyte x = 10, y = 20;
```

The following assignment statement will produce a compilation error, because the arithmetic expression on the right-hand side of the assignment operator evaluates to **int** by default.

```
sbyte z = x + y;   // Error: conversion from int to sbyte
```

To fix this problem, use a cast:

```
sbyte z = (byte)(x + y);   // OK: explicit conversion
```

It is possible though to use the following statements, where the destination variable has the same storage size or a larger storage size:

```
sbyte x = 10, y = 20;
int m = x + y;
long n = x + y;
```

Notice also that there is no implicit conversion from floating-point types to **sbyte**. For example, the following statement generates a compiler error unless an explicit cast is used:

```
sbyte x = 3.0;         // Error: no implicit conversion from double
sbyte y = (sbyte)3.0;  // OK: explicit conversion
```

For information on arithmetic expressions with mixed floating-point types and integral types, see float and double.

For more information on implicit numeric conversion rules, see the Implicit Numeric Conversions Table.

See Also

C# Keywords | Integral Types Table | Built-in Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | SByte Structure

short

The **short** keyword denotes an integral data type that stores values according to the size and range shown in the following table.

Type	Range	Size	.NET Framework type
short	-32,768 to 32,767	Signed 16-bit integer	**System.Int16**

Literals

You can declare and initialize a **short** variable like this example:

```
short x = 32767;
```

In the preceding declaration, the integer literal `32767` is implicitly converted from **int** to **short**. If the integer literal does not fit into a **short** storage location, a compilation error will occur.

A cast must be used when calling overloaded methods. Consider, for example, the following overloaded methods that use **short** and **int** parameters:

```
public static void MyMethod(int i) {}
public static void MyMethod(short s) {}
```

Using the **short** cast guarantees that the correct type is called, for example:

```
MyMethod(5);         // Calling the method with the int parameter
MyMethod((short)5);  // Calling the method with the short parameter
```

Conversions

There is a predefined implicit conversion from **short** to **int**, **long**, **float**, **double**, or **decimal**.

You cannot implicitly convert nonliteral numeric types of larger storage size to **short** (see Integral Types Table for the storage sizes of integral types). Consider, for example, the following two **short** variables `x` and `y`:

```
short x = 5, y = 12;
```

The following assignment statement will produce a compilation error, because the arithmetic expression on the right-hand side of the assignment operator evaluates to **int** by default.

```
short z = x + y;   // Error: no conversion from int to short
```

To fix this problem, use a cast:

```
short z = (short)(x + y);   // OK: explicit conversion
```

It is possible though to use the following statements, where the destination variable has the same storage size or a larger storage size:

```
int m = x + y;
long n = x + y;
```

There is no implicit conversion from floating-point types to **short**. For example, the following statement generates a compiler error unless an explicit cast is used:

```
short x = 3.0;          // Error: no implicit conversion from double
short y = (short)3.0;   // OK: explicit conversion
```

For information on arithmetic expressions with mixed floating-point types and integral types, see float and double.

For more information on implicit numeric conversion rules, see the Implicit Numeric Conversions Table.

C# Keywords | Integral Types Table | Built-in Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | Int16 Structure

struct

A **struct** type is a value type that can contain constructors, constants, fields, methods, properties, indexers, operators, events, and nested types. The declaration of a **struct** takes the following form:

```
[attributes] [modifiers] struct identifier [:interfaces] body [;]
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see 17. Attributes.
modifiers (Optional)
The allowed modifiers are new and the four access modifiers.
identifier
The **struct** name.
interfaces (Optional)
A list that contains the interfaces implemented by the struct, all separated by commas.
body
The struct body that contains member declarations.

Remarks

The **struct** type is suitable for representing lightweight objects such as Point, Rectangle, and Color. Although it is possible to represent a point as a class, a struct is more efficient in some scenarios. For example, if you declare an array of 1000 Point objects, you will allocate additional memory for referencing each object. In this case, the struct is less expensive.

It is an error to declare a default (parameterless) constructor for a struct. A default constructor is always provided to initialize the struct members to their default values.

It is an error to initialize an instance field in a struct.

When you create a struct object using the **new** operator, it gets created and the appropriate constructor is called. Unlike classes, structs can be instantiated without using the **new** operator. If you do not use **new**, the fields will remain unassigned and the object cannot be used until all of the fields are initialized.

There is no inheritance for structs as there is for classes. A struct cannot inherit from another struct or class, and it cannot be the base of a class. Structs, however, inherit from the base class **Object**. A struct can implement interfaces, and it does that exactly as classes do.

Unlike C++, you cannot declare a class using the keyword **struct**. In C#, classes and structs are semantically different. A struct is a value type, while a class is a reference type. For more information on the features of value types, see Value Types.

Unless you need reference type semantics, a class that is smaller than 16 bytes may be more efficiently handled by the system as a struct.

For more information on structs, see 11. Structs and the Structs Tutorial.

In Managed Extensions for C++, the equivalents to a C# class and a C# struct are as follows:

C#	Managed Extensions for C++	For more information
class	__gc struct or __gc class	__gc keyword
struct	__value struct or __value class	__value keyword

Example 1

This example demonstrates **struct** initialization using both default and parameterized constructors.

```
// keyword_struct.cs
// struct declaration and initialization
```

```
using System;
public struct Point
{
   public int x, y;

   public Point(int p1, int p2)
   {
      x = p1;
      y = p2;
   }
}

class MainClass
{
   public static void Main()
   {
      // Initialize:
      Point myPoint = new Point();
      Point yourPoint = new Point(10,10);

      // Display results:
      Console.Write("My Point:   ");
      Console.WriteLine("x = {0}, y = {1}", myPoint.x, myPoint.y);
      Console.Write("Your Point: ");
      Console.WriteLine("x = {0}, y = {1}", yourPoint.x, yourPoint.y);
   }
}
```

Output

```
My Point:   x = 0, y = 0
Your Point: x = 10, y = 10
```

Example 2

This example demonstrates a feature that is unique to structs. It creates a Point object without using the **new** operator. If you replace the word **struct** with the word **class**, the program won't compile.

```
// keyword_struct2.cs
// Declare a struct object without "new"
using System;
public struct Point
{
   public int x, y;

   public Point(int x, int y)
   {
      this.x = x;
      this.y = y;
   }
}

class MainClass
{
   public static void Main()
   {
      // Declare an object:
      Point myPoint;

      // Initialize:
      myPoint.x = 10;
      myPoint.y = 20;

      // Display results:
      Console.WriteLine("My Point:");
```

```
        Console.WriteLine("x = {0}, y = {1}", myPoint.x, myPoint.y);
    }
}
```

Output

```
My Point:
x = 10, y = 20
```

C# Keywords | Structs Tutorial | Default Values Table | Built-in Types Table | Types | Value Types | class | interface

uint

The **uint** keyword denotes an integral type that stores values according to the size and range shown in the following table.

Type	Range	Size	.NET Framework type
uint	0 to 4,294,967,295	Unsigned 32-bit integer	**System.UInt32**

Literals

You can declare and initialize a variable of the type **uint** like this example:

```
uint myUint = 4294967290;
```

When an integer literal has no suffix, its type is the first of these types in which its value can be represented: **int**, **uint**, **long**, **ulong**. In this example, it is **uint**.

You can also use the suffix u or U, like this:

```
uint myUint = 123U;
```

When you use the suffix U or u, the literal type is determined to be either **uint** or **ulong** according to its size. In this example, it is **uint**.

Conversions

There is a predefined implicit conversion from **uint** to **long**, **ulong**, **float**, **double**, or **decimal**. For example:

```
float myFloat = 4294967290;   // OK: implicit conversion to float
```

There is a predefined implicit conversion from **byte**, **ushort**, or **char** to **uint**. Otherwise you must use a cast. For example, if you have a **long** variable, `myLong`, the following assignment statement will produce a compilation error without a cast:

```
long myLong = 22;
uint myUint = myLong;        // Error: no implicit conversion from long
uint myUint = (uint)myLong;  // OK: explicit conversion
```

Notice also that there is no implicit conversion from floating-point types to **uint**. For example, the following statement generates a compiler error unless an explicit cast is used:

```
uint x = 3.0;         // Error: no implicit conversion from double
uint y = (uint)3.0;   // OK: explicit conversion
```

For information on arithmetic expressions with mixed floating-point types and integral types, see float and double.

For more information on implicit numeric conversion rules, see the Implicit Numeric Conversions Table.

See Also

C# Keywords | Integral Types Table | Built-in Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | UInt32 Structure

ulong

The **ulong** keyword denotes an integral type that stores values according to the size and range shown in the following table.

Type	Range	Size	.NET Framework type
ulong	0 to 18,446,744,073,709,551,615	Unsigned 64-bit integer	**System.UInt64**

Literals

You can declare and initialize a **ulong** variable like this example:

```
ulong myUlong = 9223372036854775808;
```

When an integer literal has no suffix, its type is the first of these types in which its value can be represented: **int**, **uint**, **long**, **ulong**. In this example, it is of the type **ulong**.

You can also use suffixes to specify the type of the literal according to the following rules:

- If you use L or l, the type of the literal integer will be either **long** or **ulong** according to its size.

  Note You can use the lowercase letter "l" as a suffix. However, this generates a compiler warning because the letter "l" is easily confused with the digit "1." Use "L" for clarity.

- If you use U or u, the type of the literal integer will be either **uint** or **ulong** according to its size.
- If you use UL, ul, Ul, uL, LU, lu, Lu, or lU, the type of the literal integer will be **ulong**.

  For example, the output of the following three statements will be the system type **UInt64**, which corresponds to the alias **ulong**:

  ```
  Console.WriteLine(9223372036854775808L.GetType());
  Console.WriteLine(123UL.GetType());
  Console.WriteLine((123UL + 456).GetType());
  ```

A common use of the suffix is with calling overloaded methods. Consider, for example, the following overloaded methods that use **ulong** and **int** parameters:

```
public static void MyMethod(int i) {}
public static void MyMethod(ulong l) {}
```

Using a suffix with the **ulong** parameter guarantees that the correct type is called, for example:

```
MyMethod(5);    // Calling the method with the int parameter
MyMethod(5UL);  // Calling the method with the ulong parameter
```

Conversions

There is a predefined implicit conversion from **ulong** to **float**, **double**, or **decimal**.

There is no implicit conversion from **ulong** to any integral type. For example, the following statement will produce a compilation error without an explicit cast:

```
long myLong = 8UL;   // Error: no implicit conversion from ulong
```

There is a predefined implicit conversion from **byte, ushort**, **uint**, or **char** to **ulong**.

Also, there is no implicit conversion from floating-point types to **ulong**. For example, the following statement generates a compiler error unless an explicit cast is used:

```
ulong x = 3.0;         // Error: no implicit conversion from double
```

```
ulong y = (ulong)3.0;  // OK: explicit conversion
```

For information on arithmetic expressions with mixed floating-point types and integral types, see float and double.

For more information on implicit numeric conversion rules, see the Implicit Numeric Conversions Table.

See Also

C# Keywords | Integral Types Table | Built-in Types Table | Implicit Numeric Conversions Table | Explicit Numeric Conversions Table | UInt64 Structure

ushort

The **ushort** keyword denotes an integral data type that stores values according to the size and range shown in the following table.

Type	Range	Size	.NET Framework type
ushort	0 to 65,535	Unsigned 16-bit integer	**System.UInt16**

Literals

You can declare and initialize a **ushort** variable like this example:

```
ushort myShort = 65535;
```

In the preceding declaration, the integer literal `65535` is implicitly converted from **int** to **ushort**. If the integer literal exceeds the range of **ushort**, a compilation error will occur.

A cast must be used when calling overloaded methods. Consider, for example, the following overloaded methods that use **ushort** and **int** parameters:

```
public static void MyMethod(int i) {}
public static void MyMethod(ushort s) {}
```

Using the **ushort** cast guarantees that the correct type is called, for example:

```
MyMethod(5);          // Calling the method with the int parameter
MyMethod((ushort)5);  // Calling the method with the ushort parameter
```

Conversions

There is a predefined implicit conversion from **ushort** to **int**, **uint**, **long**, **ulong**, **float**, **double**, or **decimal**.

There is a predefined implicit conversion from **byte** or **char** to **ushort**. Otherwise a cast must be used to perform an explicit conversion. Consider, for example, the following two **ushort** variables `x` and `y`:

```
ushort x = 5, y = 12;
```

The following assignment statement will produce a compilation error, because the arithmetic expression on the right-hand side of the assignment operator evaluates to **int** by default.

```
ushort z = x + y;   // Error: conversion from int to ushort
```

To fix this problem, use a cast:

```
ushort z = (ushort)(x + y);   // OK: explicit conversion
```

It is possible though to use the following statements, where the destination variable has the same storage size or a larger storage size:

```
int m = x + y;
long n = x + y;
```

Notice also that there is no implicit conversion from floating-point types to **ushort**. For example, the following statement generates a compiler error unless an explicit cast is used:

```
ushort x = 3.0;          // Error: no implicit conversion from double
ushort y = (ushort)3.0;  // OK: explicit conversion
```

For information on arithmetic expressions with mixed floating-point types and integral types, see float and double.

For more information on implicit numeric conversion rules, see the Implicit Numeric Conversions Table.

Boxing and Unboxing

Boxing and unboxing enable value types to be treated as objects. Value types, including both struct types and built-in types, such as **int**, can be converted to and from the type **object**.

See Also

Reference Types | Value Types

Boxing Conversion

Boxing is an implicit conversion of a value type to the type **object** or to any interface type implemented by this value type. Boxing a value of a value allocates an object instance and copies the value into the new object.

Consider the following declaration of a value-type variable:

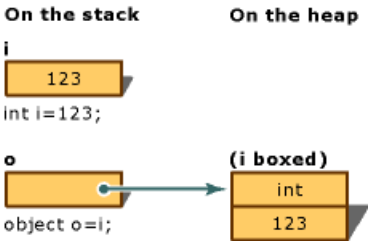
```
int i = 123;
```

The following statement implicitly applies the boxing operation on the variable `i`:

```
object o = i;
```

The result of this statement is creating an object `o`, on the stack, that references a value of the type **int**, on the heap. This value is a copy of the value-type value assigned to the variable `i`. The difference between the two variables, `i` and `o`, is illustrated in the following figure.

Boxing Conversion



It also possible, but never needed, to perform the boxing explicitly as in the following example:

```
int i = 123;
object o = (object) i;
```

Example

This example converts an integer variable `i` to an object `o` via boxing. Then the value stored in the variable `i` is changed from `123` to `456`. The example shows that the object keeps the original copy of the contents, `123`.

```
// boxing.cs
// Boxing an integer variable
using System;
class TestBoxing
{
   public static void Main()
   {
      int i = 123;
      object o = i;  // Implicit boxing
      i = 456;       // Change the contents of i
      Console.WriteLine("The value-type value = {0}", i);
      Console.WriteLine("The object-type value = {0}", o);
   }
}
```

Output

```
The value-type value = 456
The object-type value = 123
```

See Also

Unboxing Conversion

Unboxing is an explicit conversion from the type **object** to a value type or from an interface type to a value type that implements the interface. An unboxing operation consists of:

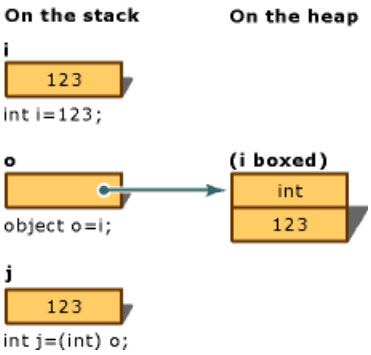
- Checking the object instance to make sure it is a boxed value of the given value type.
- Copying the value from the instance into the value-type variable.

The following statements demonstrate both boxing and unboxing operations:

```
int i = 123;          // A value type
object box = i;       // Boxing
int j = (int)box;     // Unboxing
```

The following figure demonstrates the result of the preceding statements.

Unboxing Conversion



For an unboxing conversion to a given value type to succeed at run time, the value of the source argument must be a reference to an object that was previously created by boxing a value of that value type. If the source argument is **null** or a reference to an incompatible object, an **InvalidCastException** is thrown.

Example

The following example demonstrates a case of invalid unboxing, of how incorrect unboxing leads to InvalidCastException. By using **try** and **catch**, an error message is displayed when the error occurs.

```
using System;
public class UnboxingTest
{
   public static void Main()
   {
      int intI = 123;

      // Boxing
      object o = intI;

      // Reference to incompatible object produces InvalidCastException
      try
      {
         int intJ = (short) o;
         Console.WriteLine("Unboxing OK.");
      }

      catch (InvalidCastException e)
      {
         Console.WriteLine("{0} Error: Incorrect unboxing.",e);
      }
   }
}
```

Output

```
System.InvalidCastException
   at UnboxingTest.Main() Error: Incorrect unboxing.
```

If you change the statement:

```
int intJ = (short) o;
```

to:

```
int intJ = (int) o;
```

the conversion will be performed, and you will get the output `Unboxing OK`.

Boxing and Unboxing | Boxing Conversion

Reference Types

Variables of reference types, referred to as objects, store references to the actual data. This section introduces the following keywords used to declare reference types:

- class
- interface
- delegate

This section also introduces the following built-in reference types:

- object
- string

See Also

C# Keywords | Types | Value Types

class

Classes are declared using the keyword **class**. It takes the following form::

```
[attributes] [modifiers] class identifier [:base-list] { class-body }[;]
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see 17. Attributes.
modifiers (Optional)
The allowed modifiers are new, abstract, sealed, and the four access modifiers.
identifier
The class name.
base-list (Optional)
A list that contains the one base class and any implemented interfaces, all separated by commas.
class-body
Declarations of the class members.

Remarks

Unlike C++, only single inheritance is allowed in C#. In other words, a class can inherit implementation from one base class only. However, a class can implement more that one interface. The following table shows examples of class inheritance and interface implementation:

Inheritance	Example
None	`class ClassA { }`
Single	`class DerivedClass: BaseClass { }`
None, implements two interfaces	`class ImplClass: IFace1, IFace2 { }`
Single, implements one interface	`class ImplDerivedClass: BaseClass, IFace1 { }`

The access levels protected and private are only allowed on nested classes.

A class can contain declarations of the following members:

- Constructors (see Constructors and Destructors, 10.10 Instance constructors)
- Destructors (see Destructors, 10.12 Destructors)
- Constants (see 10.3 Constants)
- Fields (see 10.4 Fields)
- Methods (see 10.5 Methods)
- Properties (see Properties, 10.6 Properties)
- Indexers (see Indexers, 10.8 Indexers)
- Operators (see C# Operators, 10.9 Operators)
- Events (see event, 10.7 Events)
- Delegates (see delegate, 15. Delegates)
- Classes (see 10. Classes)
- Interfaces (see interface, 13. Interfaces)
- Structs (see struct, 11. Structs)

In Managed Extensions for C++, the equivalents to a C# class and a C# struct are as follows:

C#	Managed Extensions for C++	For more information
class	__gc struct or __gc class	__gc keyword
struct	__value struct or __value class	__value keyword

Example

The following example demonstrates declaring class fields, constructors, and methods. It also demonstrates object instantiation and printing instance data. In this example, two classes are declared, the `Kid` class, which contains two private fields (`name` and `age`) and two public methods. The second class is `MainClass`, used for data processing.

```
// keyword_class.cs
// class example
using System;
public class Kid
{
   private int age;
   private string name;

   // Default constructor:
   public Kid()
   {
      name = "N/A";
   }

   // Constructor:
   public Kid(string name, int age)
   {
      this.name = name;
      this.age = age;
   }

   // Printing method:
   public void PrintKid()
   {
      Console.WriteLine("{0}, {1} years old.", name, age);
   }
}

public class MainClass
{
   public static void Main()
   {
      // Create objects
      // Objects must be created using the new operator:
      Kid kid1 = new Kid("Craig", 11);
      Kid kid2 = new Kid("Sally", 10);

      // Create an object using the default constructor:
      Kid kid3 = new Kid();

      // Display results:
      Console.Write("Kid #1: ");
      kid1.PrintKid();
      Console.Write("Kid #2: ");
      kid2.PrintKid();
      Console.Write("Kid #3: ");
      kid3.PrintKid();
   }
}
```

Output

```
Kid #1: Craig, 11 years old.
Kid #2: Sally, 10 years old.
Kid #3: N/A, 0 years old.
```

Notice, in the preceding example, that the private fields (`name` and `age`) can only be accessed through the public methods of the `Kid` class. For example, you cannot print the kid's name, from the `Main` method, using a statement like this:

```
Console.Write(kid1.name);   // Error
```

However, it is possible to do that if the `Main` method is a member of the `Kid` class.

Notice also that the **private** modifier is the default modifier for class members. If you remove the modifier, you still get private members. For more information on access level modifiers, see Access Modifiers.

Notice also that for the object created using the default constructor (`kid3`), the age field was initialized to zero.

For more information on classes, see 10. Classes.

See Also

C# Keywords | Reference Types | C. Grammar | interface | struct

delegate

A **delegate** declaration defines a reference type that can be used to encapsulate a method with a specific signature. A delegate instance encapsulates a static or an instance method. Delegates are roughly similar to function pointers in C++; however, delegates are type-safe and secure.

This declaration takes the following form::

```
[attributes] [modifiers] delegate result-type identifier ([formal-parameters]);
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see 17. Attributes.
modifiers (Optional)
The allowed modifiers are new and the four access modifiers.
result-type
The result type, which matches the return type of the method.
identifier
The delegate name.
formal-parameters (Optional)
Parameter list. If a parameter is a pointer, the delegate must be declared with the unsafe modifier.

Remarks

A delegate lets you pass a function as a parameter. The type safety of delegates requires the function you pass as a delegate to have the same signature as the delegate declaration. See the Delegates Tutorial for more information on using delegates.

The Delegates Tutorial shows how to compose delegates, that is, create delegates from other delegates. A delegate that contains an out parameter cannot be composed.

Delegates are the basis for events.

For more information on delegates, see 15. Delegates.

Example 1

The following is a simple example of declaring and using a delegate.

```
// keyword_delegate.cs
// delegate declaration
delegate void MyDelegate(int i);

class Program
{
   public static void Main()
   {
      TakesADelegate(new MyDelegate(DelegateFunction));
   }

   public static void TakesADelegate(MyDelegate SomeFunction)
   {
      SomeFunction(21);
   }

   public static void DelegateFunction(int i)
   {
      System.Console.WriteLine("Called by delegate with number: {0}.", i);
   }
}
```

Output

```
Called by delegate with number: 21.
```

Example 2

In the following example, one delegate is mapped to both static and instance methods and returns specific information from each.

```
// keyword_delegate2.cs
// Calling both static and instance methods from delegates
using System;

// delegate declaration
delegate void MyDelegate();

public class MyClass
{
   public void InstanceMethod()
   {
      Console.WriteLine("A message from the instance method.");
   }

   static public void StaticMethod()
   {
      Console.WriteLine("A message from the static method.");
   }
}

public class MainClass
{
   static public void Main()
   {
      MyClass p = new MyClass();

      // Map the delegate to the instance method:
      MyDelegate d = new MyDelegate(p.InstanceMethod);
      d();

      // Map to the static method:
      d = new MyDelegate(MyClass.StaticMethod);
      d();
   }
}
```

Output

```
A message from the instance method.
A message from the static method.
```

See Also

C# Keywords | Reference Types | C. Grammar | Delegates Tutorial

interface

An interface defines a contract. A class or struct that implements an interface must adhere to its contract. The declaration takes the following form::

```
[attributes] [modifiers] interface identifier [:base-list] {interface-body}[;]
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see 17. Attributes.
modifiers (Optional)
The allowed modifiers are new and the four access modifiers.
identifier
The interface name.
base-list (Optional)
A list that contains one or more explicit base interfaces separated by commas.
interface-body
Declarations of the interface members.

Remarks

An interface can be a member of a namespace or a class and can contain signatures of the following members:

- Methods
- Properties
- Indexers
- Events

An interface can inherit from one or more base interfaces. In the following example, the interface `IMyInterface` inherits from two base interfaces, `IBase1` and `IBase2`:

```
interface IMyInterface: IBase1, IBase2
{
   void MethodA();
   void MethodB();
}
```

Interfaces can be implemented by classes and structs. The identifier of the implemented interface appears in the class base list. For example:

```
class Class1: Iface1, Iface2
{
   // class members
}
```

When a class base list contains a base class and interfaces, the base class comes first in the list. For example:

```
class ClassA: BaseClass, Iface1, Iface2
{
   // class members
}
```

For more information on interfaces, see Interfaces.

For more information on properties and indexers, see Property Declaration and Indexer Declaration.

Example

The following example demonstrates interface implementation. In this example, the interface `IPoint` contains the property

declaration, which is responsible for setting and getting the values of the fields. The class `MyPoint` contains the property implementation.

```
// keyword_interface.cs
// Interface implementation
using System;
interface IPoint
{
   // Property signatures:
   int x
   {
      get;
      set;
   }

   int y
   {
      get;
      set;
   }
}

class MyPoint : IPoint
{
   // Fields:
   private int myX;
   private int myY;

   // Constructor:
   public MyPoint(int x, int y)
   {
      myX = x;
      myY = y;
   }

   // Property implementation:
   public int x
   {
      get
      {
         return myX;
      }

      set
      {
         myX = value;
      }
   }

   public int y
   {
      get
      {
         return myY;
      }
      set
      {
         myY = value;
      }
   }
}

class MainClass
{
   private static void PrintPoint(IPoint p)
   {
      Console.WriteLine("x={0}, y={1}", p.x, p.y);
   }
```

```
    public static void Main()
    {
       MyPoint p = new MyPoint(2,3);
       Console.Write("My Point: ");
       PrintPoint(p);
    }
}
```

Output

```
My Point: x=2, y=3
```

C# Keywords | Reference Types | Properties | Indexers | C. Grammar | Explicit Interface Implementation Tutorial | class | struct

object

The **object** type is an alias for **System.Object** in the .NET Framework. You can assign values of any type to variables of type **object**.

All data types, predefined and user-defined, inherit from the **System.Object** class. The **object** data type is the type to and from which objects are boxed.

Example

The following sample shows how variables of type **object** can accept values of any data type and how variables of type **object** can use methods on **System.Object** from the .NET Framework.

```
// keyword_object.cs
using System;
public class MyClass1
{
   public int i = 10;
}

public class MyClass2
{
   public static void Main()
   {
      object a;
      a = 1;   // an example of boxing
      Console.WriteLine(a);
      Console.WriteLine(a.GetType());
      Console.WriteLine(a.ToString());
      Console.WriteLine();

      a = new MyClass1 ();
      MyClass1 ref_MyClass1;
      ref_MyClass1 = (MyClass1)a;
      Console.WriteLine(ref_MyClass1.i);
   }
}
```

Output

```
1
System.Int32
1

10
```

See Also

C# Keywords | Reference Types | Value Types

string

The **string** type represents a string of Unicode characters. **string** is an alias for System.String in the .NET Framework.

Although **string** is a reference type, the equality operators (== and !=) are defined to compare the *values* of **string** objects, not references (7.9.7 String equality operators). This makes testing for string equality more intuitive.

```
string a = "hello";
string b = "h";
b += "ello"; // append to b
Console.WriteLine( a == b );          // output: True -- same value
Console.WriteLine( (object)a == b );  // False -- different objects
```

The + operator concatenates strings:

```
string a = "good " + "morning";
```

The [] operator accesses individual characters of a **string**:

```
char x = "test"[2];  // x = 's';
```

String literals are of type **string** and can be written in two forms, quoted and @-quoted. Quoted string literals are enclosed in double quotation marks ("):

```
"good morning"  // a string literal
```

and can contain any character literal, including escape sequences:

```
string a = "\\\u0066\n";  // backslash, letter f, new line
```

> **Note** The escape code \u*dddd* (where *dddd* is a four-digit number) represents the Unicode character U+*dddd*. Eight-digit Unicode escape codes are also recognized: \u*dddd*\u*dddd*.

@-quoted string literals start with @ and are enclosed in double quotation marks. For example:

```
@"good morning"  // a string literal
```

The advantage of @-quoting is that escape sequences are *not* processed, which makes it easy to write, for example, a fully qualified file name:

```
@"c:\Docs\Source\a.txt"  // rather than "c:\\Docs\\Source\\a.txt"
```

To include a double quotation mark in an @-quoted string, double it:

```
@"""Ahoy!"" cried the captain." // "Ahoy!" cried the captain.
```

Another use of the @ symbol is to use referenced (/reference) identifiers that happen to be C# keywords. For more information, see 2.4.2 Identifiers.

Example

```
// keyword_string.cs
using System;
class test
{
   public static void Main( String[] args )
   {
```

```
        string a = "\u0068ello ";
        string b = "world";
        Console.WriteLine( a + b );
        Console.WriteLine( a + b == "hello world" );
    }
}
```

Output

```
hello world
True
```

C# Keywords | Reference Types | Value Types | Formatting Numeric Results Table

void

When used as the return type for a method, **void** specifies that the method does not return a value.

void is not allowed in a method's parameter list. A method that takes no parameters and returns no value is declared as follows:

```
void MyMethod();
```

void is also used in an unsafe context to declare a pointer to an unknown type. For more information, see A.2 Pointer types.

C# Keywords | Reference Types | Value Types

Types Reference Tables

The following reference tables summarize the C# types:

- Built-in types
- Integral types
- Floating-point types
- Default values
- Value types
- Implicit numeric conversions
- Explicit numeric conversions

For information on formatting the output of numeric types, see Formatting Numeric Results Table.

See Also

Reference Types | Value Types

Built-in Types Table

The following table shows the keywords for built-in C# types, which are aliases of predefined types in the **System** namespace.

C# Type	.NET Framework type
bool	**System.Boolean**
byte	**System.Byte**
sbyte	**System.SByte**
char	**System.Char**
decimal	**System.Decimal**
double	**System.Double**
float	**System.Single**
int	**System.Int32**
uint	**System.UInt32**
long	**System.Int64**
ulong	**System.UInt64**
object	**System.Object**
short	**System.Int16**
ushort	**System.UInt16**
string	**System.String**

Remarks

All of the types in the table, except **object** and **string**, are referred to as simple types.

The C# type keywords and their aliases are interchangeable. For example, you can declare an integer variable by using either of the following declarations:

```
int x = 123;
System.Int32 x = 123;
```

To display the actual type for any C# type use the system method `GetType()`. For example, the following statement displays the system alias that represents the type of `myVariable`:

```
Console.WriteLine(myVariable.GetType());
```

You can also use the typeof operator.

See Also

C# Keywords | Value Types | Default Values Table | Formatting Numeric Results Table | Types Reference Tables

Integral Types Table

The following table shows the sizes and ranges of the integral types, which constitute a subset of simple types.

Type	Range	Size
sbyte	-128 to 127	Signed 8-bit integer
byte	0 to 255	Unsigned 8-bit integer
char	U+0000 to U+ffff	Unicode 16-bit character
short	-32,768 to 32,767	Signed 16-bit integer
ushort	0 to 65,535	Unsigned 16-bit integer
int	-2,147,483,648 to 2,147,483,647	Signed 32-bit integer
uint	0 to 4,294,967,295	Unsigned 32-bit integer
long	-9,223,372,036,854,775,808 to 9,223,372,036,854,775,807	Signed 64-bit integer
ulong	0 to 18,446,744,073,709,551,615	Unsigned 64-bit integer

Remarks

If the value represented by an integer literal exceeds the range of **ulong**, a compilation error will occur.

Default Values Table | Built-in Types Table | Integral Types Table | Formatting Numeric Results Table | Types Reference Tables | decimal

Default Values Table

The following table shows the default values of value types returned by the default constructors. Default constructors are invoked by using the **new** operator, for example:

```
int myInt = new int();
```

The preceding statement has the same effect as the following statement:

```
int myInt = 0;
```

Remember that using uninitialized variables in C# is not allowed.

Value type	Default value
bool	**false**
byte	0
char	'\0'
decimal	0.0M
double	0.0D
enum	The value produced by the expression (E)0, where E is the enum identifier.
float	0.0F
int	0
long	0L
sbyte	0
short	0
struct	The value produced by setting all value-type fields to their default values and all reference-type fields to **null**.
uint	0
ulong	0
ushort	0

Implicit Numeric Conversions Table

The following table shows the predefined implicit numeric conversions. Implicit conversions might occur in many situations, including method invoking and assignment statements.

From	To
sbyte	**short**, **int**, **long**, **float**, **double**, or **decimal**
byte	**short**, **ushort**, **int**, **uint**, **long**, **ulong**, **float**, **double**, or **decimal**
short	**int**, **long**, **float**, **double**, or **decimal**
ushort	**int**, **uint**, **long**, **ulong**, **float**, **double**, or **decimal**
int	**long**, **float**, **double**, or **decimal**
uint	**long**, **ulong**, **float**, **double**, or **decimal**
long	**float**, **double**, or **decimal**
char	**ushort**, **int**, **uint**, **long**, **ulong**, **float**, **double**, or **decimal**
float	**double**
ulong	**float**, **double**, or **decimal**

Remarks

- The conversions from **int**, **uint**, or **long** to **float** and from **long** to **double** may cause a loss of precision, but not a loss of magnitude.
- There are no implicit conversions to the **char** type.
- There are no implicit conversions between floating-point types and the **decimal** type.
- A constant expression of type **int** can be converted to **sbyte**, **byte**, **short**, **ushort**, **uint**, or **ulong**, provided the value of the constant expression is within the range of the destination type.

For more information on implicit conversion, see 6.1 Implicit conversions.

For more information on constant expressions, see 7.15 Constant expressions.

See Also

Integral Types Table | Built-in Types Table | Explicit Numeric Conversions Table

Explicit Numeric Conversions Table

Explicit numeric conversion is used to convert any numeric type to any other numeric type, for which there is no implicit conversion, by using a cast expression. The following table shows these conversions.

From	To
sbyte	**byte**, **ushort**, **uint**, **ulong**, or **char**
byte	**sbyte** or **char**
short	**sbyte**, **byte**, **ushort**, **uint**, **ulong**, or **char**
ushort	**sbyte**, **byte**, **short**, or **char**
int	**sbyte**, **byte**, **short**, **ushort**, **uint**, **ulong**, or **char**
uint	**sbyte**, **byte**, **short**, **ushort**, **int**, or **char**
long	**sbyte**, **byte**, **short**, **ushort**, **int**, **uint**, **ulong**, or **char**
ulong	**sbyte**, **byte**, **short**, **ushort**, **int**, **uint**, **long**, or **char**
char	**sbyte**, **byte**, or **short**
float	**sbyte**, **byte**, **short**, **ushort**, **int**, **uint**, **long**, **ulong**, **char**, or **decimal**
double	**sbyte**, **byte**, **short**, **ushort**, **int**, **uint**, **long**, **ulong**, **char**, **float**, or **decimal**
decimal	**sbyte**, **byte**, **short**, **ushort**, **int**, **uint**, **long**, **ulong**, **char**, **float**, or **double**

Remarks

- The explicit numeric conversion may cause loss of precision or result in throwing exceptions.
- When you convert a **decimal** value to an integral type, this value is rounded towards zero to the nearest integral value. If the resulting integral value is outside the range of the destination type, an **OverflowException** is thrown.
- When you convert from a **double** or **float** value to an integral type, the value is rounded towards zero to the nearest integral value. If the resulting integral value is outside the range of the destination value, the result depends on the overflow checking context. In a checked context, an **OverflowException** is thrown, while in an unchecked context, the result is an unspecified value of the destination type.
- When you convert **double** to **float**, the **double** value is rounded to the nearest **float** value. If the **double** value is too small or too large to fit into the destination type, the result will be zero or infinity.
- When you convert **float** or **double** to **decimal**, the source value is converted to **decimal** representation and rounded to the nearest number after the 28th decimal place if required. Depending on the value of the source value, one of the following results may occur:
    - If the source value is too small to be represented as a **decimal**, the result becomes zero.
    - If the source value is NaN (not a number), infinity, or too large to be represented as a **decimal**, an **OverflowException** is thrown.
- When you convert **decimal** to **float** or **double**, the **decimal** value is rounded to the nearest **double** or **float** value.

For more information on explicit conversion, see 6.2 Explicit conversions.

Formatting Numeric Results Table

You can format numeric results by using the **String.Format** method, or through the **Console.Write** method, which calls **String.Format**. The format is specified using format strings. The following table contains the supported standard format strings. The format string takes the following form: *Axx*, where *A* is the *format specifier* and *xx* is the *precision specifier*. The format specifier controls the type of formatting applied to the numerical value, and the precision specifier controls the number of significant digits or decimal places of the formatted output.

For more information on standard and custom formatting strings, see Formatting Overview. For more information on the **String.Format** method, see String.Format Method.

Character	Description	Examples	Output
C or c	Currency	Console.Write("{0:C}", 2.5); Console.Write("{0:C}", -2.5);	$2.50 ($2.50)
D or d	Decimal	Console.Write("{0:D5}", 25);	00025
E or e	Scientific	Console.Write("{0:E}", 250000);	2.500000E+005
F or f	Fixed-point	Console.Write("{0:F2}", 25); Console.Write("{0:F0}", 25);	25.00 25
G or g	General	Console.Write("{0:G}", 2.5);	2.5
N or n	Number	Console.Write("{0:N}", 2500000);	2,500,000.00
X or x	Hexadecimal	Console.Write("{0:X}", 250); Console.Write("{0:X}", 0xffff);	FA FFFF

Modifiers

Modifiers are used to modify declarations of types and type members. This section introduces the C# modifiers:

Modifier	Purpose
Access Modifiers • public • private • internal • protected	Specify the declared accessibility of types and type members.
abstract	Indicate that a class is intended only to be a base class of other classes.
const	Specify that the value of the field or the local variable cannot be modified.
event	Declare an event.
extern	Indicate that the method is implemented externally.
override	Provide a new implementation of a virtual member inherited from a base class.
readonly	Declare a field that can only be assigned values as part of the declaration or in a construct or in the same class.
sealed	Specify that a class cannot be inherited.
static	Declare a member that belongs to the type itself rather than to a specific object.
unsafe	Declare an unsafe context.
virtual	Declare a method or an accessor whose implementation can be changed by an overriding member in a derived class.
volatile	Indicate that a field can be modified in the program by something such as the operating s ystem, the hardware, or a concurrently executing thread.

C# Keywords

Access Modifiers

Access modifiers are keywords used to specify the declared accessibility of a member or a type. This section introduces the four access modifiers:

- public
- protected
- internal
- private

The following five accessibility levels can be specified using the access modifiers:

public **protected** **internal** **internal protected** **private**

This section also introduces the following topics:

- Accessibility Levels
- Accessibility Domain
- Restrictions on Using Accessibility Levels

See Also

C# Keywords | Modifiers | 3.5 Member access | 10.2.3 Access modifiers

Accessibility Levels

When access is allowed to a member, it said to be accessible. Otherwise, it is inaccessible. Use the access modifiers, public, protected, internal, or private, to specify one of the following declared accessibilities for members.

Declared accessibility	Meaning
public	Access is not restricted.
protected	Access is limited to the containing class or types derived from the containing class.
internal	Access is limited to the current assembly.
protected internal	Access is limited to the current assembly or types derived from the containing class .
private	Access is limited to the containing type.

Only one access modifier is allowed for a member or type, except for the **protected internal** combination.

Access modifiers are not allowed on namespaces. Namespaces have no access restrictions.

Depending on the context in which a member declaration takes place, only certain declared accessibilities are permitted. If no access modifier is specified in a member declaration, a default accessibility is used.

Top-level types, which are not nested into other types, can only have **internal** or **public** accessibility. The default accessibility for these types is **internal**.

Nested types, which are members of other types, can have declared accessibilities as indicated in the following table.

Members of	Default member accessibility	Allowed declared accessibility of the member
enum	**public**	None
class	**private**	**public** **protected** **internal** **private** **protected internal**
interface	**public**	None
struct	**private**	**public** **internal** **private**

The accessibility of a nested type depends on its accessibility domain, which is determined by both the declared accessibility of the member and the accessibility domain of the immediately containing type. However, the accessibility domain of a nested type cannot exceed that of the containing type.

See Also

Access Modifiers | Accessibility Domain | Restrictions on Using Accessibility Levels | 3.5 Member access | 3.5.1 Declared accessibility

Accessibility Domain

The accessibility domain of a member specifies where, in the program sections, a member can be referenced. If the member is nested within another type, its accessibility domain is determined by both the accessibility level of the member and the accessibility domain of the immediately containing type.

The accessibility domain of a top-level type is at least the program text of the project in which it is declared. That is, the entire source files of this project. The accessibility domain of a nested type is at least the program text of the type in which it is declared. That is, the type body, including any nested types. The accessibility domain of a nested type never exceeds that of the containing type. These concepts are demonstrated in the following example.

For more information, see 3.5.2 Accessibility domains.

Example

This example contains a top-level type, `T1`, and two nested classes, `M1` and `M2`. The classes contain fields with different declared accessibilities. In the `Main` method, a comment follows each statement to indicate the accessibility domain of each member. Notice that the statements that attempt to reference the inaccessible members are commented out. If you want to see the compiler errors caused by referencing an inaccessible member, remove the comments one at a time.

```
// cs_Accessibility_Domain.cs
using System;
namespace MyNameSpace
{
   public class T1
   {
      public static int myPublicInt;
      internal static int myInternalInt;
      private static int myPrivateInt = 0;

      public class M1
      {
         public static int myPublicInt;
         internal static int myInternalInt;
         private static int myPrivateInt = 0;
      }

      private class M2
      {
         public static int myPublicInt = 0;
         internal static int myInternalInt = 0;
         private static int myPrivateInt = 0;
      }
   }

   public class MainClass
   {
      public static int Main()
      {
         // Access to T1 fields:
         T1.myPublicInt = 1;      // Access is unlimited
         T1.myInternalInt = 2;    // Accessible only in current assembly
         // T1.myPrivateInt = 3;  // Error: inaccessible outside T1

         // Access to the M1 fields:
         T1.M1.myPublicInt = 1;     // Access is unlimited
         T1.M1.myInternalInt = 2;   // Accessible only in current assembly
         // T1.M1.myPrivateInt = 3; // Error: inaccessible outside M1

         // Access to the M2 fields:
         // T1.M2.myPublicInt = 1;   // Error: inaccessible outside T1
         // T1.M2.myInternalInt = 2; // Error: inaccessible outside T1
         // T1.M2.myPrivateInt = 3;  // Error: inaccessible outside M2

         return 0;
      }
```

```
    }
}
```

See Also

Access Modifiers | Accessibility Levels | Restrictions on Using Accessibility Levels | 10.2.3 Access modifiers | 3.5.2 Accessibility domains

Restrictions on Using Accessibility Levels

When you declare a type, it is essential to see if that type has to be *at least as accessible as* another member or type. For example, the direct base class must be at least as accessible as the derived class. The following declarations will result in a compiler error, because the base class `BaseClass` is less accessible than `MyClass`:

```
class BaseClass {...}
public class MyClass: BaseClass {...} // Error
```

The following table summarizes the restrictions on using declared accessibility levels.

Context	Remarks
Classes	The direct base class of a class type must be at least as accessible as the class type itself.
Interfaces	The explicit base interfaces of an interface type must be at least as accessible as the interface type itself.
Delegates	The return type and parameter types of a delegate type must be at least as accessible as the delegate type itself.
Constants	The type of a constant must be at least as accessible as the constant itself.
Fields	The type of a field must be at least as accessible as the field itself.
Methods	The return type and parameter types of a method must be at least as accessible as the method itself.
Properties	The type of a property must be at least as accessible as the property itself.
Events	The type of an event must be at least as accessible as the event itself.
Indexers	The type and parameter types of an indexer must be at least as accessible as the indexer itself.
Operators	The return type and parameter types of an operator must be at least as accessible as the operator itself.
Constructors	The parameter types of a constructor must be at least as accessible as the constructor itself.

Example

The following example contains erroneous declarations of different types. The comment following each declaration indicates the expected compiler error.

```
// Restrictions_on_Using_Accessibility_Levels.cs
// CS0052 expected as well as CS0053, CS0056, and CS0057
// To make the program work, change access level of both class B
// and MyPrivateMethod() to public.

using System;

// A delegate:
delegate int MyDelegate();

class B
{
   // A private method:
   static int MyPrivateMethod()
   {
      return 0;
   }
}

public class A
{
   // Fields:
   public B myField = new B();   // Error: The type B is less accessible
                                 // than the field A.myField.
   // Constants:
   public readonly B myConst = new B();   // Error: The type B is less accessible
                                          // than the constant A.myConst.

   // Methods:
```

```
    public B MyMethod()
    {
       return new B();   // Error: The type B is less accessible
    }                    // than the method A.MyMethod.

    // Properties:
    public  B MyProp
    {
       set
       {
       }
    }   // Error: The type B is less accessible than the property A.MyProp

    // Delegates:
    MyDelegate d = new MyDelegate(B.MyPrivateMethod);
    // Even when B is declared public, you still get the error:
    // "The parameter B.MyPrivateMethod is not accessible due to
    // protection level."

    // Operators:
    public static B operator + (A m1, B m2)
    {
       return new B();   // Error: The type B is less accessible
                         // than the operator A.operator +(A,B)
    }

    static void Main()
    {
       Console.Write("Compiled successfully");
    }
  }
```

See Also

Access Modifiers | Accessibility Domain | Accessibility Levels | 3.5 Member access

internal

The **internal** keyword is an access modifier for types and type members. Internal members are accessible only within files in the same assembly. For more information on assemblies, see Components and Assemblies.

A common use of internal access is in component-based development because it enables a group of components to cooperate in a private manner without being exposed to the rest of the application code. For example, a framework for building graphical user interfaces could provide Control and Form classes that cooperate using members with internal access. Since these members are internal, they are not exposed to code that is using the framework.

It is an error to reference a member with internal access outside the assembly within which it was defined.

> **Caution** An **internal virtual** method can be overridden in some languages, such as textual Microsoft intermediate language (MSIL) using Ilasm.exe, even though it cannot be overridden using C#.

For a comparison of **internal** with the other access modifiers, see Accessibility Levels.

Example

This example contains two files, `Assembly1.cs` and `Assembly2.cs`. The first file contains an internal base class, `BaseClass`. In the second file, an attempt to access the member of the base class will produce an error.

File Assembly1.cs:

```
// Assembly1.cs
// compile with: /target:library
internal class BaseClass
{
   public static int IntM = 0;
}
```

File Assembly2.cs

```
// Assembly2.cs
// compile with: /reference:Assembly1.dll
// CS0122 expected
class TestAccess
{
   public static void Main()
   {
      BaseClass myBase = new BaseClass();   // error, BaseClass not visible outside assembly
   }
}
```

See Also

C# Keywords | Access Modifiers | Accessibility Levels | Modifiers | 3.5.1 Declared accessibility

private

The **private** keyword is a member access modifier. Private access is the least permissive access level. Private members are accessible only within the body of the class or the struct in which they are declared.

Nested types in the same body can also access those private members.

It is a compile-time error to reference a private member outside the class or the struct in which it is declared.

For a comparison of **private** with the other access modifiers, see Accessibility Levels.

Example

In this example, the `Employee` class contains a public member, `Name`, and a private member, `Salary`. The public member can be accessed directly, while the private member must be accessed through the public method `AccessSalary()`.

```
// private_keyword.cs
using System;
class Employee
{
   public string name = "xx";
   double salary = 100.00;   // private access by default
   public double AccessSalary() {
      return salary;
   }
}

class MainClass
{
   public static void Main()
   {
      Employee e = new Employee();

      // Accessing the public field:
      string n = e.name;

      // Accessing the private field:
      double s = e.AccessSalary();
   }
}
```

In the preceding example, if you attempt to access the private members directly by using a statement like this:

```
double s = e.salary;
```

you will get the error message:

```
'Employee.Salary' is inaccessible due to its protection level.
```

See Also

C# Keywords | Access Modifiers | Accessibility Levels | Modifiers | 3.5.1 Declared accessibility

protected

The **protected** keyword is a member access modifier. A protected member is accessible from within the class in which it is declared, and from within any class derived from the class that declared this member.

A protected member of a base class is accessible in a derived class only if the access takes place through the derived class type. For example, consider the following code segment:

```
class A
{
   protected int x = 123;
}

class B : A
{
   void F()
   {
      A a = new A();
      B b = new B();
      a.x = 10;   // Error
      b.x = 10;   // OK
   }
}
```

The statement `a.x =10` generates an error because A is not derived from B.

Struct members cannot be protected because the struct cannot be inherited.

It is an error to reference a protected member from a class, which is not derived from the protected member's class.

For more information on protected members, see 3.5.3 Protected access for instance members.

For a comparison of **protected** with the other access modifiers, see Accessibility Levels.

Example

In this example, the class `MyDerivedC` is derived from `MyClass`; therefore, you can access the protected members of the base class directly from the derived class.

```
// protected_keyword.cs
using System;
class MyClass
{
   protected int x;
   protected int y;
}

class MyDerivedC: MyClass
{
   public static void Main()
   {
      MyDerivedC mC = new MyDerivedC();

      // Direct access to protected members:
      mC.x = 10;
      mC.y = 15;
      Console.WriteLine("x = {0}, y = {1}", mC.x, mC.y);
   }
}
```

Output

```
x = 10, y = 15
```

If you change the access levels of `x` and `y` to **private**, the compiler will issue the error messages:

```
'MyClass.y' is inaccessible due to its protection level.
'MyClass.x' is inaccessible due to its protection level.
```

See Also

C# Keywords | Access Modifiers | Accessibility Levels | Modifiers | 3.5.1 Declared accessibility

public

The **public** keyword is an access modifier for types and type members. Public access is the most permissive access level. There are no restrictions on accessing public members.

For a comparison of **public** with the other access modifiers, see Accessibility Levels.

Example

In the following example, two classes are declared, `MyClass1` and `MyClass2`. The public members x and y of the `MyClass1` are accessed directly from `MyClass2`.

```
// protected_public.cs
// Public access
using System;
class MyClass1
{
   public int x;
   public int y;
}

class MyClass2
{
   public static void Main()
   {
      MyClass1 mC = new MyClass1();

      // Direct access to public members:
      mC.x = 10;
      mC.y = 15;
      Console.WriteLine("x = {0}, y = {1}", mC.x, mC.y);
   }
}
```

Output

```
x = 10, y = 15
```

If you change the **public** access level to **private** or **protected**, you will get the error message:

```
'MyClass1.y' is inaccessible due to its protection level.
```

See Also

C# Keywords | Access Modifiers | Accessibility Levels | Modifiers | 3.5.1 Declared accessibility

abstract

The **abstract** modifier can be used with classes, methods, properties, indexers, and events.

Use the **abstract** modifier in a class declaration to indicate that a class is intended only to be a base class of other classes.

Abstract classes have the following features:

- An abstract class cannot be instantiated.
- An abstract class may contain abstract methods and accessors.
- It is not possible to modify an abstract class with the sealed modifier, which means that the class cannot be inherited.
- A non-abstract class derived from an abstract class must include actual implementations of all inherited abstract methods and accessors.

Use the **abstract** modifier in a method or property declaration to indicate that the method or property does not contain implementation.

Abstract methods have the following features:

- An abstract method is implicitly a virtual method.
- Abstract method declarations are only permitted in abstract classes.
- Because an abstract method declaration provides no actual implementation, there is no method body; the method declaration simply ends with a semicolon and there are no braces ({ }) following the signature. For example:

  ```
  public abstract void MyMethod();
  ```

- The implementation is provided by an overriding method, which is a member of a non-abstract class.
- It is an error to use the **static** or **virtual** modifiers in an abstract method declaration.

Abstract properties behave like abstract methods, except for the differences in declaration and invocation syntax.

- It is an error to use the **abstract** modifier on a static property.
- An abstract inherited property can be overridden in a derived class by including a property declaration that uses the **override** modifier.

An abstract class must provide implementation for all interface members.

An abstract class that implements an interface might map the interface methods onto abstract methods. For example:

```
interface I
{
   void M();
}
abstract class C: I
{
   public abstract void M();
}
```

For more information, see 10.1.1.1 Abstract classes and 10.5.6 Abstract methods.

Example

In this example, the class `MyDerivedC` is derived from an abstract class `MyBaseC`. The abstract class contains an abstract method, `MyMethod()`, and two abstract properties, `GetX()` and `GetY()`.

```
// abstract_keyword.cs
// Abstract Classes
using System;
abstract class MyBaseC   // Abstract class
{
   protected int x = 100;
   protected int y = 150;
   public abstract void MyMethod();   // Abstract method
```

```
    public abstract int GetX   // Abstract property
    {
       get;
    }

    public abstract int GetY   // Abstract property
    {
       get;
    }
 }

 class MyDerivedC: MyBaseC
 {
    public override void MyMethod()
    {
       x++;
       y++;
    }

    public override int GetX   // overriding property
    {
       get
       {
          return x+10;
       }
    }

    public override int GetY   // overriding property
    {
       get
       {
          return y+10;
       }
    }

    public static void Main()
    {
       MyDerivedC mC = new MyDerivedC();
       mC.MyMethod();
       Console.WriteLine("x = {0}, y = {1}", mC.GetX, mC.GetY);
    }
 }
```

Output

```
x = 111, y = 161
```

In the preceding example, if you attempt to instantiate the abstract class by using a statement like this:

```
MyBaseC mC1 = new MyBaseC();   // Error
```

you will get the following error message:

```
Cannot create an instance of the abstract class 'MyBaseC'.
```

See Also

virtual | override | C# Keywords | Modifiers | 10.1.1.1 Abstract classes | 10.5.6 Abstract methods | 10.6.3 Virtual, sealed, override, and abstract accessors

const

The **const** keyword is used to modify a declaration of a field or local variable. It specifies that the value of the field or the local variable cannot be modified. A constant declaration introduces one or more constants of a given type. The declaration takes the form:

```
[attributes] [modifiers] const type declarators;
```

where:

attributes (optional)
Optional declarative information. For more information on attributes and attribute classes, see C# Attributes.
modifiers (optional)
Optional modifiers that include the **new** modifier and one of the four access modifiers.
type
One of the types: **byte**, **char**, **short**, **int**, **long**, **float**, **double**, **decimal**, **bool**, **string**, an enum type, or a reference type.
declarators
A comma-separated list of declarators. A declarator takes the form:

identifier = constant-expression

The *attributes* and *modifiers* apply to all of the members declared by the constant declaration.

The *type* of a constant declaration specifies the type of the members introduced by the declaration. A constant expression must yield a value of the target type, or of a type that can be implicitly converted to the target type.

A constant expression is an expression that can be fully evaluated at compile time. Therefore, the only possible values for constants of reference types are **string** and **null**.

Remarks

The constant declaration can declare multiple constants, for example:

```
public const double x = 1.0, y = 2.0, z = 3.0;
```

The **static** modifier is not allowed in a constant declaration.

A constant can participate in a constant expression, for example:

```
public const int c1 = 5.0;
public const int c2 = c1 + 100;
```

Example

```
// const_keyword.cs
// Constants
using System;
public class ConstTest
{
   class MyClass
   {
      public int x;
      public int y;
      public const int c1 = 5;
      public const int c2 = c1 + 5;

      public MyClass(int p1, int p2)
      {
         x = p1;
         y = p2;
      }
   }
```

```
    public static void Main()
    {
       MyClass mC = new MyClass(11, 22);
       Console.WriteLine("x = {0}, y = {1}", mC.x, mC.y);
       Console.WriteLine("c1 = {0}, c2 = {1}", MyClass.c1, MyClass.c2 );
    }
}
```

Output

```
x = 11, y = 22
c1 = 5, c2 = 10
```

Example

This example demonstrates using constants as local variables.

```
// const_keyword2.cs
using System;
public class TestClass
{
    public static void Main()
    {
       const int c = 707;
       Console.WriteLine("My local constant = {0}", c);
    }
}
```

Output

```
My local constant = 707
```

> **Note** The readonly keyword is different from the **const** keyword. A **const** field can only be initialized at the declaration of the field. A **readonly** field can be initialized either at the declaration or in a constructor. Therefore, **readonly** fields can have different values depending on the constructor used. Also, while a **const** field is a compile-time constant, the **readonly** field can be used for runtime constants, as in the following example:
>
> `public static readonly uint l1 = (uint) DateTime.Now.Ticks;`

C# Keywords | Modifiers

event

Specifies an event.

```
[attributes] [modifiers] event type declarator;
[attributes] [modifiers] event type member-name {accessor-declarations};
```

where:

attributes (optional)
Optional declarative information. For more information on attributes and attribute classes, see C# Attributes.
modifiers (optional)
Optional modifiers that include:

- abstract
- new
- override
- static
- virtual
- extern
- one of the four access modifiers

type
The delegate to which you want to associate this event.
declarator
The name of the event.
member-name
The name of the event.
accessor-declarations (optional)
Declaration of the accessors, which are used to add and remove event handlers in client code. The accessor functions are `add` and `remove`. It is an error to define one but not the other.

Remarks

The **event** keyword lets you specify a delegate that will be called upon the occurrence of some "event" in your code. The delegate can have one or more associated methods that will be called when your code indicates that the event has occurred. An event in one program can be made available to other programs that target the .NET Framework common language runtime.

The following steps must be taken in order to create and use C# events:

1. Create or identify a delegate. If you are defining your own event, you must also ensure that there is a delegate to use with the event keyword. If the event is predefined, in the .NET Framework for example, then consumers of the event need only know the name of the delegate.
2. Create a class that contains:
   a. An event created from the delegate.
   b. (optional) A method that verifies that an instance of the delegate declared with the **event** keyword exists. Otherwise, this logic must be placed in the code that fires the event.
   c. Methods that call the event. These methods can be overrides of some base class functionality.

   This class defines the event.

3. Define one or more classes that connect methods to the event. Each of these classes will include:

   - Associate one or more methods, using the += and -= operators, with the event in the base class.
   - The definition of the method(s) that will be associated with the event.

4. Use the event:

   - Create an object of the class that contains the event declaration.
   - Create an object of the class that contains the event definition, using the constructor that you defined.

For more information on events, see:

- 10.7 Events
- Events Tutorial
- Events and Delegates

Examples

A basic example of defining and using events can be found in the Events Tutorial. The following examples in this topic also demonstrate events.

Example	Comment
Example 1	Declaring an event in an interface and implementing it in a class.
Example 2	Using a hash table to store event instances.
Example 3	Implementing, via event properties, two interfaces that have an event with the same name .

Example 1

This example shows that it is possible to declare an event in an interface and implement it in a class:

```
// event_keyword.cs
using System;
public delegate void MyDelegate();   // delegate declaration

public interface I
{
   event MyDelegate MyEvent;
   void FireAway();
}

public class MyClass: I
{
   public event MyDelegate MyEvent;

   public void FireAway()
   {
      if (MyEvent != null)
         MyEvent();
   }
}

public class MainClass
{
   static private void f()
   {
      Console.WriteLine("This is called when the event fires.");
   }

   static public void Main ()
   {
      I i = new MyClass();

      i.MyEvent += new MyDelegate(f);
      i.FireAway();
   }
}
```

Example 2

One use for *accessor-declarations* is to expose a large number of events without allocating a field for each event, but instead using a hash table to store the event instances. This is only useful if you have a very large number of events, but you expect most of the events will not be implemented.

```
// event_keyword2.cs
using System;
using System.Collections;

public delegate void MyDelegate1(int i);
public delegate void MyDelegate2(string s);
public delegate void MyDelegate3(int i, object o);
public delegate void MyDelegate4();

public class PropertyEventsSample
{
   private Hashtable eventTable = new Hashtable();

   public event MyDelegate1 Event1
   {
      add
      {
         eventTable["Event1"] = (MyDelegate1)eventTable["Event1"] + value;
      }
      remove
      {
         eventTable["Event1"] = (MyDelegate1)eventTable["Event1"] - value;
      }
   }

   public event MyDelegate1 Event2
   {
      add
      {
         eventTable["Event2"] = (MyDelegate1)eventTable["Event2"] + value;
      }
      remove
      {
         eventTable["Event2"] = (MyDelegate1)eventTable["Event2"] - value;
      }
   }

   public event MyDelegate2 Event3
   {
      add
      {
         eventTable["Event3"] = (MyDelegate2)eventTable["Event3"] + value;
      }
      remove
      {
         eventTable["Event3"] = (MyDelegate2)eventTable["Event3"] - value;
      }
   }

   public event MyDelegate3 Event4
   {
      add
      {
         eventTable["Event4"] = (MyDelegate3)eventTable["Event4"] + value;
      }
      remove
      {
         eventTable["Event4"] = (MyDelegate3)eventTable["Event4"] - value;
      }
   }

   public event MyDelegate3 Event5
   {
      add
      {
         eventTable["Event5"] = (MyDelegate3)eventTable["Event5"] + value;
      }
      remove
```

```
        {
            eventTable["Event5"] = (MyDelegate3)eventTable["Event5"] - value;
        }
    }

    public event MyDelegate4 Event6
    {
        add
        {
            eventTable["Event6"] = (MyDelegate4)eventTable["Event6"] + value;
        }
        remove
        {
            eventTable["Event6"] = (MyDelegate4)eventTable["Event6"] - value;
        }
    }
}

public class MyClass
{
    public static void Main()
    {
    }
}
```

Example 3

Another use for event properties covers the situation where you are implementing two interfaces, each with an event of the same name. In such a case, you must use an explicit implementation event property:

```
// event_keyword3.cs
using System;

public delegate void MyDelegate1();

public interface I1
{
    event MyDelegate1 MyEvent;
}

public delegate int MyDelegate2(string s);

public interface I2
{
    event MyDelegate2 MyEvent;
}

public class ExplicitEventsSample: I1, I2
{
    public event MyDelegate1 MyEvent;  // normal implementation of I1.MyEvent.

    event MyDelegate2 I2.MyEvent   // explicit implementation of I2.MyEvent
    {
        add
        {
            MyEvent2Storage += value;
        }
        remove
        {
            MyEvent2Storage -= value;
        }
    }

    private MyDelegate2 MyEvent2Storage;  // underlying storage for I2.MyEvent.

    private void FireEvents()
    {
```

```
        if (MyEvent != null)
           MyEvent();
        if (MyEvent2Storage != null)
           MyEvent2Storage("hello");
     }
  }

  public class MyClass
  {
     public static void Main()
     {
     }
  }
```

C# Keywords | Modifiers | 1.7.5 Events

extern

Use the **extern** modifier in a method declaration to indicate that the method is implemented externally. A common use of the extern modifier is with the **DllImport** attribute. (See DllImportAttribute Class for more information.)

It is an error to use the abstract and **extern** modifiers together to modify the same member. Using the **extern** modifier means that the method is implemented outside the C# code, while using the **abstract** modifier means that the method implementation is not provided in the class.

Because an external method declaration provides no actual implementation, there is no method body; the method declaration simply ends with a semicolon and there are no braces ({ }) following the signature. For example:

```
public static extern int MyMethod(int x);
```

> **Note** The **extern** keyword is more limited in use than in C++. To compare with the C++ keyword, see Using extern to Specify Linkage in the *C++ Language Reference*.

For more information on external methods, see 10.5.7 External methods.

For more information on attributes, see 17. Attributes.

Example

In this example, the program receives a string from the user and displays it inside a message box. The program uses the `MessageBox` method imported from the `User32.dll` library.

```
using System;
using System.Runtime.InteropServices;
class MyClass
{
   [DllImport("User32.dll")]
   public static extern int MessageBox(int h, string m, string c, int type);

   public static int Main()
   {
      string myString;
      Console.Write("Enter your message: ");
      myString = Console.ReadLine();
      return MessageBox(0, myString, "My Message Box", 0);
   }
}
```

Sample Run

```
Enter your message: Where do you want to go today?
```

When the previous text is entered, a message box that contains the text will pop up on the screen.

Example

This example uses two files, `CM.cs` and `Cmdll.c`, to demonstrate **extern**. The C file is an external DLL that is invoked from within the C# program.

File: Cmdll.c

```
// cmdll.c
// compile with: /LD /MD
int __declspec(dllexport) MyMethod(int i)
{
   return i*10;
}
```

File: CM.cs

```
// cm.cs
using System;
using System.Runtime.InteropServices;
public class MyClass
{
   [DllImport("Cmdll.dll")]
   public static extern int MyMethod(int x);
   public static void Main()
   {
      Console.WriteLine("MyMethod() returns {0}.", MyMethod(5));
   }
}
```

Output

```
MyMethod() returns 50.
```

Compilation

To build the project, use the following steps:

- Compile `Cmdll.c` to a DLL using the Visual C++ command line:

  ```
  cl /LD /MD Cmdll.c
  ```

- Compile `CM.cs` using the command line:

  ```
  csc CM.cs
  ```

This will create the executable file `CM.exe`. When you run this program, `MyMethod` will pass the value 5 to the DLL file, which returns the value multiplied by 10.

C# Keywords | Modifiers

override

Use the **override** modifier to modify a method, a property, an indexer, or an event. An override method provides a new implementation of a member inherited from a base class. The method overridden by an override declaration is known as the overridden base method. The overridden base method must have the same signature as the override method.

You cannot override a non-virtual or static method. The overridden base method must be virtual, abstract, or override.

An override declaration cannot change the accessibility of the virtual method. Both the override method and the virtual method must have the same access level modifier.

You cannot use the following modifiers to modify an override method:

new static virtual abstract

An overriding property declaration must specify the exact same access modifier, type, and name as the inherited property, and the overridden property must be virtual, abstract, or override.

For more information on accessing the base class members, see 7.5.8 Base access.

For more information on overriding methods, see 10.5.4 Override methods.

Example

See the example for the virtual keyword.

From within the derived class that has an override method, you still can access the overridden base method that has the same name by using the **base** keyword. For example, if you have a virtual method `MyMethod()`, and an override method on a derived class, you can access the virtual method from the derived class by using the call:

```
base.MyMethod()
```

Compare this to the C++ way, where you use the scope resolution operator (`::`) and the base class name, for example:

```
My_Base_Class_Name::MyMethod()
```

Example

In this example, there is a base class, `Square`, and a derived class, `Cube`. Because the area of a cube is the sum of the areas of six squares, it is possible to calculate it by calling the `Area()` method on the base class.

```
// cs_override_keyword.cs
// Calling overriden methods from the base class
using System;
class TestClass
{
   public class Square
   {
      public double x;

      // Constructor:
      public Square(double x)
      {
         this.x = x;
      }

      public virtual double Area()
      {
         return x*x;
      }
   }

   class Cube: Square
   {
      // Constructor:
```

```
        public Cube(double x): base(x)
        {
        }

        // Calling the Area base method:
        public override double Area()
        {
           return (6*(base.Area()));
        }
     }

     public static void Main()
     {
        double x = 5.2;
        Square s = new Square(x);
        Square c = new Cube(x);
        Console.WriteLine("Area of Square = {0:F2}", s.Area());
        Console.WriteLine("Area of Cube = {0:F2}", c.Area());
     }
  }
```

Output

```
Area of Square = 27.04
Area of Cube = 162.24
```

abstract | virtual | C# Keywords | Modifiers | Versioning Tutorial | 10.5.4 Override methods

readonly

The **readonly** keyword is a modifier that you can use on fields. When a field declaration includes a **readonly** modifier, assignments to the fields introduced by the declaration can only occur as part of the declaration or in a constructor in the same class.

You can assign a value to a readonly field only in the following contexts:

- When the variable is initialized in the declaration, for example:

  ```
  public readonly int y = 5;
  ```

- For an instance field, in the instance constructors of the class that contains the field declaration, or for a static field, in the static constructor of the class that contains the field declaration. These are also the only contexts in which it is valid to pass a `readonly` field as an **out** or **ref** parameter.

Example

```
// cs_readonly_keyword.cs
// Readonly fields
using System;
public class ReadOnlyTest
{
   class MyClass
   {
      public int x;
      public readonly int y = 25; // Initialize a readonly field
      public readonly int z;

      public MyClass()
      {
         z = 24;   // Initialize a readonly instance field
      }

      public MyClass(int p1, int p2, int p3)
      {
         x = p1;
         y = p2;
         z = p3;
      }
   }

   public static void Main()
   {
      MyClass p1= new MyClass(11, 21, 32);   // OK
      Console.WriteLine("p1: x={0}, y={1}, z={2}" , p1.x, p1.y, p1.z);
      MyClass p2 = new MyClass();
      p2.x = 55;   // OK
      Console.WriteLine("p2: x={0}, y={1}, z={2}" , p2.x, p2.y, p2.z);
   }
}
```

Output

```
p1: x=11, y=21, z=32
p2: x=55, y=25, z=24
```

In the preceding example, if you use a statement like this:

```
p2.y = 66;        // Error
```

you will get the compiler error message:

```
The left-hand side of an assignment must be an l-value
```

which is the same error you get when you attempt to assign a value to a constant.

> **Note** The **readonly** keyword is different from the const keyword. A **const** field can only be initialized at the declaration of the field. A **readonly** field can be initialized either at the declaration or in a constructor. Therefore, **readonly** fields can have different values depending on the constructor used. Also, while a **const** field is a compile-time constant, the **readonly** field can be used for runtime constants as in the following example:
>
> ```
> public static readonly uint l1 = (uint) DateTime.Now.Ticks;
> ```

See Also

C# Keywords | Modifiers

sealed

A sealed class cannot be inherited. It is an error to use a sealed class as a base class. Use the **sealed** modifier in a class declaration to prevent inheritance of the class.

It is not permitted to use the abstract modifier with a sealed class.

Structs are implicitly sealed; therefore, they cannot be inherited.

Example

```
// cs_sealed_keyword.cs
// Sealed classes
using System;
sealed class MyClass
{
   public int x;
   public int y;
}

class MainClass
{
   public static void Main()
   {
      MyClass mC = new MyClass();
      mC.x = 110;
      mC.y = 150;
      Console.WriteLine("x = {0}, y = {1}", mC.x, mC.y);
   }
}
```

Output

```
x = 110, y = 150
```

In the preceding example, if you attempt to inherit from the sealed class by using a statement like this:

```
class MyDerivedC: MyClass {}   // Error
```

you will get the error message:

```
'MyDerivedC' cannot inherit from sealed class 'MyBaseC'.
```

C# Keywords | Modifiers

static

Use the **static** modifier to declare a static member, which belongs to the type itself rather than to a specific object. The **static** modifier can be used with fields, methods, properties, operators, events and constructors, but cannot be used with indexers, destructors, or types.

Remarks

- A constant or type declaration is implicitly a static member.
- A static member cannot be referenced through an instance. Instead, it is referenced through the type name. For example, consider the following class:

  ```
  public class MyBaseC
  {
     public struct MyStruct {
        public static int x = 100;
     }
  }
  ```

  To refer to the static member `x`, use the fully qualified name (unless it is accessible from the same scope):

  ```
  MyBaseC.MyStruct.x
  ```

- While an instance of a class contains a separate copy of all instance fields of the class, there is only one copy of each static field.
- It is not possible to use **this** to reference static methods or property accessors.

> **Note** The **static** keyword is more limited in use than in C++. To compare with the C++ keyword, see static in the *C++ Language Reference*.

To demonstrate instance members, consider a class that represents a company employee. Assume that the class contains a method to count employees and a field to store the number of employees. Both the method and the field do not belong to any instance employee. Instead they belong to the company class. Therefore, they should be declared as static members of the class.

For more information on constructors, see 10.10 Instance constructors.

Example

This example reads the name and ID of a new employee, increments the employee counter by one, and displays the information for the new employee as well as the new number of employees. For simplicity, this program reads the current number of employees from the keyboard. In a real application, this information should be read from a file.

```
// cs_static_keyword.cs
// Static members
using System;
public class Employee
{
   public string id;
   public string name;

   public Employee ()
   {
   }

   public Employee (string name, string id)
   {
      this.name = name;
      this.id = id;
   }

   public static int employeeCounter;
```

```
   public static int AddEmployee()
   {
      return ++employeeCounter;
   }
}

class MainClass: Employee
{
   public static void Main()
   {
      Console.Write("Enter the employee's name: ");
      string name = Console.ReadLine();
      Console.Write("Enter the employee's ID: ");
      string id = Console.ReadLine();
      // Create the employee object:
      Employee e = new Employee (name, id);
      Console.Write("Enter the current number of employees: ");
      string n = Console.ReadLine();
      Employee.employeeCounter = Int32.Parse(n);
      Employee.AddEmployee();
      // Display the new information:
      Console.WriteLine("Name: {0}", e.name);
      Console.WriteLine("ID:   {0}", e.id);
      Console.WriteLine("New Number of Employees: {0}",
                        Employee.employeeCounter);
   }
}
```

Input

```
Tara Strahan
AF643G
15
```

Sample Output

```
Enter the employee's name: Tara Strahan
Enter the employee's ID: AF643G
Enter the current number of employees: 15
Name: Tara Strahan
ID:   AF643G
New Number of Employees: 16
```

C# Keywords | Modifiers

unsafe

The **unsafe** keyword denotes an unsafe context, which is required for any operation involving pointers.

You can use the **unsafe** modifier in the declaration of a type or a member. The entire textual extent of the type or member is therefore considered an unsafe context. For example, the following is a method declared with the **unsafe** modifier:

```
unsafe static void FastCopy ( byte[] src, byte[] dst, int count )
{
   // unsafe context: can use pointers here
}
```

The scope of the unsafe context extends from the parameter list to the end of the method, so pointers can also be used in the parameter list:

```
unsafe static void FastCopy ( byte* ps, byte* pd, int count ) {...}
```

You can also use an unsafe block to enable the use of an unsafe code inside this block. For example:

```
unsafe
{
   // unsafe context: can use pointers here
}
```

To compile unsafe code, you must specify the /unsafe compiler option. Unsafe code is not verifiable by the common language runtime.

Example

```
// cs_unsafe_keyword.cs
// compile with: /unsafe
using System;
class UnsafeTest
{
   // unsafe method: takes pointer to int:
   unsafe static void SquarePtrParam (int* p)
   {
      *p *= *p;
   }
   unsafe public static void Main()
   {
      int i = 5;
      // unsafe method: uses address-of operator (&)
      SquarePtrParam (&i);
      Console.WriteLine (i);
   }
}
```

Output

```
25
```

C# Keywords | fixed Statement | Unsafe Code Tutorial | A. Unsafe code

virtual

The **virtual** keyword is used to modify a method or property declaration, in which case the method or the property is called a virtual member. The implementation of a virtual member can be changed by an overriding member in a derived class.

When a virtual method is invoked, the run-time type of the object is checked for an overriding member. The overriding member in the most derived class is called, which might be the original member, if no derived class has overridden the member. (For more information on run-time type and most derived implementation, see 10.5.3 Virtual methods.)

By default, methods are non-virtual. You cannot override a non-virtual method.

You cannot use the **virtual** modifier with the following modifiers:

static abstract override

Virtual properties behave like abstract methods, except for the differences in declaration and invocation syntax.

- It is an error to use the **virtual** modifier on a static property.
- A virtual inherited property can be overridden in a derived class by including a property declaration that uses the **override** modifier.

For more information on virtual methods, see 10.5.3 Virtual methods.

Example

In this example, the class `Dimensions` contains the two coordinates `x`, `y`, and the `Area()` virtual method. Different shape classes such as `Circle`, `Cylinder`, and `Sphere` inherit the `Dimensions` class, and the surface area is calculated for each figure. Each derived class has it own override implementation of `Area()`. The program calculates and displays the proper area for each figure by invoking the proper implementation of `Area()` according to the object associated with the method.

```
// cs_virtual_keyword.cs
// Virtual and override
using System;
class TestClass
{
   public class Dimensions
   {
      public const double pi = Math.PI;
      protected double x, y;
      public Dimensions()
      {
      }
      public Dimensions (double x, double y)
      {
         this.x = x;
         this.y = y;
      }

      public virtual double Area()
      {
         return x*y;
      }
   }

   public class Circle: Dimensions
   {
      public Circle(double r): base(r, 0)
      {
      }

      public override double Area()
      {
         return pi * x * x;
      }
   }
```

```
    class Sphere: Dimensions
    {
       public Sphere(double r): base(r, 0)
       {
       }

       public override double Area()
       {
          return 4 * pi * x * x;
       }
    }

    class Cylinder: Dimensions
    {
       public Cylinder(double r, double h): base(r, h)
       {
       }

       public override double Area()
       {
          return 2*pi*x*x + 2*pi*x*y;
       }
    }

    public static void Main()
    {
       double r = 3.0, h = 5.0;
       Dimensions c = new Circle(r);
       Dimensions s = new Sphere(r);
       Dimensions l = new Cylinder(r, h);
       // Display results:
       Console.WriteLine("Area of Circle   = {0:F2}", c.Area());
       Console.WriteLine("Area of Sphere   = {0:F2}", s.Area());
       Console.WriteLine("Area of Cylinder = {0:F2}", l.Area());
    }
 }
```

Output

```
Area of Circle   = 28.27
Area of Sphere   = 113.10
Area of Cylinder = 150.80
```

In the preceding example, notice that the inherited classes `Circle`, `Sphere`, and `Cylinder` are all using constructors that initialize the base class, for example:

```
public Cylinder(double r, double h): base(r, h) {}
```

This is analogous to the C++ initialization list.

abstract | override | C# Keywords | Modifiers | Versioning Tutorial | 10.5.3 Virtual methods

volatile

The **volatile** keyword indicates that a field can be modified in the program by something such as the operating system, the hardware, or a concurrently executing thread.

```
volatile declaration
```

where:

declaration
The declaration of a field.

Remarks

The system always reads the current value of a volatile object at the point it is requested, even if the previous instruction asked for a value from the same object. Also, the value of the object is written immediately on assignment.

The **volatile** modifier is usually used for a field that is accessed by multiple threads without using the lock statement to serialize access. Using the **volatile** modifier ensures that one thread retrieves the most up-to-date value written by another thread.

The type of a field marked as volatile is restricted to the following types:

- Any reference type.
- Any pointer type (in an unsafe context).
- The types sbyte, byte, short, ushort, int, uint, char, float, bool.
- An enum type with an enum base type of byte, sbyte, short, ushort, int, or uint.

For more information on volatile, see 10.4.3 Volatile fields.

Example

The following sample shows how to declare a public field variable as volatile.

```
// csharp_volatile.cs
class Test
{
   public volatile int i;

   Test(int _i)
   {
      i = _i;
   }
   public static void Main()
   {

   }
}
```

C# Keywords | Modifiers | 10.4.3 Volatile fields

Statements

Statements are program instructions. Except as described, statements are executed in sequence. C# has the following categories of statements.

Category	C# keywords
Selection statements	if, else, switch, case
Iteration statements	do, for, foreach, in, while
Jump statements	break, continue, default, goto, return
Exception handling statements	throw, try-catch, try-finally, try-catch-finally
Checked and unchecked	checked, unchecked
fixed Statement	fixed
lock Statement	lock

See Also

C# Keywords

Selection Statements

A selection statement causes the program control to be transferred to a specific flow based upon whether a certain condition is true or not.

The following keywords are used in selection statements:

- if
- else
- switch
- case

See Also

C# Keywords | Statements | 8.7 Selection statements

if-else

The **if** statement selects a statement for execution based on the value of a Boolean expression. It takes the following form:

```
if (expression)
   statement1
[else
   statement2]
```

where:

expression
An expression that can be implicitly converted to **bool** or a type that contains overloading of the true and false operators.
statement1
The embedded statement(s) to be executed if *expression* is **true**.
statement2
The embedded statement(s) to be executed if *expression* is **false**.

Remarks

If *expression* is **true**, *statement1* is executed. If the optional **else** clause exists and *expression* evaluates to **false**, *statement2* is executed. After executing the **if** statement, control is transferred to the next statement.

If any of the two results of the **if** statement (**true** or **false**) results in executing more than one statement, multiple statements can be conditionally executed by including them into blocks.

The statement(s) to be executed upon testing the condition can be of any kind, including another **if** statement nested into the original **if** statement. In nested **if** statements, the **else** clause belongs to the last **if** that does not have a corresponding **else**. For example:

```
if (x > 10)
   if (y > 20)
      Console.Write("Statement_1");
   else
      Console.Write("Statement_2");
```

In this example, `Statement_2` will be displayed if the condition `(y > 20)` evaluates to **false**. However, if you want to associate `Statement_2` with the condition `(x >10)`, use braces:

```
if (x > 10)
{
   if (y > 20)
      Console.Write("Statement_1");
}
else
   Console.Write("Statement_2");
```

In this case, `Statement_2` will be displayed if the condition `(x > 10)` evaluates to **false**

Example

In this example, you enter a character from the keyboard and the program checks if the input character is an alphabetic character. If so, it checks if it is lowercase or uppercase. In each case, the proper message is displayed.

```
// statements_if_else.cs
// if-else example
using System;
public class IfTest
{
   public static void Main()
   {
      Console.Write("Enter a character: ");
```

```
      char c = (char) Console.Read();
      if (Char.IsLetter(c))
         if (Char.IsLower(c))
            Console.WriteLine("The character is lowercase.");
         else
            Console.WriteLine("The character is uppercase.");
      else
         Console.WriteLine("The character is not an alphabetic character.");
   }
}
```

Input

```
2
```

Sample Output

```
Enter a character: 2
The character is not an alphabetic character.
```

Additional sample might look as follows:

Run #2:

```
Enter a character: A
The character is uppercase.
```

Run #3:

```
Enter a character: h
The character is lowercase.
```

It is also possible to extend the **if** statement to handle multiple conditions using the following else-if arrangement:

```
if (Condition_1)
   Statement_1;
else if (Condition_2)
   Statement_2;
else if (Condition_3)
   Statement_3;
...
else
   Statement_n;
```

Example

This example checks if the input character is lowercase, uppercase, or a number. Otherwise, it is not an alphanumeric character. The program makes use of the else-if ladder.

```
// statements_if_else2.cs
// else-if
using System;
public class IfTest
{
   public static void Main()
   {
      Console.Write("Enter a character: ");
      char c = (char) Console.Read();

      if (Char.IsUpper(c))
```

```
            Console.WriteLine("The character is uppercase.");
        else if (Char.IsLower(c))
            Console.WriteLine("The character is lowercase.");
        else if (Char.IsDigit(c))
            Console.WriteLine("The character is a number.");
        else
            Console.WriteLine("The character is not alphanumeric.");
    }
}
```

Input

```
E
```

Sample Output

```
Enter a character: E
The character is uppercase.
```

Additional sample runs might look as follows:

Run #2

```
Enter a character: e
The character is lowercase.
```

Run #3:

```
Enter a character: 4
The character is a number.
```

Run #4:

```
Enter a character: $
The character is not alphanumeric.
```

C# Keywords | ?: Operator | Compare to C++ | switch | C. Grammar

switch

The **switch** statement is a control statement that handles multiple selections by passing control to one of the **case** statements within its body. It takes the following form:

```
switch (expression)
{
   case constant-expression:
      statement
      jump-statement
   [default:
      statement
      jump-statement]
}
```

Where:

expression
An integral or string type expression.
statement
The embedded statement(s) to be executed if control is transferred to the **case** or the **default**.
jump-statement
A jump statement that transfers control out of the **case** body.
constant-expression
Control is transferred to a specific **case** according to the value of this expression.

Remarks

Control is transferred to the **case** statement whose *constant-expression* matches *expression*. The **switch** statement can include any number of **case** instances, but no two case constants within the same **switch** statement can have the same value. Execution of the statement body begins at the selected statement and proceeds until the *jump-statement* transfers control out of the **case** body.

Notice that the *jump-statement* is required after each block, including the last block whether it is a **case** statement or a **default** statement. Unlike the C++ **switch** statement, C# does not support an explicit fall through from one case label to another. If you want, you can use **goto** a switch-case, or **goto default**.

If *expression* does not match any *constant-expression*, control is transferred to the *statement*(s) that follow the optional **default** label. If there is no **default** label, control is transferred outside the **switch**.

Example

```
// statements_switch.cs
using System;
class SwitchTest
{
   public static void Main()
   {
      Console.WriteLine("Coffee sizes: 1=Small 2=Medium 3=Large");
      Console.Write("Please enter your selection: ");
      string s = Console.ReadLine();
      int n = int.Parse(s);
      int cost = 0;
      switch(n)
      {
         case 1:
            cost += 25;
            break;
         case 2:
            cost += 25;
            goto case 1;
         case 3:
            cost += 50;
            goto case 1;
```

```
            default:
               Console.WriteLine("Invalid selection. Please select 1, 2, or 3.");
               break;
         }
         if (cost != 0)
            Console.WriteLine("Please insert {0} cents.", cost);
         Console.WriteLine("Thank you for your business.");
      }
   }
```

Input

```
2
```

Sample Output

```
Coffee sizes: 1=Small 2=Medium 3=Large
Please enter your selection: 2
Please insert 50 cents.
Thank you for your business.
```

Code Discussion

- In the preceding example, an integral type variable, n, was used for the switch cases. Notice that you can also use the string variable, `s`, directly. In this case, you can use switch cases like these:

  ```
  switch(s)
  {
     case "1":
        ...
     case "2":
        ...
  }
  ```

- Although fall through from one case label to another is not supported, it is allowed to stack case labels, for example:

  ```
     case 0:
     case 1:
        // do something;
  ```

C# Keywords | Compare to C++ | if | C. Grammar

Iteration Statements

You can create loops by using the iteration statements. Iteration statements cause embedded statements to be executed a number of times, subject to the loop-termination criteria. These statements are executed in order, except when a jump statement is encountered.

The following keywords are used in iteration statements:

- do
- for
- foreach
- in
- while

See Also

C# Keywords | Statements | 8.8 Iteration statements

do

The **do** statement executes a statement or a block of statements repeatedly until a specified expression evaluates to **false**. It takes the following form:

```
do statement while (expression);
```

where:

expression
An expression that can be implicitly converted to **bool** or a type that contains overloading of the true and false operators. The expression is used to test the loop-termination criteria.

statement
The embedded statement(s) to be executed.

Remarks

Unlike the while statement, the body loop of the **do** statement is executed at least once regardless of the value of the *expression*.

Example

```
// statements_do.cs
using System;
public class TestDoWhile
{
   public static void Main ()
   {
      int x;
      int y = 0;

      do
      {
         x = y++;
         Console.WriteLine(x);
      }

      while(y < 5);
   }
}
```

Output

```
0
1
2
3
4
```

Example

Notice in this example that although the condition evaluates to **false**, the loop will be executed once.

```
// statements_do2.cs
using System;
class DoTest {
   public static void Main()
   {
      int n = 10;
      do
      {
```

```
            Console.WriteLine("Current value of n is {0}", n);
            n++;
        } while (n < 6);
    }
}
```

Output

```
Current value of n is 10
```

See Also

C# Keywords | Compare to C++ | Iteration Statements | C. Grammar

for

The **for** loop executes a statement or a block of statements repeatedly until a specified expression evaluates to **false**. It takes the following form:

```
for ([initializers]; [expression]; [iterators]) statement
```

where:

initializers
A comma separated list of expressions or assignment statements to initialize the loop counters.
expression
An expression that can be implicitly converted to **bool** or a type that contains overloading of the true and false operators. The expression is used to test the loop-termination criteria.
iterators
Expression statement(s) to increment or decrement the loop counters.
statement
The embedded statement(s) to executed.

Remarks

The **for** statement executes the *statement* repeatedly as follows:

- First, the *initializers* are evaluated.
- Then, while the *expression* evaluates to **true**, the *statement*(s) are executed and the *iterators* are evaluated.
- When the *expression* becomes **false**, control is transferred outside the loop.

Because the test of *expression* takes place before the execution of the loop, a **for** statement executes zero or more times.

All of the expressions of the **for** statement are optional; for example, the following statement is used to write an infinite loop:

```
for (;;) {
   ...
}
```

Example

```
// statements_for.cs
// for loop
using System;
public class ForLoopTest
{
   public static void Main()
   {
      for (int i = 1; i <= 5; i++)
         Console.WriteLine(i);
   }
}
```

Output

```
1
2
3
4
5
```

See Also

foreach, in

The **foreach** statement repeats a group of embedded statements for each element in an array or an object collection. The **foreach** statement is used to iterate through the collection to get the desired information, but should not be used to change the contents of the collection to avoid unpredictable side effects. The statement takes the following form:

```
foreach (type identifier in expression) statement
```

where:

type
The type of *identifier*.

identifier
The iteration variable that represents the collection element. If the iteration variable is a value type, it is effectively a read-only variable that cannot be modified.

expression
Object collection or array expression. The type of the collection element must be convertible to the *identifier* type. Do not use an expression that evaluates to **null**.

Evaluates to a type that implements **IEnumerable** or a type that declares a **GetEnumerator** method. In the latter case, **GetEnumerator** should either return a type that implements **IEnumerator** or declares all the methods defined in **IEnumerator**.

statement
The embedded statement(s) to be executed.

Remarks

The embedded statements continue to execute for each element in the array or collection. After the iteration has been completed for all the elements in the collection, control is transferred to the next statement following the **foreach** block.

For more information on the **foreach** keyword, including code samples, see the following topics:

- Using foreach with Arrays
- Using foreach with Collections

See Also

C# Keywords | Iteration Statements | C. Grammar

Using foreach with Arrays

When used with an array, the foreach statement repeats the embedded statement(s) for each element in the array.

Example

In this example, an array of integers is searched for even and odd numbers. A counter for each type of number stores the number of occurrences.

```
// statements_foreach_arrays.cs
// Using foreach with arrays
using System;
class MainClass
{
   public static void Main()
   {
      int odd = 0, even = 0;
      int[] arr = new int [] {0,1,2,5,7,8,11};

      foreach (int i in arr)
      {
         if (i%2 == 0)
            even++;
         else
            odd++;
      }

      Console.WriteLine("Found {0} Odd Numbers, and {1} Even Numbers.",
                        odd, even) ;
   }
}
```

Output

```
Found 4 Odd Numbers, and 3 Even Numbers.
```

See Also

foreach, in | Arrays | Using foreach with Collections

Using foreach with Collections

To iterate through a collection, the collection must meet specific requirements. For example, in the following foreach statement:

```
foreach (ItemType item in myCollection)
```

`myCollection` must meet the following requirements:

- The collection type:
  - Must be one of the types: **interface**, **class**, or **struct**.
  - Must include an instance method named **GetEnumerator** that returns a type, for example, `Enumerator` (explained below).
- The type `Enumerator` (a class or struct) must contain:
  - A property named **Current** that returns `ItemType` or a type that can be converted to it. The property accessor returns the current element of the collection.
  - A **bool** method, named **MoveNext**, that increments the item counter and returns **true** if there are more items in the collection.

There are three approaches to using collections:

1. Create a collection using the above instructions. This collection can only be used in a C# program.
2. Create a generic collection using the above instructions, in addition to implementing the **IEnumerable** interface. This collection can be used from other languages such as Visual Basic.
3. Use one of the predefined collections in the collection classes.

The following examples demonstrate the three approaches.

Example	Demonstrates	Comment
Example 1	A C#-specific collection.	This example creates a collection by using the instructions above.
Example 2a	A generic collection.	This example creates a collection by using the instructions above and implements the **IEnumerable** and **IEnumerat or** interfaces.
Example 2b	A generic collection with a Dispose method.	Same as Example 2a except that a user-defined enumerat or inherits from **IDisposable** and implements a **Dispose** method.
Example 3	Using one of the predefined collection class es.	This example creates a **Hashtable** instance and uses the **Hashtable** class members to manipulate the collection. T he **Hashtable** class represents a dictionary of associated keys and values, implemented as a hash table.

For more information on the interfaces **IEnumerator** and **IEnumerable**, and the **Hashtable** class, see the System.Collections section in the .NET Framework SDK.

Example 1

```
// statements_foreach_collections.cs
// Using foreach with C#-specific collections:
using System;

// Declare the collection:
public class MyCollection
{
   int[] items;

   public MyCollection()
   {
      items = new int[5] {12, 44, 33, 2, 50};
   }
```

```
    public MyEnumerator GetEnumerator()
    {
       return new MyEnumerator(this);
    }

    // Declare the enumerator class:
    public class MyEnumerator
    {
       int nIndex;
       MyCollection collection;
       public MyEnumerator(MyCollection coll)
       {
          collection = coll;
          nIndex = -1;
       }

       public bool MoveNext()
       {
          nIndex++;
          return(nIndex < collection.items.GetLength(0));
       }

       public int Current
       {
          get
          {
             return(collection.items[nIndex]);
          }
       }
    }
 }

 public class MainClass
 {
    public static void Main()
    {
       MyCollection col = new MyCollection();
       Console.WriteLine("Values in the collection are:");

       // Display collection items:
       foreach (int i in col)
       {
          Console.WriteLine(i);
       }
    }
 }
```

Output

```
Values in the collection are:
12
44
33
2
50
```

Example 2a

This example repeats the same algorithm of Example 1, but uses a generic collection that can be enumerated from other languages such as Visual Basic. This type of collection must implement the **IEnumerable** interface from the **System.Collections** namespace.

```
// statements_foreach_generic_collection.cs
// Using foreach with a generic collection
```

```
using System;
using System.Collections;

// Declare the collection and implement the IEnumerable interface:
public class MyCollection: IEnumerable
{
   int[] items;
   public MyCollection()
   {
      items = new int[5] {12, 44, 33, 2, 50};
   }

   public MyEnumerator GetEnumerator()
   {
      return new MyEnumerator(this);
   }

   // Implement the GetEnumerator() method:
   IEnumerator IEnumerable.GetEnumerator()
   {
      return GetEnumerator();
   }

   // Declare the enumerator and implement the IEnumerator interface:
   public class MyEnumerator: IEnumerator
   {
      int nIndex;
      MyCollection collection;
      public MyEnumerator(MyCollection coll)
      {
         collection = coll;
         nIndex = -1;
      }

      public void Reset()
      {
         nIndex = -1;
      }

      public bool MoveNext() {
         nIndex++;
         return(nIndex < collection.items.GetLength(0));
      }

      public int Current
      {
         get
         {
            return(collection.items[nIndex]);
         }
      }

      // The current property on the IEnumerator interface:
      object IEnumerator.Current
      {
         get
         {
            return(Current);
         }
      }
   }
}

public class MainClass
{
   public static void Main(string [] args)
   {
      MyCollection col = new MyCollection();
```

```
        Console.WriteLine("Values in the collection are:");

        // Display collection items:
        foreach (int i in col)
        {
           Console.WriteLine(i);
        }
     }
  }
```

Output

```
Values in the collection are:
12
44
33
2
50
```

Example 2b

This example is the same as Example 2a except that it also implements a **Dispose** method. **Dispose** is implemented in a user-defined enumerator that inherits from **IDisposable**.

The **foreach** statement provides support for disposable enumerators. If an enumerator implements the **IDisposable** interface, the **foreach** statement guarantees that the **Dispose** method is called on the enumerator no matter how the enumeration loop is terminated.

```
// statements_foreach_generic_collection2.cs
// Using foreach with a generic collection
using System;
using System.Collections;

// Declare the collection and implement the IEnumerable interface:
public class MyCollection: IEnumerable
{
   int[] items;
   public MyCollection()
   {
      items = new int[5] {12, 44, 33, 2, 50};
   }

   public MyEnumerator GetEnumerator()
   {
      return new MyEnumerator(this);
   }

   // Implement the GetEnumerator() method:
   IEnumerator IEnumerable.GetEnumerator()
   {
      return GetEnumerator();
   }

   // Declare the enumerator and implement the IEnumerator
   // and IDisposable interfaces
   public class MyEnumerator: IEnumerator, IDisposable
   {
      int nIndex;
      MyCollection collection;
      public MyEnumerator(MyCollection coll)
      {
         collection = coll;
         nIndex = -1;
      }
```

```
      public void Reset()
      {
         nIndex = -1;
      }

      public bool MoveNext()
      {
         nIndex++;
         return (nIndex < collection.items.GetLength(0));
      }

      public int Current
      {
         get
         {
            return (collection.items[nIndex]);
         }
      }

      // The current property on the IEnumerator interface:
      object IEnumerator.Current
      {
         get
         {
            return (Current);
         }
      }

      public void Dispose()
      {
         Console.WriteLine("In Dispose");
         collection = null;
      }
   }
}

public class MainClass
{
   public static void Main(string [] args)
   {
      MyCollection col = new MyCollection();
      Console.WriteLine("Values in the collection are:");

      // Display collection items:
      foreach (int i in col)
      {
         Console.WriteLine(i);
      }
   }
}
```

Output

```
Values in the collection are:
12
44
33
2
50
In Dispose
```

Example 3

In this example, the predefined **Hashtable** collection class is used. By using the **System.Collections** namespace in your program, you can have access to the **Hashtable** class and its members. To add entries to the **Hashtable** object, use the **Add** method.

```
// statements_foreach_hashtable.cs
// Using the Hashtable collection class
using System;
using System.Collections;
public class MainClass
{
   public static void Main(string [] args)
   {
      // Declare a Hashtable object:
      Hashtable ziphash = new Hashtable();

      // Add entries using the Add() method:
      ziphash.Add("98008", "Bellevue");
      ziphash.Add("98052", "Redmond");
      ziphash.Add("98201", "Everett");
      ziphash.Add("98101", "Seattle");
      ziphash.Add("98371", "Puyallup");

      // Display contents:
      Console.WriteLine("Zip code       City");
      foreach (string zip in ziphash.Keys)
      {
         Console.WriteLine(zip + "          " + ziphash[zip]);
      }
   }
}
```

Output

```
Zip code       City
98201          Everett
98052          Redmond
98101          Seattle
98008          Bellevue
98371          Puyallup
```

foreach, in | Collection Classes Tutorial | Using foreach with Arrays

while

The **while** statement executes a statement or a block of statements until a specified expression evaluates to **false**. It takes the following form:

```
while (expression) statement
```

where:

expression
An expression that can be implicitly converted to **bool** or a type that contains overloading of the true and false operators. The expression is used to test the loop-termination criteria.

statement
The embedded statement(s) to be executed.

Remarks

Because the test of *expression* takes place before each execution of the loop, a **while** loop executes zero or more times.

A **while** loop can be terminated when a **break**, **goto**, **return**, or **throw** statement transfers control outside the loop. To pass control to the next iteration without exiting the loop, use the **continue** statement.

Example

```
// statements_while.cs
using System;
class WhileTest
{
   public static void Main()
   {
      int n = 1;

      while (n < 6)
      {
         Console.WriteLine("Current value of n is {0}", n);
         n++;
      }
   }
}
```

Output

```
Current value of n is 1
Current value of n is 2
Current value of n is 3
Current value of n is 4
Current value of n is 5
```

C# Keywords | Compare to C++ | Iteration Statements | C. Grammar

Jump Statements

Branching is performed using jump statements, which cause an immediate transfer of the program control. The following keywords are used in jump statements:

- break
- continue
- default
- goto
- return

See Also

C# Keywords | Statements | 8.9 Jump statements

break

The **break** statement terminates the closest enclosing loop or **switch** statement in which it appears. Control is passed to the statement that follows the terminated statement, if any. This statement takes the following form:

```
break;
```

Example

In this example, the conditional statement contains a counter that is supposed to count from 1 to 100; however, the **break** statement terminates the loop after 4 counts.

```
// statements_break.cs
using System;
class BreakTest
{
   public static void Main()
   {
      for (int i = 1; i <= 100; i++)
      {
         if (i == 5)
            break;
         Console.WriteLine(i);
      }
   }
}
```

Output

```
1
2
3
4
```

Example

This example demonstrates the use of **break** in a **switch** statement.

```
// statements_break2.cs
// break and switch
using System;
class Switch
{
   public static void Main()
   {
      Console.Write("Enter your selection (1, 2, or 3): ");
      string s = Console.ReadLine();
      int n = Int32.Parse(s);

      switch(n)
      {
         case 1:
            Console.WriteLine("Current value is {0}", 1);
            break;
         case 2:
            Console.WriteLine("Current value is {0}", 2);
            break;
         case 3:
            Console.WriteLine("Current value is {0}", 3);
            break;
         default:
```

```
            Console.WriteLine("Sorry, invalid selection.");
            break;
        }
    }
}
```

Input

```
1
```

Sample Output

```
Enter your selection (1, 2, or 3): 1
Current value is 1
```

If you entered `4`, the output would be:

```
Enter your selection (1, 2, or 3): 4
Sorry, invalid selection.
```

C# Keywords | Compare to C++ | switch | Jump Statements | C. Grammar

continue

The **continue** statement passes control to the next iteration of the enclosing iteration statement in which it appears. It takes the following form:

```
continue;
```

Example

In this example, a counter is initialized to count from 1 to 10. By using the **continue** statement in conjunction with the expression `(i < 9)`, the statements between **continue** and the end of the **for** body are skipped.

```
// statements_continue.cs
using System;
class ContinueTest
{
   public static void Main()
   {
      for (int i = 1; i <= 10; i++)
      {
         if (i < 9)
            continue;
         Console.WriteLine(i);
      }
   }
}
```

Output

```
9
10
```

See Also

C# Keywords | Compare to C++ | Jump Statements | C. Grammar

goto

The **goto** statement transfers the program control directly to a labeled statement. It takes one of the following forms:

```
goto identifier;
goto case constant-expression;
goto default;
```

where:

identifier
A label.

constant-expression
A switch-case label.

Remarks

In the first form, the *identifier* indicates a label located in the current body, the same lexical scope, or an enclosing scope of the **goto** statement.

A common use of **goto** is to transfer control to a specific switch-case label or the default label in a **switch** statement.

The **goto** statement is also useful to get out of deeply nested loops.

A warning message may be issued if the label has never been referenced in the program. For more information on labels, see 3.3 Declarations.

Example

For an example of using **goto** to transfer control to a specific switch-case label, see the switch example.

Example

The following example demonstrates using **goto** to break out from nested loops.

```
// statements_goto.cs
// Nested search loops
using System;
public class GotoTest1
{
   public static void Main()
   {
      int x = 200, y = 4;
      int count = 0;
      string[,] myArray = new string[x,y];

      // Initialize the array:
      for (int i = 0; i < x; i++)
         for (int j = 0; j < y; j++)
            myArray[i,j] = (++count).ToString();

      // Read input:
      Console.Write("Enter the number to search for: ");

      // Input a string:
      string myNumber = Console.ReadLine();

      // Search:
      for (int i = 0; i < x; i++)
         for (int j = 0; j < y; j++)
            if (myArray[i,j].Equals(myNumber))
               goto Found;

      Console.WriteLine("The number {0} was not found.", myNumber);
      goto Finish;
```

```
   Found:
      Console.WriteLine("The number {0} is found.", myNumber);

   Finish:
      Console.WriteLine("End of search.");
   }
}
```

Input

```
44
```

Sample Output

```
Enter the number to search for: 44
The number 44 is found.
End of search.
```

Example

```
// statements_goto2.cs
// CS0159 expected
// Labels outside the scope
using System;
class UnreachableCode
{
   public static void Main()
   {
      int x = 55;
      Console.WriteLine("x = {0}", x);

      if (x == 55)
      {
         x = 135;
         goto A;   // Error
      }

      x = x + 1;

      for (int i=1; i<=5; i++)
      {
         A: Console.WriteLine(i);
      }

      Console.WriteLine("x = {0}", x);
   }
}
```

In the preceding example, the **goto** statement is referencing a label `A` outside its scope. The compiler will issue the error message:

```
No such label 'A' within the scope of the goto statement
```

A warning message may also be issued because the label has never been referenced.

If you move the label `A` to the beginning of the **for** loop, the program would compile and run normally, that is:

```
A:      for (int i=1; i<=5; i++) {   // Now the program compiles.
```

See Also

C# Keywords | Compare to C++ | Jump Statements | C. Grammar

return

The **return** statement terminates execution of the method in which it appears and returns control to the calling method. It can also return the value of the optional *expression*. If the method is of the type **void**, the **return** statement can be omitted. This statement takes the following form:

```
return [expression];
```

where:

expression
The value returned by a method. The *expression* is not used with methods of the type **void**.

Example

In the following example, the method `A()` returns the variable `Area` as a **double** value.

```
// statements_return.cs
using System;
class ReturnTest
{
   static double CalculateArea(int r)
   {
      double area;
      area = r*r*Math.PI;
      return area;
   }

   public static void Main()
   {
      int radius = 5;
      Console.WriteLine("The area is {0:0.00}", CalculateArea(radius));
   }
}
```

Output

```
The area is 78.54
```

C# Keywords | Compare to C++ | Jump Statements | C. Grammar

Exception Handling Statements

C# provides built-in support for handling anomalous situations, known as exceptions, which may occur during the execution of your program. These exceptions are handled by code that is outside the normal flow of control. The **try**, **throw**, **catch**, and **finally** keywords implement exception handling.

The following exception handling topics are explained in this section:

- throw
- try-catch
- try-finally
- try-catch-finally

See Also

C# Keywords | Statements | 8.10 The try statement

throw

The **throw** statement is used to signal the occurrence of an anomalous situation (exception) during the program execution. It takes the following form:

```
throw [expression];
```

where:

expression
The exception object. This is omitted when rethrowing the current exception object in a **catch** clause.

Remarks

The thrown exception is an object whose class is derived from **System.Exception**, for example:

```
class MyException : System.Exception {}
throw new MyException();
```

Usually the **throw** statement is used with try-catch or try-finally statements. When an exception is thrown, the program looks for the **catch** statement that handles this exception.

You can also rethrow a caught exception using the **throw** statement. For more information and examples, see try-catch, 8.10 The try statement and Throwing Exceptions.

Example

This example demonstrates how to throw an exception using the **throw** statement.

```
// throw example
using System;
public class ThrowTest
{
   public static void Main()
   {
      string s = null;

      if (s == null)
      {
         throw(new ArgumentNullException());
      }

      Console.Write("The string s is null"); // not executed
   }
}
```

Output

The following exception occurs:

```
System.ArgumentNullException
```

Example

See the try-catch, try-finally, and try-catch-finally examples.

See Also

Compare to C++ | C# Keywords | Exception Handling Statements | Throwing Exceptions | C. Grammar

try-catch

The try-catch statement consists of a **try** block followed by one or more **catch** clauses, which specify handlers for different exceptions. This statement takes one of the following forms:

```
try try-block
catch (exception-declaration-1) catch-block-1
catch (exception-declaration-2) catch-block-2
...
try try-block catch catch-block
```

where:

try-block
Contains the code segment expected to raise the exception.
exception-declaration, *exception-declaration-1*, *exception-declaration-2*
The exception object declaration.
catch-block, *catch-block-1*, *catch-block-2*
Contains the exception handler.

Remarks

The *try-block* contains the guarded code block that may cause the exception. The block is executed until an exception is thrown or it is completed successfully. For example, the following attempt to cast a **null** object raises the **NullReferenceException** exception:

```
object o2 = null;
try
{
   int i2 = (int) o2;   // Error
}
```

The **catch** clause can be used without arguments, in which case it catches any type of exception, and referred to as the general catch clause. It can also take an object argument derived from **System.Exception**, in which case it handles a specific exception. For example:

```
catch (InvalidCastException e)
{
}
```

It is possible to use more than one specific **catch** clause in the same try-catch statement. In this case, the order of the **catch** clauses is important because the **catch** clauses are examined in order. Catch the more specific exceptions before the less specific ones.

A throw statement can be used in the **catch** block to rethrow the exception, which has been caught by the **catch** statement. For example:

```
catch (InvalidCastException e)
{
   throw (e);   // Rethrowing exception e
}
```

If you want to rethrow the exception currently handled by a parameterless **catch** clause, use the **throw** statement without arguments. For example:

```
catch
{
   throw;
}
```

When inside a **try** block, only initialize variables that are declared therein; otherwise, an exception can occur before the execution of the block is completed. For example, in the following code example, the variable `x` is initialized inside the **try** block. An attempt to use this variable outside the **try** block in the `Write(x)` statement will generate the compiler error: Use of unassigned local variable.

```
public static void Main()
{
   int x;
   try
   {
      x = 123;   //   Don't do that.
      // ...
   }
   catch
   {
      // ...
   }
   Console.Write(x);   // Error: Use of unassigned local variable 'x'.
}
```

For more information on **catch**, see try-catch-finally.

Example

In this example, the **try** block contains a call to the method `MyFn()` that may cause an exception. The **catch** clause contains the exception handler that simply displays a message on the screen. When the **throw** statement is called from inside `MyFn()`, the system looks for the **catch** statement and displays the message `Exception caught`.

```
// Rethrowing exceptions:
using System;
class MyClass
{
   public static void Main()
   {
      MyClass x = new MyClass();
      try
      {
         string s = null;
         x.MyFn(s);
      }

      catch (Exception e)
      {
         Console.WriteLine("{0} Exception caught.", e);
      }
   }

   public void MyFn(string s)
   {
      if (s == null)
         throw(new ArgumentNullException());
   }
}
```

Output

The following exception occurs:

```
System.ArgumentNullException
```

Example

In this example, two catch statements are used. The most specific exception, which comes first, is caught.

```
// Ordering catch clauses
using System;
class MyClass
{
   public static void Main()
   {
      MyClass x = new MyClass();
      try
      {
         string s = null;
         x.MyFn(s);
      }

      // Most specific:
      catch (ArgumentNullException e)
      {
         Console.WriteLine("{0} First exception caught.", e);
      }

      // Least specific:
      catch (Exception e)
      {
         Console.WriteLine("{0} Second exception caught.", e);
      }

   }

   public void MyFn(string s)
   {
      if (s == null)
         throw new ArgumentNullException();
   }
}
```

Output

The following exception occurs:

```
System.ArgumentNullException
```

In the preceding example, if you start with the least specific catch clause, you will get the error message:

```
A previous catch clause already catches all exceptions of this or a super type ('System.Exception')
```

However, to catch the least specific exception, replace the throw statement by the following one:

```
throw new Exception();
```

See Also

C# Keywords | Compare to C++ | Exception Handling Statements | throw | try-finally | Throwing Exceptions | C. Grammar

try-finally

The **finally** block is useful for cleaning up any resources allocated in the try block. Control is always passed to the finally block regardless of how the try block exits. This statement takes the following form:

```
try try-block finally finally-block
```

where:

try-block
Contains the code segment expected to raise the exception.

finally-block
Contains the exception handler and the cleanup code.

Remarks

Whereas **catch** is used to handle exceptions that occur in a statement block, **finally** is used to guarantee a statement block of code executes regardless of how the preceding **try** block is exited.

Example

In this example, there is one invalid conversion statement that causes an exception. When you run the program, you get a run-time error message, but the **finally** clause will still be executed and display the output.

```
// try-finally
using System;
public class TestTryFinally
{
   public static void Main()
   {
      int i = 123;
      string s = "Some string";
      object o = s;

      try
      {
         // Invalid conversion; o contains a string not an int
         i = (int) o;
      }

      finally
      {
         Console.Write("i = {0}", i);
      }
   }
}
```

Output

The following exception occurs:

```
System.InvalidCastException
```

Although an exception was caught, the output statement included in the **finally** block will still be executed, that is:

```
i = 123
```

For more information on **finally**, see try-catch-finally.

See Also

try-catch-finally

A common usage of **catch** and **finally** together is to obtain and use resources in a **try** block, deal with exceptional circumstances in a **catch** block, and release the resources in the **finally** block.

Example

```
// try-catch-finally
using System;
public class EHClass
{
   public static void Main ()
   {
      try
      {
         Console.WriteLine("Executing the try statement.");
         throw new NullReferenceException();
      }

      catch(NullReferenceException e)
      {
         Console.WriteLine("{0} Caught exception #1.", e);
      }

      catch
      {
         Console.WriteLine("Caught exception #2.");
      }

      finally
      {
         Console.WriteLine("Executing finally block.");
      }
   }
}
```

Output

```
Executing the try statement.
System.NullReferenceException: Attempted to dereference a null object reference.
   at EHClass.Main() Caught exception #1.
Executing finally block.
```

For more information and examples on rethrowing exceptions, see try-catch, 8.10 The try statement and Throwing Exceptions.

See Also

C# Keywords | Compare to C++ | Exception Handling Statements | throw | Throwing Exceptions | C. Grammar

Checked and Unchecked

C# statements can execute in either checked or unchecked context. In a checked context, arithmetic overflow raises an exception. In an unchecked context, arithmetic overflow is ignored and the result is truncated.

- checked Specify checked context.
- unchecked Specify unchecked context.

If neither **checked** nor **unchecked** is specified, the default context depends on external factors such as compiler options.

The following operations are affected by the overflow checking:

- Expressions using the following predefined operators on integral types:

  ++ — - (unary) + - * /

- Explicit numeric conversions between integral types.

The /checked compiler option lets you specify checked or unchecked context for all integer arithmetic statements that are not explicitly in the scope of a **checked** or **unchecked** keyword.

See Also

C# Keywords | Statements | 8.11 The checked and unchecked statements

checked

The **checked** keyword is used to control the overflow-checking context for integral-type arithmetic operations and conversions. It can be used as an operator or a statement according to the following forms.

The **checked** statement:

```
checked block
```

The **checked** operator:

```
checked (expression)
```

where:

block
The statement block that contains the expressions to be evaluated in a checked context.

expression
The expression to be evaluated in a checked context. Notice that the expression must be in parentheses ( ).

Remarks

In a checked context, if an expression produces a value that is outside the range of the destination type, the result depends on whether the expression is constant or non-constant. Constant expressions cause compile time errors, while non-constant expressions are evaluated at run time and raise exceptions.

If neither **checked** nor unchecked is used, a constant expression uses the default overflow checking at compile time, which is **checked**. Otherwise, if the expression is non-constant, the run-time overflow checking depends on other factors such as compiler options and environment configuration.

The following three examples demonstrate the **checked** and **unchecked** operators on non-constant expressions. All use the same algorithm, but different checking contexts. The overflow checking is evaluated at run time.

- Example 1: Using a **checked** expression.
- Example 2: Using an **unchecked** expression.
- Example 3: Using default overflow checking.

Only the first example throws an overflow exception at run time, in which case, you have the option to go to the debugging mode, or abort the program execution. The other two examples produce truncated values.

See also the unchecked examples on using the **checked** and **unchecked** statements.

Example 1

```
// statements_checked.cs
// The overflow of non-constant expressions is checked at run time
using System;

class OverFlowTest
{
   static short x = 32767;   // Max short value
   static short y = 32767;

   // Using a checked expression
   public static int myMethodCh()
   {
      int z = 0;

      try
      {
        z =  checked((short)(x + y));
      }
      catch (System.OverflowException e)
```

```
      {
        System.Console.WriteLine(e.ToString());
      }
      return z;   // Throws the exception OverflowException
   }

   public static void Main()
   {
      Console.WriteLine("Checked output value is: {0}", myMethodCh());
   }
}
```

Sample Output

When you run the program, it throws the exception `OverflowException`. You can debug the program or abort execution.

```
System.OverflowException: An exception of type System.OverflowException was thrown.
   at OverFlowTest.myMethodCh()
Checked output value is: 0
```

Example 2

```
// statements_checked2.cs
// Using unchecked expressions
// The overflow of non-constant expressions is checked at run time
using System;

class OverFlowTest
{
   static short x = 32767;   // Max short value
   static short y = 32767;

   public static int myMethodUnch()
   {
      int z =  unchecked((short)(x + y));
      return z;   // Returns -2
   }

   public static void Main()
   {
      Console.WriteLine("Unchecked value is: {0}", myMethodUnch());
   }
}
```

Output

```
Unchecked value is: -2
```

Example 3

```
// statements_checked3.cs
// Using default overflow checking
// The overflow of non-constant expressions is checked at run time
using System;

class OverFlowTest
{
   static short x = 32767;   // Max short value
   static short y = 32767;

   public static int myMethodUnch()
```

```
    {
       int z =  (short)(x + y);
       return z;   // Returns -2
    }

    public static void Main()
    {
       Console.WriteLine("Default checking ouput value is: {0}", myMethodUnch());
    }
 }
```

Output

```
Default checking ouput value is: -2
```

C# Keywords | Checked and Unchecked | unchecked

unchecked

The **unchecked** keyword is used to control the overflow-checking context for integral-type arithmetic operations and conversions. It can be used as an operator or a statement according to the following forms.

The **unchecked** statement:

```
unchecked block
```

The **unchecked** operator:

```
unchecked (expression)
```

where:

block
The statement block that contains the expressions to be evaluated in an unchecked context.

expression
The expression to be evaluated in an unchecked context. Notice that the expression must be in parentheses ( ).

Remarks

In an unchecked context, if an expression produces a value that is outside the range of the destination type, the result is truncated.

If neither checked nor **unchecked** is used, a constant expression uses the default overflow checking at compile time, which is **checked**. Otherwise, if the expression is non-constant, the run-time overflow checking depends on other factors such as compiler options and environment configuration.

The following are three examples demonstrating the checked and unchecked statements. All use the same algorithm, but different checking contexts. The three examples are using constant expressions, for which the overflow checking is evaluated at compile time.

- Example 1: Using the **unchecked** statement.
- Example 2: Using default overflow checking.
- Example 3: Using the **checked** statement.

Only the **unchecked** statement produces a truncated value. The other two statements produce compile-time errors.

See also the checked examples on using the **checked** and **unchecked** operators.

Example 1

```
// statements_unchecked.cs
// Using the unchecked statement with constant expressions
// Overflow is checked at compile time
using System;

class TestClass
{
   const int x = 2147483647;   // Max int
   const int y = 2;

   public int MethodUnCh()
   {
      // Unchecked statement:
      unchecked
      {
         int z = x * y;
         return z;   // Returns -2
      }
   }

   public static void Main()
```

```
    {
       TestClass myObject = new TestClass();
       Console.WriteLine("Unchecked output value: {0}",
          myObject.MethodUnCh());
    }
 }
```

Output

```
Unchecked output value: -2
```

Example 2

```
// statements_unchecked2.cs
// CS0220 expected
// Using default overflow checking with constant expressions
// Overflow is checked at compile time
using System;

class TestClass
{
   const int x = 2147483647;   // Max int
   const int y = 2;

   public int MethodDef()
   {
      // Using default overflow checking:
      int z = x * y;
      return z;   // Compiler error
   }

   public static void Main()
   {
      TestClass myObject = new TestClass();
      Console.WriteLine("Default checking value: {0}",
         myObject.MethodDef());
   }
}
```

Output

The warning: `The operation overflows at compile time in checked mode.`

Example 3

```
// statements_unchecked3.cs
// CS0220 expected
// Using the checked statement with constant expressions
// Overflow is checked at compile time
using System;

class TestClass
{
   const int x = 2147483647;   // Max int
   const int y = 2;

   public int MethodCh()
   {
      // Checked statement:
      checked
      {
         int z = (x * y);
```

```
            return z;   // Compiler error
        }
    }

    public static void Main()
    {
        TestClass myObject = new TestClass();
        Console.WriteLine("Checked value: {0}", myObject.MethodCh());
    }
}
```

Output

The warning: `The operation overflows at compile time in checked mode.`

C# Keywords | Checked and Unchecked | checked

fixed Statement

Prevents relocation of a variable by the garbage collector. It takes the following form:

```
fixed ( type* ptr = expr ) statement
```

where:

type
An unmanaged type or void.
ptr
A pointer name.
expr
An expression that is implicitly convertible to *type**.
statement
Executable statement or block.

Remarks

The **fixed** statement is only permitted in an unsafe context.

The **fixed** statement sets a pointer to a managed variable and "pins" that variable during the execution of *statement*. Without **fixed**, pointers to managed variables would be of little use since garbage collection could relocate the variables unpredictably. (In fact, the C# compiler will not allow you to set a pointer to a managed variable except in a **fixed** statement.)

```
// assume class Point { public int x, y; }
Point pt = new Point();    // pt is a managed variable, subject to g.c.
fixed ( int* p = &pt.x ){  // must use fixed to get address of pt.x and
    *p = 1;                //   pin pt in place while we use the pointer
}
```

You can initialize a pointer with the address of an array or a string:

```
fixed (int* p = arr) ...  // equivalent to p = &arr[0]
fixed (char* p = str) ... // equivalent to p = &str[0]
```

You can initialize multiple pointers, as long as they are all of the same type:

```
fixed (byte* ps = srcarray, pd = dstarray) {...}
```

To initialize pointers of different type, simply nest **fixed** statements:

```
fixed (int* p1 = &p.x)
   fixed (double* p2 = &array[5])
      // do something with p1 and p2
```

Pointers initialized in fixed statements cannot be modified.

After *statement* is executed, any pinned variables are unpinned and subject to garbage collection. Therefore, do not point to those variables outside the **fixed** statement.

In unsafe mode, you can allocate memory on the stack, where it is not subject to garbage collection and therefore does not need to be pinned. See stackalloc for more information.

Example

```
// statements_fixed.cs
// compile with: /unsafe
using System;
```

```
class Point {
   public int x, y;
}

class FixedTest
{
   // unsafe method: takes pointer to int
   unsafe static void SquarePtrParam (int* p)
   {
      *p *= *p;
   }

   unsafe public static void Main()
   {
      Point pt = new Point();
      pt.x = 5;
      pt.y = 6;
      // pin pt in place:
      fixed (int* p = &pt.x)
      {
         SquarePtrParam (p);
      }
      // pt now unpinned
      Console.WriteLine ("{0} {1}", pt.x, pt.y);
   }
}
```

Output

```
25 6
```

See Also

C# Keywords | unsafe | Unsafe Code Tutorial | A.6 The fixed statement

lock Statement

The **lock** keyword marks a statement block as a critical section by obtaining the mutual-exclusion lock for a given object, executing a statement, and then releasing the lock. This statement takes the following form:

```
lock(expression) statement_block
```

where:

expression
Specifies the object that you want to lock on. *expression* must be a reference type.

Typically, *expression* will either be this, if you want to protect an instance variable, or typeof**(***class***)**, if you want to protect a static variable (or if the critical section occurs in a static method in the given class).

statement_block
The statements of the critical section.

Remarks

lock ensures that one thread does not enter a critical section while another thread is in the critical section of code. If another thread attempts to enter a locked code, it will wait (block) until the object is released.

8.12 The lock statement discusses **lock**.

Example 1

The following sample shows a simple use of threads in C#.

```
// statements_lock.cs
using System;
using System.Threading;

class ThreadTest
{
   public void runme()
   {
      Console.WriteLine("runme called");
   }

   public static void Main()
   {
      ThreadTest b = new ThreadTest();
      Thread t = new Thread(new ThreadStart(b.runme));
      t.Start();
   }
}
```

Output

```
runme called
```

Example 2

The following sample uses threads and **lock**. As long as the **lock** statement is present, the statement block is a critical section and `balance` will never become a negative number.

```
// statements_lock2.cs
using System;
using System.Threading;
```

```
class Account
{
   int balance;

   Random r = new Random();

   public Account(int initial)
   {
      balance = initial;
   }

   int Withdraw(int amount)
   {

      // This condition will never be true unless the lock statement
      // is commented out:
      if (balance < 0)
      {
         throw new Exception("Negative Balance");
      }

      // Comment out the next line to see the effect of leaving out
      // the lock keyword:
      lock (this)
      {
         if (balance >= amount)
         {
            Console.WriteLine("Balance before Withdrawal :  " + balance);
            Console.WriteLine("Amount to Withdraw        : -" + amount);
            balance = balance - amount;
            Console.WriteLine("Balance after Withdrawal  :  " + balance);
            return amount;
         }
         else
         {
            return 0; // transaction rejected
         }
      }
   }

   public void DoTransactions()
   {
      for (int i = 0; i < 100; i++)
      {
         Withdraw(r.Next(1, 100));
      }
   }
}

class Test
{
   public static void Main()
   {
      Thread[] threads = new Thread[10];
      Account acc = new Account (1000);
      for (int i = 0; i < 10; i++)
      {
         Thread t = new Thread(new ThreadStart(acc.DoTransactions));
         threads[i] = t;
      }
      for (int i = 0; i < 10; i++)
      {
         threads[i].Start();
      }
   }
}
```

C# Keywords | Statements | Threading Tutorial | 8.12 The lock statement | MethodImplAttributes Enumeration

Method Parameters

If a parameter is declared for a method without **ref** or **out**, the parameter can have a value associated with it. That value can be changed in the method, but the changed value will not be retained when control passes back to the calling procedure. By using a method parameter keyword, you can change this behavior.

This section describes the keywords you can use when declaring method parameters:

- params
- ref
- out

See Also

C# Keywords

params

The **params** keyword lets you specify a method parameter that takes an argument where the number of arguments is variable.

No additional parameters are permitted after the **params** keyword in a method declaration, and only one **params** keyword is permitted in a method declaration.

Example

```
// cs_params.cs
using System;
public class MyClass
{

   public static void UseParams(params int[] list)
   {
      for ( int i = 0 ; i < list.Length ; i++ )
         Console.WriteLine(list[i]);
      Console.WriteLine();
   }

   public static void UseParams2(params object[] list)
   {
      for ( int i = 0 ; i < list.Length ; i++ )
         Console.WriteLine(list[i]);
      Console.WriteLine();
   }

   public static void Main()
   {
      UseParams(1, 2, 3);
      UseParams2(1, 'a', "test");

      int[] myarray = new int[3] {10,11,12};
      UseParams(myarray);
   }
}
```

Output

```
1
2
3

1
a
test

10
11
12
```

See Also

C# Keywords | Method Parameters

ref

The **ref** method parameter keyword on a method parameter causes a method to refer to the same variable that was passed into the method. Any changes made to the parameter in the method will be reflected in that variable when control passes back to the calling method.

To use a **ref** parameter, the argument must explicitly be passed to the method as a **ref** argument. The value of a **ref** argument will be passed to the **ref** parameter.

An argument passed to a **ref** parameter must first be initialized. Compare this to an out parameter, whose argument does not have to be explicitly initialized before being passed to an **out** parameter.

A property is not a variable and cannot be passed as a **ref** parameter.

An overload will occur if declarations of two methods differ only in their use of **ref**. However, it is not possible to define an overload that only differs by **ref** and **out**. For example, the following overload declarations are valid:

```
class MyClass
{
   public void MyMethod(int i) {i = 10;}
   public void MyMethod(ref int i) {i = 10;}
}
```

but the following overload declarations are invalid:

```
class MyClass
{
   public void MyMethod(out int i) {i = 10;}
   public void MyMethod(ref int i) {i = 10;}
}
```

For information on passing an array, see Passing Arrays Using ref and out.

Example

```
// cs_ref.cs
using System;
public class MyClass
{
   public static void TestRef(ref char i)
   {
      // The value of i will be changed in the calling method
      i = 'b';
   }

   public static void TestNoRef(char i)
   {
      // The value of i will be unchanged in the calling method
      i = 'c';
   }

   // This method passes a variable as a ref parameter; the value of the
   // variable is changed after control passes back to this method.
   // The same variable is passed as a value parameter; the value of the
   // variable is unchanged after control is passed back to this method.
   public static void Main()
   {

      char i = 'a';    // variable must be initialized
      TestRef(ref i);  // the arg must be passed as ref
      Console.WriteLine(i);
      TestNoRef(i);
      Console.WriteLine(i);
   }
```

```
}
```

Output

```
b
b
```

See Also

C# Keywords | Method Parameters

out

The **out** method parameter keyword on a method parameter causes a method to refer to the same variable that was passed into the method. Any changes made to the parameter in the method will be reflected in that variable when control passes back to the calling method.

Declaring an **out** method is useful when you want a method to return multiple values. A method that uses an **out** parameter can still return a value. A method can have more than one **out** parameter.

To use an **out** parameter, the argument must explicitly be passed to the method as an **out** argument. The value of an **out** argument will not be passed to the **out** parameter.

A variable passed as an **out** argument need not be initialized. However, the **out** parameter must be assigned a value before the method returns.

A property is not a variable and cannot be passed as an **out** parameter.

An overload will occur if declarations of two methods differ only in their use of **out**. However, it is not possible to define an overload that only differs by **ref** and **out**. For example, the following overload declarations are valid:

```
class MyClass
{
   public void MyMethod(int i) {i = 10;}
   public void MyMethod(out int i) {i = 10;}
}
```

while the following overload declarations are invalid:

```
class MyClass
{
   public void MyMethod(out int i) {i = 10;}
   public void MyMethod(ref int i) {i = 10;}
}
```

For information on passing an array, see Passing Arrays Using ref and out.

Example

```
// cs_out.cs
using System;
public class MyClass
{
   public static int TestOut(out char i)
   {
      i = 'b';
      return -1;
   }

   public static void Main()
   {
      char i;   // variable need not be initialized
      Console.WriteLine(TestOut(out i));
      Console.WriteLine(i);
   }
}
```

Output

```
-1
b
```

C# Keywords | Method Parameters

Namespaces

This section describes the keywords that are associated with using namespaces:

- namespace
- using

See Also

C# Keywords

namespace

The **namespace** keyword is used to declare a scope. This namespace scope lets you organize code and gives you a way to create globally-unique types.

```
namespace name[.name1] ...] {
   type-declarations
}
```

where:

name, *name1*
A namespace name can be any legal identifier. A namespace name can contain periods.
type-declarations
Within a namespace, you can declare one or more of the following types:

- another namespace
- class
- interface
- struct
- enum
- delegate

Remarks

Even if you do not explicitly declare one, a default namespace is created. This unnamed namespace, sometimes called the global namespace, is present in every file. Any identifier in the global namespace is available for use in a named namespace.

Namespaces implicitly have public access and this is not modifiable.

3.8 Namespace and type names and 9. Namespaces discuss namespaces in more detail.

See 7.3 Member lookup for information about how the compiler resolves names.

See Access Modifiers for a discussion of the access modifiers you can assign to elements within a namespace.

It is possible to define a namespace in two or more declarations. For example, the following sample defines both classes as part of namespace `MyCompany`:

```
namespace MyCompany.Proj1
{
   class MyClass
   {
   }
}

namespace MyCompany.Proj1
{
   class MyClass1
   {
   }
}
```

Example

The following example shows how to call a static method in a nested namespace.

```
// cs_namespace_keyword.cs
using System;
namespace SomeNameSpace
{
   public class MyClass
   {
```

```
        public static void Main()
        {
           Nested.NestedNameSpaceClass.SayHello();
        }
     }

     namespace Nested   // a nested namespace
     {
        public class NestedNameSpaceClass
        {
           public static void SayHello()
           {
              Console.WriteLine("Hello");
           }
        }
     }
  }
```

Output

```
Hello
```

See Also

C# Keywords | using

using

The **using** keyword has two major uses:

- using Directive Creates an alias for a namespace or imports types defined in other namespaces.
- using Statement Defines a scope at the end of which an object will be disposed.

See Also

C# Keywords | namespace

using Directive

The **using** directive has two uses:

- Create an alias for a namespace (a **using** alias).
- Permit the use of types in a namespace, such that, you do not have to qualify the use of a type in that namespace (a **using** directive).

```
using [alias = ]class_or_namespace;
```

where:

alias (optional)
A user-defined symbol that you want to represent a namespace. You will then be able to use *alias* to represent the namespace name.

class_or_namespace
The namespace name that you want to either use or alias, or the class name that you want to alias.

Remarks

Create a **using** alias to make it easier to qualify an identifier to a namespace or class.

Create a **using** directive to use the types in a namespace without having to specify the namespace. A **using** directive does not give you access to any namespaces that may be nested in the namespace you specify.

Namespaces come in two categories: user-defined and system-defined. User-defined namespaces are namespaces defined in your code. See the documentation for the .NET Framework for a list of the system-defined namespaces.

For examples on referencing methods in other assemblies, see Creating and Using C# DLLs.

Example

The following sample shows how to define and use a **using** alias for a namespace:

```
// cs_using_directive.cs
using MyAlias = MyCompany.Proj.Nested;  // define an alias to represent a namespace

namespace MyCompany.Proj
{
   public class MyClass
   {
      public static void DoNothing()
      {
      }
   }

   namespace Nested   // a nested namespace
   {
      public class ClassInNestedNameSpace
      {
         public static void SayHello()
         {
            System.Console.WriteLine("Hello");
         }
      }
   }

}

public class UnNestedClass
{
   public static void Main()
   {
      MyAlias.ClassInNestedNameSpace.SayHello();   // using alias
```

```
    }
}
```

Output

```
Hello
```

Example

The following sample shows how to define a **using** directive and a **using** alias for a class:

```
// cs_using_directive2.cs
using System;   // using directive
using AliasToMyClass = NameSpace1.MyClass;   // using alias for a class

namespace NameSpace1
{
   public class MyClass
   {
      public override string ToString()
      {
         return "You are in NameSpace1.MyClass";
      }
   }
}

namespace NameSpace2
{
   class MyClass
   {
   }
}

namespace NameSpace3
{
   using NameSpace1;   // using directive
   using NameSpace2;   // using directive

   class Test
   {
      public static void Main()
      {
         AliasToMyClass somevar = new AliasToMyClass();
         Console.WriteLine(somevar);
      }
   }
}
```

Output

```
You are in NameSpace1.MyClass
```

See Also

C# Keywords | namespace | using Statement

using Statement

The **using** statement defines a scope at the end of which an object will be disposed.

```
using (expression | type identifier = initializer) statement
```

where:

expression
An expression you want to call **Dispose** on upon exiting the **using** statement.
type
The type of *identifier*.
identifier
The name, or identifier, of the type *type*. It is possible to define more than one *identifier* of type *type*. Precede each *identifier* **=** *initializer* with a comma.
initializer
An expression that creates an object.
statement
The embedded statement or statements to executed.

Remarks

You create an instance in a **using** statement to ensure that **Dispose** is called on the object when the **using** statement is exited. A **using** statement can be exited either when the end of the **using** statement is reached or if, for example, an exception is thrown and control leaves the statement block before the end of the statement.

The object you instantiate must implement the **System.IDisposable** interface.

Example

```
// cs_using_statement.cs
// compile with /reference:System.Drawing.dll
using System.Drawing;
class a
{
   public static void Main()
   {
      using (Font MyFont = new Font("Arial", 10.0f), MyFont2 = new Font("Arial", 10.0f))
      {
         // use MyFont and MyFont2
      }   // compiler will call Dispose on MyFont and MyFont2

      Font MyFont3 = new Font("Arial", 10.0f);
      using (MyFont3)
      {
         // use MyFont3
      }   // compiler will call Dispose on MyFont3

   }
}
```

C# Keywords | using Directive | Implementing Finalize and Dispose to Clean Up Unmanaged Resources

Operator Keywords

This section introduces the following keywords:

- as Convert an object to a compatible type.
- is Check the run-time type of an object.
- new
    - new operator Create objects.
    - new modifier Hide an inherited member.
- sizeof Obtain the size of a type.
- typeof Obtain the **System.Type** object for a type.
- true Return the boolean value true.
- false Return the boolean value false.
- stackalloc Allocate a block of memory on the stack.

The following keywords, which can be used as operators and as statements, are covered in the Statements section:

- checked Specify checked context.
- unchecked Specify unchecked context.

See Also

C# Keywords | C# Operators

as

The **as** operator is used to perform conversions between compatible types. The **as** operator is used in an expression of the form:

```
expression as type
```

where:

expression
An expression of a reference type.
type
A reference type.

Remarks

The **as** operator is like a cast except that it yields null on conversion failure instead of raising an exception. More formally, an expression of the form:

```
expression as type
```

is equivalent to:

```
expression is type ? (type)expression : (type)null
```

except that `expression` is evaluated only once.

Note that the **as** operator only performs reference conversions and boxing conversions. The **as** operator cannot perform other conversions, such as user-defined conversions, which should instead be performed using cast expressions.

Example

```
// cs_keyword_as.cs
// The as operator
using System;
class MyClass1
{
}

class MyClass2
{
}

public class IsTest
{
   public static void Main()
   {
      object [] myObjects = new object[6];
      myObjects[0] = new MyClass1();
      myObjects[1] = new MyClass2();
      myObjects[2] = "hello";
      myObjects[3] = 123;
      myObjects[4] = 123.4;
      myObjects[5] = null;

      for (int i=0; i<myObjects.Length; ++i)
      {
         string s = myObjects[i] as string;
         Console.Write ("{0}:", i);
         if (s != null)
            Console.WriteLine ( "'" + s + "'" );
         else
            Console.WriteLine ( "not a string" );
```

```
        }
    }
}
```

Output

```
0:not a string
1:not a string
2:'hello'
3:not a string
4:not a string
5:not a string
```

C# Keywords | is | ?: | Operator Keywords

is

The **is** operator is used to check whether the run-time type of an object is compatible with a given type. The **is** operator is used in an expression of the form:

```
expression is type
```

Where:

expression
An expression of a reference type.
type
A type.

Remarks

An **is** expression evaluates to true if both of the following conditions are met:

- *expression* is not **null**.
- *expression* can be cast to *type*. That is, a cast expression of the form `(type)(expression)` will complete without throwing an exception. For more information, see 7.6.6 Cast expressions.

A compile-time warning will be issued if the expression `expression is type` is known to always be true or always be false.

The **is** operator cannot be overloaded.

Note that the **is** operator only considers reference conversions, boxing conversions, and unboxing conversions. Other conversions, such as user-defined conversions, are not considered by the **is** operator.

Example

```
// cs_keyword_is.cs
// The is operator
using System;
class Class1
{
}

class Class2
{
}

public class IsTest
{
   public static void Test (object o)
   {
      Class1 a;
      Class2 b;

      if (o is Class1)
      {
         Console.WriteLine ("o is Class1");
         a = (Class1)o;
         // do something with a
      }

      else if (o is Class2)
      {
         Console.WriteLine ("o is Class2");
         b = (Class2)o;
         // do something with b
      }

      else
```

```
        {
           Console.WriteLine ("o is neither Class1 nor Class2.");
        }
     }
     public static void Main()
     {
        Class1 c1 = new Class1();
        Class2 c2 = new Class2();
        Test (c1);
        Test (c2);
        Test ("a string");
     }
  }
```

Output

```
o is Class1
o is Class2
o is neither Class1 nor Class2.
```

C# Keywords | typeof | as | Operator Keywords

new

In C#, the **new** keyword can be used as an operator or as a modifier.

- new operator Used to create objects on the heap and invoke constructors.
- new modifier Used to hide an inherited member from a base class member.

new Operator

The **new** operator is used to create objects and invoke constructors, for example:

```
Class1 MyClass  = new Class1();
```

It is also used to invoke the default constructor for value types, for example:

```
int myInt = new int();
```

In the preceding statement, `myInt` is initialized to `0`, which is the default value for the type **int**. The statement has the same effect as:

```
int myInt = 0;
```

For a complete list of default values, see Default Values Table.

Remember that it is an error to declare a default constructor for a struct, because every value type implicitly has a public default constructor. It is possible though to declare parameterized constructors on a struct type.

Value-type objects such as structs are created on the stack, while reference-type objects such as classes are created on the heap.

The **new** operator cannot be overloaded.

If the new operator fails to allocate memory, it throws the exception **OutOfMemoryException**.

Example

In the following example, a struct object and a class object are created and initialized by using the **new** operator and then assigned values. The default and the assigned values are displayed

```
// cs_operator_new.cs
// The new operator
using System;
class NewTest
{
   struct MyStruct
   {
      public int x;
      public int y;
      public MyStruct (int x, int y)
      {
         this.x = x;
         this.y = y;
      }
   }

   class MyClass
   {
      public string name;
      public int id;

      public MyClass ()
      {
      }
```

```
      public MyClass (int id, string name)
      {
         this.id = id;
         this.name = name;
      }
   }

   public static void Main()
   {
      // Create objects using default constructors:
      MyStruct Location1 = new MyStruct();
      MyClass Employee1 = new MyClass();

      // Display values:
      Console.WriteLine("Default values:");
      Console.WriteLine("   Struct members: {0}, {1}",
         Location1.x, Location1.y);
      Console.WriteLine("   Class members: {0}, {1}",
         Employee1.name, Employee1.id);

      // Create objects using parameterized constructors::
      MyStruct Location2 = new MyStruct(10, 20);
      MyClass Employee2 = new MyClass(1234, "John Martin Smith");

      // Display values:
      Console.WriteLine("Assigned values:");
      Console.WriteLine("   Struct members: {0}, {1}",
         Location2.x, Location2.y);
      Console.WriteLine("   Class members: {0}, {1}",
         Employee2.name, Employee2.id);
   }
}
```

Output

```
Default values:
   Struct members: 0, 0
   Class members: , 0
Assigned values:
   Struct members: 10, 20
   Class members: John Martin Smith, 1234
```

Notice in the example that the default value of a string is **null**. Therefore, it was not displayed.

new Modifier

Use the **new** modifier to explicitly hide a member inherited from a base class. To hide an inherited member, declare it in the derived class using the same name, and modify it with the **new** modifier.

Consider the following class:

```
public class MyBaseC
{
   public int x;
   public void Invoke() {}
}
```

Declaring a member with the name `Invoke` in a derived class will hide the method `Invoke` in the base class, that is:

```
public class MyDerivedC : MyBaseC
{
   new public void Invoke() {}
}
```

However, the field `x` will not be affected because it is not hidden by a similar name.

Name hiding through inheritance takes one of the following forms:

- A constant, field, property, or type introduced in a class or struct hides all base class members with the same name.
- A method introduced in a class or struct hides properties, fields, and types, with the same name, in the base class. It also hides all base class methods with the same signature. For more information, see 3.6 Signatures and overloading.
- An indexer introduced in a class or struct hides all base class indexers with the same signature.

It is an error to use both **new** and override on the same member.

Using the **new** modifier in a declaration that does not hide an inherited member generates a warning.

For more information on hiding names, see 3.7.1 Name hiding.

For more information on fully qualified names, see 3.8.1 Fully qualified names.

Example

In this example, a base class, `MyBaseC`, and a derived class, `MyDerivedC`, use the same field name `x`, thus hiding the value of the inherited field. The example demonstrates the use of the **new** modifier. It also demonstrates how to access the hidden members of the base class by using the fully qualified names.

```
// cs_modifier_new.cs
// The new modifier
using System;
public class MyBaseC
{
   public static int x = 55;
   public static int y = 22;
}

public class MyDerivedC : MyBaseC
{
   new public static int x = 100;   // Name hiding
   public static void Main()
   {
      // Display the overlapping value of x:
      Console.WriteLine(x);

      // Access the hidden value of x:
      Console.WriteLine(MyBaseC.x);

      // Display the unhidden member y:
      Console.WriteLine(y);
   }
}
```

Output

```
100
55
22
```

If you remove the **new** modifier, the program will still compile and run, but you will get the warning:

```
The keyword new is required on 'MyDerivedC.x' because it hides inherited member 'MyBaseC.x'.
```

You can also use the **new** modifier to modify a nested type if the nested type is hiding another type, as demonstrated in the following example.

Example

In this example, a nested class, `MyClass`, hides a class with the same name in the base class. The example demonstrates using the **new** modifier to eliminate the warning message, as well as accessing the hidden class members by using the fully qualified names.

```
// cs_modifer_new_nested.cs
// Using the new modifier with nested types
using System;
public class MyBaseC
{
   public class MyClass
   {
      public int x = 200;
      public int y;
   }
}

public class MyDerivedC : MyBaseC
{
   new public class MyClass   // nested type hiding the base type members
   {
      public int x = 100;
      public int y;
      public int z;
   }

   public static void Main()
   {
      // Creating object from the overlapping class:
      MyClass S1  = new MyClass();

      // Creating object from the hidden class:
      MyBaseC.MyClass S2 = new MyBaseC.MyClass();

      Console.WriteLine(S1.x);
      Console.WriteLine(S2.x);
   }
}
```

Output

```
100
200
```

C# Keywords | Operator Keywords | Modifiers

sizeof

The **sizeof** operator is used to obtain the size in bytes for a value type. A **sizeof** expression takes the form:

```
sizeof(type)
```

where:

type
The value type for which the size is obtained.

Remarks

The **sizeof** operator can be applied only to value types, not reference types.

The **sizeof** operator can only be used in the unsafe mode.

The **sizeof** operator cannot be overloaded.

Example

```
// cs_operator_sizeof.cs
// compile with: /unsafe

// Using the sizeof operator
using System;
class SizeClass
{
   // Notice the unsafe declaration of the method:
   unsafe public static void SizesOf()
   {
      Console.WriteLine("The size of short is {0}.", sizeof(short));
      Console.WriteLine("The size of int is {0}.", sizeof(int));
      Console.WriteLine("The size of long is {0}.", sizeof(long));
   }
}

class MainClass
{
   public static void Main()
   {
      SizeClass.SizesOf();
   }
}
```

Output

```
The size of short is 2.
The size of int is 4.
The size of long is 8.
```

See Also

C# Keywords | Operator Keywords

typeof

The **typeof** operator is used to obtain the **System.Type** object for a type. A **typeof** expression takes the form:

```
typeof(type)
```

where:

type
The type for which the **System.Type** object is obtained.

Remarks

The **typeof** operator cannot be overloaded.

To obtain the run-time type of an expression, you can use the .NET Framework method **GetType**.

Example

```
// cs_operator_typeof.cs
// Using typeof operator
using System;
using System.Reflection;

public class MyClass
{
   public int intI;
   public void MyMeth()
   {
   }

   public static void Main()
   {
      Type t = typeof(MyClass);

      // alternatively, you could use
      // MyClass t1 = new MyClass();
      // Type t = t1.GetType();

      MethodInfo[] x = t.GetMethods();
      foreach (MethodInfo xtemp in x)
      {
         Console.WriteLine(xtemp.ToString());
      }

      Console.WriteLine();

      MemberInfo[] x2 = t.GetMembers();
      foreach (MemberInfo xtemp2 in x2)
      {
         Console.WriteLine(xtemp2.ToString());
      }
   }
}
```

Output

```
Int32 GetHashCode()
Boolean Equals(System.Object)
System.String ToString()
Void MyMeth()
Void Main()
System.Type GetType()
```

```
Int32 intI
Int32 GetHashCode()
Boolean Equals(System.Object)
System.String ToString()
Void MyMeth()
Void Main()
System.Type GetType()
Void .ctor()
```

Example

```
// cs_operator_typeof2.cs
// Using GetType method
using System;
class GetTypeTest
{
   public static void Main()
   {
      int radius = 3;
      Console.WriteLine("Area = {0}", radius*radius*Math.PI);
      Console.WriteLine("The type is {0}",
               (radius*radius*Math.PI).GetType());
   }
}
```

Output

```
Area = 28.2743338823081
The type is System.Double
```

C# Keywords | is | Operator Keywords

true

In C#, the **true** keyword can be used as an overloaded operator or as a literal:

- true Operator
- true Literal

true Operator

User-defined types can define a **true** operator that returns the bool value true to indicate true and returns false otherwise. This is useful for types that represent true, false, and null (neither true nor false), as used in databases.

Such types can be used for the controlling expression in if, do, while, and for statements and in conditional expressions.

If a type defines operator **true**, it must also define operator false.

A type cannot directly overload the conditional logical operators (&& and ||), but an equivalent effect can be achieved by overloading the regular logical operators and operators **true** and **false** (see 7.11.2 User-defined conditional logical operators).

Example

See the example in 11.4.2 Database boolean type.

true Literal

The **true** keyword is a literal of type bool representing the boolean value true.

Example

```
// cs_keyword_true.cs
using System;
class test
{
   public static void Main()
   {
      bool a = true;
      Console.WriteLine( a ? "yes" : "no" );
   }
}
```

Output

```
yes
```

See Also

C# Keywords | C# Operators | false | Operator Overloading Tutorial

false

In C#, the **false** keyword can be used as an overloaded operator or as a literal:

- false Operator
- false Literal

false Operator

User-defined types can define a **false** operator that returns the bool value true to indicate false and returns false otherwise. This is useful for types that represent true, false, and null (neither true nor false), as used in databases.

Such types can be used for the controlling expression in if, do, while, and for statements and in conditional expressions.

If a type defines operator **false**, it must also define operator true.

A type cannot directly overload the conditional logical operators (&& and ||), but an equivalent effect can be achieved by overloading the regular logical operators and operators **true** and **false** (see 7.11.2 User-defined conditional logical operators).

Example

See the example in 11.4.2 Database boolean type.

false Literal

The **false** keyword is a literal of type bool representing the boolean value false.

Example

```
// cs_keyword_false.cs
using System;
class test
{
   public static void Main()
   {
      bool a = false;
      Console.WriteLine( a ? "yes" : "no" );
   }
}
```

Output

```
no
```

See Also

C# Keywords | C# Operators | true | Operator Overloading Tutorial

stackalloc

Allocates a block of memory on the stack.

```
type * ptr = stackalloc type [ expr ];
```

where:

type
An unmanaged type.
ptr
A pointer name.
expr
An integral expression.

Remarks

A block of memory of sufficient size to contain *expr* elements of type *type* is allocated on the stack, not the heap; the address of the block is stored in pointer *ptr*. This memory is not subject to garbage collection and therefore does not have to be pinned (via fixed). The lifetime of the memory block is limited to the lifetime of the method in which it is defined.

stackalloc is only valid in local variable initializers.

Because A.2 Pointer types are involved, **stackalloc** requires unsafe context.

stackalloc is similar to _alloca in the C run-time library.

Example

```
// cs_keyword_stackalloc.cs
// compile with: /unsafe
using System; class Test
{
   public static unsafe void Main()
   {
      int* fib = stackalloc int[100];
      int* p = fib;
      *p++ = *p++ = 1;
      for (int i=2; i<100; ++i, ++p)
         *p = p[-1] + p[-2];
      for (int i=0; i<10; ++i)
         Console.WriteLine (fib[i]);
   }
}
```

Output

```
1
1
2
3
5
8
13
21
34
55
```

C# Keywords | Operator Keywords

Conversion Keywords

This section describes keywords used in type conversions:

- explicit
- implicit
- operator

See Also

C# Keywords

explicit

The **explicit** keyword is used to declare an explicit user-defined type conversion operator (6.4.4 User-defined explicit conversions). For example:

```
class MyType
{
   public static explicit operator MyType(int i)
   {
      // code to convert from int to MyType
   }
}
```

Unlike implicit conversion, explicit conversion operators must be invoked via a cast.

```
int i;
MyType x = (MyType)i;   // int-to-MyType requires cast
```

Omitting the cast results in a compile-time error.

If a conversion operation can cause exceptions or lose information, you should mark it **explicit**. This prevents the compiler from silently invoking the conversion operation with possibly unforeseen consequences.

Example

The following example defines a struct, `Digit`, that represents a single decimal digit. An operator is defined for conversions from `byte` to `Digit`, but because not all bytes can be converted to a `Digit`, the conversion is explicit.

```
// cs_keyword_explicit.cs
using System;
struct Digit
{
   byte value;
   public Digit(byte value)
   {
      if (value>9) throw new ArgumentException();
      this.value = value;
   }

   // define explicit byte-to-Digit conversion operator:
   public static explicit operator Digit(byte b)
   {
      Digit d = new Digit(b);
      Console.WriteLine("conversion occurred");
      return d;
   }
}

class Test
{
   public static void Main()
   {
     try
      {
      byte b = 3;
      Digit d = (Digit)b; // explicit conversion
      }

      catch (Exception e)
      {
         Console.WriteLine("{0} Exception caught.", e);
      }
   }
}
```

Output

```
conversion occurred
```

See Also

C# Keywords | implicit | operator | User-Defined Conversions Tutorial

implicit

The **implicit** keyword is used to declare an implicit user-defined type conversion operator (6.4.3 User-defined implicit conversions). For example:

```
class MyType
{
   public static implicit operator int(MyType m)
   {
      // code to convert from MyType to int
   }
}
```

Implicit conversion operators can be called implicitly, without being specified by explicit casts in the source code.

```
MyType x;
int i = x; // implicitly call MyType's MyType-to-int conversion operator
```

By eliminating unnecessary casts, implicit conversions can improve source code readability. However, because implicit conversions can occur without the programmer's specifying them, care must be taken to prevent unpleasant surprises. In general, implicit conversion operators should never throw exceptions and never lose information so that they can be used safely without the programmer's awareness. If a conversion operator cannot meet those criteria, it should be marked **explicit**.

Example

The following example defines a struct, `Digit`, that represents a single decimal digit. An operator is defined for conversions from `Digit` to `byte`, and because any `Digit` can be converted to a `byte`, the conversion is implicit.

```
// cs_keyword_implicit.cs
using System;
struct Digit
{
   byte value;

   public Digit(byte value)
   {
      if (value > 9) throw new ArgumentException();
      this.value = value;
   }

   // define implicit Digit-to-byte conversion operator:
   public static implicit operator byte(Digit d)
   {
      Console.WriteLine( "conversion occurred" );
      return d.value;
   }
}

class Test
{
   public static void Main()
   {
      Digit d = new Digit(3);

      // implicit (no cast) conversion from Digit to byte
      byte b = d;
   }
}
```

Output

```
conversion occurred
```

See Also

C# Keywords | explicit | operator | User-Defined Conversions Tutorial

operator

The **operator** keyword is used to declare an operator in a class or struct declaration. An operator declaration can take one of the following four forms:

```
public static result-type operator unary-operator ( op-type operand )
public static result-type operator binary-operator (
   op-type operand,
   op-type2 operand2
)
public static implicit operator conv-type-out ( conv-type-in operand )
public static explicit operator conv-type-out ( conv-type-in operand )
```

where:

result-type
The type of the operator's result.
unary-operator
One of: `+` `-` `!` `~` `++` `—` `true` `false`
op-type
The type of the first (or only) parameter.
operand
The name of the first (or only) parameter.
binary-operator
One of: `+` `-` `*` `/` `%` `&` `|` `^` `<<` `>>` `==` `!=` `>` `<` `>=` `<=`
op-type2
The type of the second parameter.
operand2
The name of the second parameter.
conv-type-out
The target type of a type conversion operator.
conv-type-in
The type of the input to a type conversion operator.

Remarks

The first two forms declare user-defined operators that overload built-in operators. Note that not all the built-in operators can be overloaded (see Overloadable Operators). At least one of *op-type* and *op-type2* must be the enclosing type (that is, the type of which the operator is a member). This prevents redefining the integer addition operator, for instance.

The last two forms declare conversion operators. Exactly one of *conv-type-in* and *conv-type-out* must be the enclosing type (that is, a conversion operator can only convert from its enclosing type to some other type, or from some other type to its enclosing type).

Operators can only take value parameters, not ref or out parameters.

Any operator declaration can be preceded by an optional attribute list.

For more information, refer to 10.9 Operators.

Example

The following is an extremely simplified class for rational numbers. It overloads the + and * operators to perform fractional addition and multiplication, and also provides an operator that converts fractions to doubles.

```
// cs_keyword_operator.cs
using System;
class Fraction
{
   int num, den;
   public Fraction(int num, int den)
   {
      this.num = num;
```

```
        this.den = den;
    }

    // overload operator +
    public static Fraction operator +(Fraction a, Fraction b)
    {
        return new Fraction(a.num * b.den + b.num * a.den,
            a.den * b.den);
    }

    // overload operator *
    public static Fraction operator *(Fraction a, Fraction b)
    {
        return new Fraction(a.num * b.num, a.den * b.den);
    }

    // define operator double
    public static implicit operator double(Fraction f)
    {
        return (double)f.num / f.den;
    }
}

class Test
{
    public static void Main()
    {
        Fraction a = new Fraction(1, 2);
        Fraction b = new Fraction(3, 7);
        Fraction c = new Fraction(2, 3);
        Console.WriteLine((double)(a * b + c));
    }
}
```

Output

```
0.880952380952381
```

C# Keywords | implicit | explicit | User-Defined Conversions Tutorial

Access Keywords

This section introduces the following access keywords:

- base

  Accesses the members of the base class.

- this

  Refers to the current instance of the class.

See Also

C# Keywords

base

The **base** keyword is used to access members of the base class from within a derived class:

- Call a method on the base class that has been overridden by another method.
- Specify which base-class constructor should be called when creating instances of the derived class.

A base class access is permitted only in a constructor, an instance method, or an instance property accessor.

It is an error to use the **base** keyword from within a static method.

Example

In this example, both the base class, `Person`, and the derived class, `Employee`, have a method named `Getinfo`. By using the **base** keyword, it is possible to call the `Getinfo` method on the base class, from within the derived class.

```
// keywords_base.cs
// Accessing base class members
using System;
   public class Person
   {
      protected string ssn = "444-55-6666";
      protected string name = "John L. Malgraine";

      public virtual void GetInfo()
      {
         Console.WriteLine("Name: {0}", name);
         Console.WriteLine("SSN: {0}", ssn);
      }
   }
   class Employee: Person
   {
      public string id = "ABC567EFG";

      public override void GetInfo()
      {
         // Calling the base class GetInfo method:
         base.GetInfo();
         Console.WriteLine("Employee ID: {0}", id);
      }
   }

class TestClass {
   public static void Main()
   {
      Employee E = new Employee();
      E.GetInfo();
   }
}
```

Output

```
Name: John L. Malgraine
SSN: 444-55-6666
Employee ID: ABC567EFG
```

For additional examples, see new, virtual, and override.

Example

This example shows how to specify the base-class constructor called when creating instances of a derived class.

```
// keywords_base2.cs
using System;
public class MyBase
{
   int num;

   public MyBase()
   {
      Console.WriteLine("in MyBase()");
   }

   public MyBase(int i )
   {
      num = i;
      Console.WriteLine("in MyBase(int i)");
   }

   public int GetNum()
   {
      return num;
   }
}

public class MyDerived: MyBase
{
   // This constructor will call MyBase.MyBase()
   public MyDerived() : base()
   {
   }

    // This constructor will call MyBase.MyBase(int i)
   public MyDerived(int i) : base(i)
   {
   }

   public static void Main()
   {
      MyDerived md = new MyDerived();
      MyDerived md1 = new MyDerived(1);
   }
}
```

Output

```
in MyBase()
in MyBase(int i)
```

See Also

C# Keywords | this

this

The **this** keyword refers to the current instance of the class. Static member functions do not have a **this** pointer. The **this** keyword can be used to access members from within constructors, instance methods, and instance accessors.

The following are common uses of **this**:

- To qualify members hidden by similar names, for example:

```
public Employee(string name, string alias)
{
   this.name = name;
   this.alias = alias;
}
```

- To pass an object as a parameter to other methods, for example:

```
CalcTax(this);
```

- To declare indexers, for example:

```
public int this [int param]
{
      get
      {
         return array[param];
      }
      set
      {
         array[param] = value;
      }
   }
```

It is an error to refer to **this** in a static method, static property accessor, or variable initializer of a field declaration.

Example

In this example, **this** is used to qualify the `Employee` class members, `name` and `alias`, which are hidden by similar names. It is also used to pass an object to the method `CalcTax`, which belongs to another class.

```
// keywords_this.cs
// this example
using System;
public class Employee
{
   public string name;
   public string alias;
   public decimal salary = 3000.00m;

   // Constructor:
   public Employee(string name, string alias)
   {
      // Use this to qualify the fields, name and alias:
      this.name = name;
      this.alias = alias;
   }

   // Printing method:
   public void printEmployee()
   {
      Console.WriteLine("Name: {0}\nAlias: {1}", name, alias);
      // Passing the object to the CalcTax method by using this:
```

```
        Console.WriteLine("Taxes: {0:C}", Tax.CalcTax(this));
    }
}
public class Tax
{
    public static decimal CalcTax(Employee E)
    {
        return (0.08m*(E.salary));
    }
}

public class MainClass
{
    public static void Main()
    {
        // Create objects:
        Employee E1 = new Employee ("John M. Trainer", "jtrainer");

        // Display results:
        E1.printEmployee();
    }
}
```

Output

```
Name: John M. Trainer
Alias: jtrainer
Taxes: $240.00
```

For additional examples, see class and struct.

C# Keywords | base

Literal Keywords

C# has the following literal keywords:

- null
- true
- false

See Also

C# Keywords

null

The **null** keyword is a literal that represents a null reference, one that does not refer to any object. **null** is the default value of reference-type variables.

See Also

C# Keywords | Literal keywords | Default Values Table

C# Operators

C# provides a large set of operators, which are symbols that specify which operations to perform in an expression. C# predefines the usual arithmetic and logical operators, as well as a variety of others as shown in the following table. In addition, many operators can be overloaded by the user, thus changing their meaning when applied to a user-defined type.

Operator category	Operators
Arithmetic	+ - * / %
Logical (boolean and bitwise)	& | ^ ! ~ && || true false
String concatenation	+
Increment, decrement	++ --
Shift	<< >>
Relational	== != < > <= >=
Assignment	= += -= *= /= %= &= |= ^= <<= >>=
Member access	.
Indexing	[]
Cast	()
Conditional	?:
Delegate concatenation and removal	+ -
Object creation	new
Type information	as is sizeof typeof
Overflow exception control	checked unchecked
Indirection and Address	* -> [] &

Arithmetic Overflow

The arithmetic operators (+, -, *, /) can produce results that are outside the range of possible values for the numeric type involved. You should refer to the *C# Language Reference* section on a particular operator for details, but in general:

- Integer arithmetic overflow either throws an OverflowException or discards the most significant bits of the result (see below). Integer division by zero always throws a DivideByZeroException.
- Floating-point arithmetic overflow or division by zero never throws an exception, because floating-point types are based on IEEE 754 and so have provisions for representing infinity and NaN (Not a Number).
- Decimal arithmetic overflow always throws an OverflowException. **Decimal** division by zero always throws a DivideByZeroException.

When integer overflow occurs, what happens depends on the execution context, which can be checked or unchecked. In a checked context, an OverflowException is thrown. In an unchecked context, the most significant bits of the result are discarded and execution continues. Thus, C# gives you the choice of handling or ignoring overflow.

In addition to the arithmetic operators, integral-type to integral-type casts can cause overflow (for example, casting a long to an int) and are subject to checked or unchecked execution. Also note that bitwise operators and shift operators never cause overflow.

See Also

7.2.1 Operator precedence and associativity | Overloadable Operators | C# Keywords | C# Programmer's Reference

Overloadable Operators

C# allows user-defined types to overload operators by defining static member functions using the operator keyword. Not all operators can be overloaded, however, and others have restrictions, as listed in this table:

Operators	Overloadability
+, -, !, ~, ++, --, true, false	These unary operators can be overloaded.
+, -, *, /, %, &, |, ^, <<, >>	These binary operators can be overloaded.
==, !=, <, >, <=, >=	The comparison operators can be overloaded (but see note below).
&&, ||	The conditional logical operators cannot be overloaded, but they are evaluated using **&** and **|**, which can be overloaded; see 7.11.2 User-defined conditional logical operators.
[]	The array indexing operator cannot be overloaded, but you can define indexers.
()	The cast operator cannot be overloaded, but you can define new conversion operators (see explicit and implicit).
+=, -=, *=, /=, %=, &=, |=, ^=, <<=, >>=	Assignment operators cannot be overloaded, but **+=**, for example, is evaluated using **+**, which can be overloaded.
=, ., ?:, ->, new, is, sizeof, typeof	These operators cannot be overloaded.

Note The comparison operators, if overloaded, must be overloaded in pairs; that is, if **==** is overloaded, **!=** must also be overloaded. The reverse is also true, and similar for **<** and **>**, and for **<=** and **>=**.

See Also

C# Operators | Operator Overloading Tutorial

[] Operator

Square brackets ([]) are used for arrays, indexers, and attributes. They can also be used with pointers.

```
type []
array [ indexexpr ]
```

Where:

type
A type.
array
An array.
indexexpr
An index expression.

Remarks

An array type is a type followed by []:

```
int[] fib; // fib is of type int[], "array of int"
fib = new int[100]; // create a 100-element int array
```

To access an element of an array, the index of the desired element is enclosed in brackets:

```
fib[0] = fib[1] = 1;
for( int i=2; i<100; ++i ) fib[i] = fib[i-1] + fib[i-2];
```

An exception is thrown if an array index is out of range.

The array indexing operator cannot be overloaded; however, types can define indexers, properties that take one or more parameters. Indexer parameters are enclosed in square brackets, just like array indices, but indexer parameters can be declared to be of any type (unlike array indices, which must be integral).

For example, the .NET Framework defines a Hashtable type that associates keys and values of arbitrary type:

```
Collections.Hashtable h =  new Collections.Hashtable();
h["a"] = 123; // note: using a string as the index
```

Square brackets are also used to specify attributes:

```
[attribute(AllowMultiple=true)]
public class Attr {
}
```

You can use square brackets to index off a pointer (see A.2 Pointer types):

```
unsafe fixed ( int* p = fib )   // p points to fib from earlier example
{
   p[0] = p[1] = 1;
   for( int i=2; i<100; ++i ) p[i] = p[i-1] + p[i-2];
}
```

No bounds checking is performed.

See Also

C# Operators | Arrays | Indexers | unsafe | fixed

() Operator

In addition to being used to specify the order of operations in an expression, parentheses are used to specify casts (type conversions):

```
( type ) expr
```

Where:

type
The name of the type to which *expr* is to be converted.

expr
An expression.

Remarks

A cast explicitly invokes the conversion operator from *expr*'s type to *type*; the cast will fail if no such conversion operator is defined. To define a conversion operator, see explicit and implicit.

Example

The following program casts a **double** to an **int**. The program won't compile without the cast.

```
// cs_operator_parentheses.cs
using System;
class Test
{
   public static void Main()
   {
      double x = 1234.7;
      int a;
      a = (int)x; // cast double to int
      Console.WriteLine(a);
   }
}
```

Output

```
1234
```

See Also

C# Operators | 7.6.6 Cast expressions | explicit

. Operator

The dot operator is used for member access.

```
name1 . name2
```

Where:

name1
A name.
name2
A name.

Remarks

For example, consider the following class:

```
class Simple
{
   public int a;
   public void b()
   {
   }
}
Simple s = new Simple();
```

The variable `s` has two members, `a` and `b`; to access them, use the dot operator:

```
s.a = 6;   // assign to field a;
s.b();     // invoke member function b;
```

The dot is also used to form qualified names, names that specify the namespace or interface (for example) to which they belong.

```
System.Console.WriteLine("hello"); // class Console in namespace System
```

The using directive makes some name qualification optional:

```
using System;
...
System.Console.WriteLine("hello");
Console.WriteLine("hello");   // same thing
```

But when an identifier is ambiguous, it must be qualified:

```
using System;
using OtherSystem; // a namespace containing another Console class
...
System.Console.WriteLine( "hello" ); // must qualify Console
```

See Also

C# Operators | 7.5.4 Member access

+ Operator

The + operator can function as either a unary or a binary operator.

```
+ expr
expr1 + expr2
```

Where:

expr
An expression.
expr1
An expression.
expr2
An expression.

Remarks

Unary + operators are predefined for all numeric types. The result of a unary + operation on a numeric type is simply the value of the operand.

Binary + operators are predefined for numeric and string types. For numeric types, + computes the sum of its two operands. When one or both operands are of type string, + concatenates the string representations of the operands.

Delegate types also provide a binary + operator, which performs delegate concatenation.

User-defined types can overload the unary + and binary + operators (see operator).

Example

```
// cs_operator_plus.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(+5);        // unary plus
      Console.WriteLine(5 + 5);     // addition
      Console.WriteLine(5 + .5);    // addition
      Console.WriteLine("5" + "5"); // string concatenation
      Console.WriteLine(5.0 + "5"); // string concatenation
      // note automatic conversion from double to string
   }
}
```

Output

```
5
10
5.5
55
55
```

See Also

C# Operators | 7.6.1 Unary plus operator | 7.7.4 Addition operator

- Operator

The - operator can function as either a unary or a binary operator.

```
- expr
expr1 - expr2
```

Where:

expr
An expression.
expr1
An expression.
expr2
An expression.

Remarks

Unary - operators are predefined for all numeric types. The result of a unary - operation on a numeric type is the negation of the operand.

Binary - operators are predefined for all numeric and enumeration types to subtract the second operand from the first.

Delegate types also provide a binary - operator, which performs delegate removal.

User-defined types can overload the unary - and binary - operators (see operator).

Example

```
// cs_operator_minus.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 5;
      Console.WriteLine(-a);
      Console.WriteLine(a - 1);
      Console.WriteLine(a - .5);
   }
}
```

Output

```
-5
4
4.5
```

See Also

C# Operators | 7.6.2 Unary minus operator | 7.7.5 Subtraction operator

* Operator

The multiplication operator (*) computes the product of its operands. All numeric types have predefined multiplication operators.

```
expr1 * expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

The * operator is also used to declare pointer types and to dereference pointers (see A.2 Pointer types).

User-defined types can overload the * operator (see operator).

Example

```
// cs_operator_mult.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(5 * 2);
      Console.WriteLine(-.5 * .2);
      Console.WriteLine(-.5m * .2m); // decimal type
   }
}
```

Output

```
10
-0.1
-0.10
```

See Also

C# Operators | 7.7.1 Multiplication operator

/ Operator

The division operator (/) divides its first operand by its second. All numeric types have predefined division operators.

```
expr1 / expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined types can overload the / operator (see operator).

Example

```
// cs_operator_division.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(-5/2);
      Console.WriteLine(-5.0/2);
   }
}
```

Output

```
-2
-2.5
```

See Also

C# Operators | 7.7.2 Division operator

% Operator

The modulus operator (%) computes the remainder after dividing its first operand by its second. All numeric types have predefined modulus operators.

```
expr1 % expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined types can overload the % operator (see operator).

Example

```
// cs_operator_modulus.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(5 % 2);       // int
      Console.WriteLine(-5 % 2);      // int
      Console.WriteLine(5.0 % 2.2);   // double
      Console.WriteLine(5.0m % 2.2m); // decimal
      Console.WriteLine(-5.2 % 2.0);  // double
   }
}
```

Output

```
1
-1
0.6
0.6
-1.2
```

Note the round-off errors associated with the double type.

See Also

C# Operators | 7.7.3 Remainder operator

& Operator

The & operator can function as either a unary or a binary operator.

```
& expr
expr1 & expr2
```

Where:

expr
An expression.
expr1
An expression.
expr2
An expression.

Remarks

The unary & operator returns the address of its operand (requires unsafe context).

Binary & operators are predefined for the integral types and **bool**. For integral types, & computes the bitwise AND of its operands. For **bool** operands, & computes the logical AND of its operands; that is, the result is **true** if and only if both its operands are **true**.

User-defined types can overload the binary & operator (see operator).

Example

```
// cs_operator_ampersand.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(true & false); // logical and
      Console.WriteLine(true & true);  // logical and
      Console.WriteLine("0x{0:x}", 0xf8 & 0x3f);  // bitwise and
   }
}
```

Output

```
False
True
0x38
```

See Also

C# Operators | 7.10 Logical operators | A.2 Pointer types

| Operator

Binary | operators are predefined for the integral types and **bool**. For integral types, | computes the bitwise OR of its operands. For **bool** operands, | computes the logical OR of its operands; that is, the result is **false** if and only if both its operands are **false**.

```
expr1 | expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined types can overload the | operator (see operator).

Example

```
// cs_operator_OR.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(true | false);  // logical or
      Console.WriteLine(false | false); // logical or
      Console.WriteLine("0x{0:x}", 0xf8 | 0x3f);   // bitwise or
   }
}
```

Output

```
True
False
0xff
```

See Also

C# Operators | 7.10 Logical operators

^ Operator

Binary ^ operators are predefined for the integral types and **bool**. For integral types, ^ computes the bitwise exclusive-OR of its operands. For **bool** operands, ^ computes the logical exclusive-or of its operands; that is, the result is **true** if and only if exactly one of its operands is **true**.

```
expr1 ^ expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined types can overload the ^ operator (see operator).

Example

```
// cs_operator_bitwise_OR.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(true ^ false);  // logical exclusive-or
      Console.WriteLine(false ^ false); // logical exclusive-or
      Console.WriteLine("0x{0:x}", 0xf8 ^ 0x3f);   // bitwise exclusive-or
   }
}
```

Output

```
True
False
0xc7
```

See Also

C# Operators | 7.10.1 Integer logical operators

! Operator

The logical negation operator (!) is a unary operator that negates its operand. It is defined for **bool** and returns **true** if and only if its operand is **false**.

```
! expr
```

Where:

expr
An expression.

Remarks

User-defined types can overload the ! operator (see operator).

Example

```
// cs_operator_negation.cs
using System;
class Test
{
   public static void Main()
{
      Console.WriteLine(!true);
      Console.WriteLine(!false);
   }
}
```

Output

```
False
True
```

See Also

C# Operators | 7.6.3 Logical negation operator

~ Operator

The ~ operator performs a bitwise complement operation on its operand. Bitwise complement operators are predefined for **int**, **uint**, **long**, and **ulong**.

```
~ expr
```

Where:

expr
An expression.

Remarks

User-defined types can overload the ~ operator (see operator).

Example

```
// cs_operator_bitwise_compl.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine("!0x{0:x8} = 0x{1:x8}", 8, ~8);
      Console.WriteLine("!0x{0:x8} = 0x{1:x8}", -8, ~-8);
   }
}
```

Output

```
!0x00000008 = 0xfffffff7
!0xfffffff8 = 0x00000007
```

See Also

C# Operators | 7.6.4 Bitwise complement operator

= Operator

The assignment operator (=) stores the value of its right-hand operand in the storage location, property, or indexer denoted by its left-hand operand and returns the value as its result. The operands must be of the same type (or the right-hand operand must be implicitly convertible to the type of the left-hand operand).

```
lhs = expr
```

Where:

lhs
A storage location, property, or indexer.
expr
An expression.

Remarks

The assignment operator cannot be overloaded.

Example

```
// cs_operator_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      double x;
      int i;
      i = 5; // int to int assignment
      x = i; // implicit conversion from int to double
      i = (int)x; // needs cast
      Console.WriteLine("i is {0}, x is {1}", i, x);
      object obj = i;
      Console.WriteLine("boxed value = {0}, type is {1}",
         obj, obj.GetType());
      i = (int)obj;
      Console.WriteLine("unboxed: {0}", i);
   }
}
```

Output

```
i is 5, x is 5
boxed value = 5, type is System.Int32
unboxed: 5
```

See Also

C# Operators | 7.13 Assignment operators

< Operator

All numeric and enumeration types define a "less than" relational operator (<) that returns **true** if the first operand is less than the second, **false** otherwise.

```
expr1 < expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined types can overload the < operator (see operator). If < is overloaded, > must also be overloaded.

Example

```
// cs_operator_less_than.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(1 < 1.1);
      Console.WriteLine(1.1 < 1.1);
   }
}
```

Output

```
True
False
```

See Also

C# Operators | 7.9 Relational and type testing operators

> Operator

All numeric and enumeration types define a "greater than" relational operator (>) that returns **true** if the first operand is greater than the second, **false** otherwise.

```
expr1 > expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined types can overload the > operator (see operator). If > is overloaded, < must also be overloaded.

Example

```
// cs_operator_greater_than.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(1.1 > 1);
      Console.WriteLine(1.1 > 1.1);
   }
}
```

Output

```
True
False
```

See Also

C# Operators | 7.9 Relational and type testing operators

?: Operator

The conditional operator (?:) returns one of two values depending on the value of a Boolean expression. The conditional operator is used in an expression of the following form:

```
cond-expr ? expr1 : expr2
```

Where:

cond-expr
An expression of type **bool**.
expr1
An expression.
expr2
An expression.

Remarks

If *cond-expr* is **true**, *expr1* is evaluated and becomes the result; if *cond-expr* is **false**, *expr2* is evaluated and becomes the result. Only one of *expr1* and *expr2* is ever evaluated.

Calculations that might otherwise require an if-else construction can be expressed more concisely and elegantly with the conditional operator. For example, to avoid a division by zero in the calculation of the **sinc** function you could write either

```
if(x != 0.0) s = Math.Sin(x)/x; else s = 1.0;
```

or, using the conditional operator,

```
s = x != 0.0 ? Math.Sin(x)/x : 1.0;
```

The conditional operator is right-associative, so an expression of the form

```
a ? b : c ? d : e
```

is evaluated as

```
a ? b : (c ? d : e)
```

not

```
(a ? b : c) ? d : e
```

The conditional operator cannot be overloaded.

Example

```
// cs_operator_conditional.cs
using System;
class Test
{
   public static double sinc(double x)
   {
      return x != 0.0 ? Math.Sin(x)/x : 1.0;
   }

   public static void Main()
   {
      Console.WriteLine(sinc(0.2));
      Console.WriteLine(sinc(0.1));
```

```
        Console.WriteLine(sinc(0.0));
    }
}
```

Output

```
0.993346653975306
0.998334166468282
1
```

See Also

C# Operators | 7.12 Conditional operator | if-else

++ Operator

The increment operator (++) increments its operand by 1. The increment operator can appear before or after its operand:

```
++ var
var ++
```

Where:

var
An expression that denotes a storage location or a property or an indexer.

Remarks

The first form is a prefix increment operation. The result of the operation is the value of the operand after it has been incremented.

The second form is a postfix increment operation. The result of the operation is the value of the operand *before* it has been incremented.

Numeric and enumeration types have predefined increment operators. User-defined types can overload the ++ operator (see operator).

Example

```
// cs_operator_increment.cs
using System;
class Test
{
   public static void Main()
   {
      double x;
      x = 1.5;
      Console.WriteLine(++x);
      x = 1.5;
      Console.WriteLine(x++);
      Console.WriteLine(x);
   }
}
```

Output

```
2.5
1.5
2.5
```

See Also

C# Operators | 7.5.9 Postfix increment and decrement operators | 7.6.5 Prefix increment and decrement operators

-- Operator

The decrement operator (--) decrements its operand by 1. The decrement operator can appear before or after its operand:

```
-- var
var --
```

Where:

var
An expression that denotes a storage location or a property or an indexer.

Remarks

The first form is a prefix decrement operation. The result of the operation is the value of the operand *after* it has been decremented.

The second form is a postfix decrement operation. The result of the operation is the value of the operand *before* it has been decremented.

Numeric and enumeration types have predefined decrement operators. User-defined types can overload the -- operator (see operator).

Example

```
// cs_operator_decrement.cs
using System;
class Test
{
   public static void Main()
   {
      double x;
      x = 1.5;
      Console.WriteLine(--x);
      x = 1.5;
      Console.WriteLine(x--);
      Console.WriteLine(x);
   }
}
```

Output

```
0.5
1.5
0.5
```

C# Operators | 7.5.9 Postfix increment and decrement operators | 7.6.5 Prefix increment and decrement operators

&& Operator

The conditional-AND operator (&&) performs a logical-AND of its bool operands, but only evaluates its second operand if necessary.

```
expr1 && expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

The operation

```
x && y
```

corresponds to the operation

```
x & y
```

except that if `x` is `false`, `y` is not evaluated (because the result of the AND operation is `false` no matter what the value of `y` may be). This is known as "short-circuit" evaluation.

The conditional-AND operator cannot be overloaded, but overloads of the regular logical operators and operators true and false are, with certain restrictions, also considered overloads of the conditional logical operators (see 7.11.2 User-defined conditional logical operators).

Example

In the following example, observe that the expression using && evaluates only the first operand.

```
// cs_operator_logical_and.cs
using System;
class Test
{
   static bool fn1()
   {
      Console.WriteLine("fn1 called");
      return false;
   }

   static bool fn2()
   {
      Console.WriteLine("fn2 called");
      return true;
   }

   public static void Main()
   {
      Console.WriteLine("regular AND:");
      Console.WriteLine("result is {0}", fn1() & fn2());
      Console.WriteLine("short-circuit AND:");
      Console.WriteLine("result is {0}", fn1() && fn2());
   }
}
```

Output

```
regular AND:
fn1 called
fn2 called
result is False
short-circuit AND:
fn1 called
result is False
```

See Also

C# Operators | 7.11 Conditional logical operators

|| Operator

The conditional-OR operator (||) performs a logical-OR of its bool operands, but only evaluates its second operand if necessary.

```
expr1 || expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

The operation

```
x || y
```

corresponds to the operation

```
x | y
```

except that if `x` is `true`, `y` is not evaluated (because the result of the OR operation is `true` no matter what the value of `y` might be). This is known as "short-circuit" evaluation.

The conditional-OR operator cannot be overloaded, but overloads of the regular logical operators and operators true and false are, with certain restrictions, also considered overloads of the conditional logical operators (see 7.11.2 User-defined conditional logical operators).

Example

In the following example, observe that the expression using || evaluates only the first operand.

```
// cs_operator_short_circuit_OR.cs
using System;
class Test
{
   static bool fn1()
   {
      Console.WriteLine("fn1 called");
      return true;
   }

   static bool fn2()
   {
      Console.WriteLine("fn2 called");
      return false;
   }

   public static void Main()
   {
      Console.WriteLine("regular OR:");
      Console.WriteLine("result is {0}", fn1() | fn2());
      Console.WriteLine("short-circuit OR:");
      Console.WriteLine("result is {0}", fn1() || fn2());
   }
}
```

Output

```
regular OR:
fn1 called
fn2 called
result is True
short-circuit OR:
fn1 called
result is True
```

See Also

C# Operators | 7.11 Conditional logical operators

<< Operator

The left-shift operator (<<) shifts its first operand left by the number of bits specified by its second operand.

```
expr << count
```

Where:

expr
An expression of type **int**, **uint**, **long**, or **ulong**; the value to be shifted.
count
An expression of type **int**; the shift count.

Remarks

If *expr* is an **int** or **uint** (32-bit quantity), the shift count is given by the low-order five bits of *count* (*count* & 0x1f).

If *expr* is a **long** or **ulong** (64-bit quantity), the shift count is given by the low-order six bits of *count* (*count* & 0x3f).

The high-order bits of *expr* are discarded and the low-order empty bits are zero-filled. Shift operations never cause overflows.

User-defined types can overload the << operator (see operator); the type of the first operand must be the user-defined type, and the type of the second operand must be **int**.

Example

```
// cs_operator_left_shift.cs
using System;
class Test
{
   public static void Main()
   {
      int i = 1;
      long lg = 1;
      Console.WriteLine("0x{0:x}", i << 1);
      Console.WriteLine("0x{0:x}", i << 33);
      Console.WriteLine("0x{0:x}", lg << 33);
   }
}
```

Output

```
0x2
0x2
0x200000000
```

Note that `i<<1` and `i<<33` give the same result, because 1 and 33 have the same low-order five bits.

See Also

C# Operators | 7.8 Shift operators | >> Operator

>> Operator

The right-shift operator (>>) shifts its first operand right by the number of bits specified by its second operand.

```
expr >> count
```

Where:

expr
An expression of type **int**, **uint**, **long**, or **ulong**; the value to be shifted.
count
An expression of type **int**; the shift count.

Remarks

If *expr* is an **int** or **uint** (32-bit quantity), the shift count is given by the low-order five bits of *count* (*count* & 0x1f).

If *expr* is a **long** or **ulong** (64-bit quantity), the shift count is given by the low-order six bits of *count* (*count* & 0x3f).

If *expr* is an **int** or **long**, the right-shift is an arithmetic shift (high-order empty bits are set to the sign bit). If *expr* is of type **uint** or **ulong**, the right-shift is a logical shift (high-order bits are zero-filled).

User-defined types can overload the >> operator (see operator); the type of the first operand must be the user-defined type, and the type of the second operand must be **int**.

Example

```
// cs_operator_right_shift.cs
using System;
class Test
{
   public static void Main()
   {
      int i = -1000;
      Console.WriteLine(i >> 3);
   }
}
```

Output

```
-125
```

See Also

C# Operators | 7.8 Shift operators | << Operator

== Operator

For predefined value types, the equality operator (==) returns true if the values of its operands are equal, false otherwise. For reference types other than **string**, == returns true if its two operands refer to the same object. For the **string** type, == compares the values of the strings.

```
expr1 == expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined value types can overload the == operator (see operator). So can user-defined reference types, although by default == behaves as described above for both predefined and user-defined reference types. If == is overloaded, != must also be overloaded.

Example

```
// cs_operator_equality.cs
using System;
class Test
{
   public static void Main()
   {
      // Numeric equality: True
      Console.WriteLine((2 + 2) == 4);

      // Reference equality: different objects, same boxed value: False
      object s = 1;
      object t = 1;
      Console.WriteLine(s == t);

      // Define some string
      string a = "hello";
      string b = String.Copy(a);
      string c = "hello";

      // compare string values for a constant and an instance: True
      Console.WriteLine(a == b);

      // compare string references;
      // a is a constant but b is an instance: False
      Console.WriteLine((object)a == (object)b);

      // compare string references, both constants have the same value,
      // so string interning points to same reference: True
      Console.WriteLine((object)a == (object)c);
   }
}
```

Output

```
True
False
True
False
True
```

See Also

C# Operators | 7.9 Relational and type testing operators | != Operator

!= Operator

The inequality operator (!=) returns false if its operands are equal, true otherwise. Inequality operators are predefined for all types, including string and object. User-defined types can overload the != operator.

```
expr1 != expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

For predefined value types, the inequality operator (!=) returns true if the values of its operands are different, false otherwise. For reference types other than **string**, != returns true if its two operands refer to different objects. For the **string** type, != compares the values of the strings.

User-defined value types can overload the != operator (see operator). So can user-defined reference types, although by default != behaves as described above for both predefined and user-defined reference types. If != is overloaded, == must also be overloaded.

Example

```
// cs_operator_inequality.cs
using System;
class Test
{
   public static void Main()
   {
      // Numeric inequality:
      Console.WriteLine((2 + 2) != 4);

      // Reference equality: two objects, same boxed value
      object s = 1;
      object t = 1;
      Console.WriteLine(s != t);

      // String equality: same string value, same string objects
      string a = "hello";
      string b = "hello";

      // compare string values
      Console.WriteLine(a != b);

      // compare string references
      Console.WriteLine((object)a != (object)b);
   }
}
```

Output

```
False
True
False
False
```

See Also

<= Operator

All numeric and enumeration types define a "less than or equal" relational operator (<=) that returns **true** if the first operand is less than or equal to the second, **false** otherwise.

```
expr1 <= expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined types can overload the <= operator (see operator). If <= is overloaded, >= must also be overloaded.

Example

```
// cs_operator_less_than_or_equal.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(1 <= 1.1);
      Console.WriteLine(1.1 <= 1.1);
   }
}
```

Output

```
True
True
```

See Also

C# Operators | 7.9 Relational and type testing operators

>= Operator

All numeric and enumeration types define a "greater than or equal" relational operator (>=) that returns **true** if the first operand is greater than or equal to the second, **false** otherwise.

```
expr1 >= expr2
```

Where:

expr1
An expression.
expr2
An expression.

Remarks

User-defined types can overload the >= operator (see operator). If >= is overloaded, <= must also be overloaded.

Example

```
// cs_operator_greater_than_or_equal.cs
using System;
class Test
{
   public static void Main()
   {
      Console.WriteLine(1.1 >= 1);
      Console.WriteLine(1.1 >= 1.1);
   }
}
```

Output

```
True
True
```

See Also

C# Operators | 7.9 Relational and type testing operators

+= Operator

The addition assignment operator.

```
lhs += expr
```

Where:

lhs
A storage location, property, or indexer.
expr
An expression.

Remarks

An expression using the += assignment operator, such as

```
x += y
```

is equivalent to

```
x = x + y
```

except that `x` is only evaluated once. The meaning of the + operator is dependent on the types of `x` and `y` (addition for numeric operands, concatenation for string operands, and so forth).

The += operator cannot be overloaded directly, but user-defined types can overload the + operator (see operator).

Example

```
// cs_operator_addition_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 5;
      a += 6;
      Console.WriteLine(a);
      string s = "Micro";
      s += "soft";
      Console.WriteLine(s);
   }
}
```

Output

```
11
Microsoft
```

See Also

C# Operators | 7.13 Assignment operators

-= Operator

The subtraction assignment operator.

```
lhs -= expr
```

Where:

lhs
A storage location, property, or indexer.
expr
An expression.

Remarks

An expression using the -= assignment operator, such as

```
x -= y
```

is equivalent to

```
x = x - y
```

except that `x` is only evaluated once. The meaning of the - operator is dependent on the types of `x` and `y` (subtraction for numeric operands, delegate removal for delegate operands, and so forth).

The -= operator cannot be overloaded directly, but user-defined types can overload the - operator (see operator).

Example

```
// cs_operator_subtraction_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 5;
      a -= 6;
      Console.WriteLine(a);
   }
}
```

Output

```
-1
```

See Also

C# Operators | 7.13 Assignment operators

*= Operator

The multiplication assignment operator.

```
lhs *= expr
```

Where:

lhs
A storage location, property, or indexer.

expr
An expression.

Remarks

An expression using the *= assignment operator, such as

```
x *= y
```

is equivalent to

```
x = x * y
```

except that `x` is only evaluated once. The * operator is predefined for numeric types to perform multiplication.

The *= operator cannot be overloaded directly, but user-defined types can overload the * operator (see operator).

Example

```
// cs_operator_multiplication_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 5;
      a *= 6;
      Console.WriteLine(a);
   }
}
```

Output

```
30
```

See Also

C# Operators | 7.13 Assignment operators

/= Operator

The division assignment operator.

```
lhs /= expr
```

Where:

lhs
A storage location, property, or indexer.
expr
An expression.

Remarks

An expression using the /= assignment operator, such as

```
x /= y
```

is equivalent to

```
x = x / y
```

except that `x` is only evaluated once. The / operator is predefined for numeric types to perform division.

The /= operator cannot be overloaded directly, but user-defined types can overload the / operator (see operator).

Example

```
// cs_operator_division_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 5;
      a /= 6;
      Console.WriteLine(a);
      double b = 5;
      b /= 6;
      Console.WriteLine(b);
   }
}
```

Output

```
0
0.833333333333333
```

See Also

C# Operators | 7.13 Assignment operators

%= Operator

The modulus assignment operator.

```
lhs %= expr
```

Where:

lhs
A storage location, property, or indexer.

expr
An expression.

Remarks

An expression using the %= assignment operator, such as

```
x %= y
```

is equivalent to

```
x = x % y
```

except that `x` is only evaluated once. The % operator is predefined for numeric types to compute the remainder after division.

The %= operator cannot be overloaded directly, but user-defined types can overload the % operator (see operator).

Example

```
// cs_operator_modulus_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 5;
      a %= 3;
      Console.WriteLine(a);
   }
}
```

Output

```
2
```

See Also

C# Operators | 7.13 Assignment operators

|= Operator

The OR assignment operator.

```
lhs |= expr
```

Where:

lhs
A storage location, property, or indexer.
expr
An expression.

Remarks

An expression using the |= assignment operator, such as

```
x |= y
```

is equivalent to

```
x = x | y
```

except that `x` is only evaluated once. The | operator performs a bitwise OR operation on integral operands and logical OR on bool operands.

The |= operator cannot be overloaded directly, but user-defined types can overload the | operator (see operator).

Example

```
// cs_operator_or_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 0x0c;
      a |= 0x06;
      Console.WriteLine("0x{0:x8}", a);
      bool b = true;
      b |= false;
      Console.WriteLine(b);
   }
}
```

Output

```
0x0000000e
True
```

See Also

C# Operators | 7.13 Assignment operators

^= Operator

The exclusive-OR assignment operator.

```
lhs ^= expr
```

Where:

lhs
A storage location, property, or indexer.

expr
An expression.

Remarks

An expression of the form

```
x ^= y
```

is evaluated as

```
x = x ^ y
```

except that `x` is only evaluated once. The ^ operator performs a bitwise exclusive-OR operation on integral operands and logical exclusive-OR on bool operands.

The ^= operator cannot be overloaded directly, but user-defined types can overload the ^ operator (see operator).

Example

```
// cs_operator_xor_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 0x0c;
      a ^= 0x06;
      Console.WriteLine("0x{0:x8}", a);
      bool b = true;
      b ^= false;
      Console.WriteLine(b);
   }
}
```

Output

```
0x0000000a
True
```

See Also

C# Operators | 7.13 Assignment operators

<<= Operator

The left-shift assignment operator.

```
lhs <<= expr
```

Where:

lhs
A storage location, property, or indexer.

expr
An expression.

Remarks

An expression of the form

```
x <<= y
```

is evaluated as

```
x = x << y
```

except that x is only evaluated once. The << operator shifts `x` left by an amount specified by `y`.

The <<= operator cannot be overloaded directly, but user-defined types can overload the << operator (see operator).

Example

```
// cs_operator_left_shift_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 1000;
      a <<= 4;
      Console.WriteLine(a);
   }
}
```

Output

```
16000
```

See Also

C# Operators | 7.13 Assignment operators

>>= Operator

The right-shift assignment operator.

```
lhs >>= expr
```

Where:

lhs
A storage location, property, or indexer.

expr
An expression.

Remarks

An expression of the form

```
x >>= y
```

is evaluated as

```
x = x >> y
```

except that `x` is only evaluated once. The `>>` operator shifts `x` right by an amount specified by `y`.

The `>>=` operator cannot be overloaded directly, but user-defined types can overload the `>>` operator (see operator).

Example

```
// cs_operator_right_shift_assignment.cs
using System;
class Test
{
   public static void Main()
   {
      int a = 1000;
      a >>= 4;
      Console.WriteLine(a);
   }
}
```

Output

```
62
```

See Also

C# Operators | 7.13 Assignment operators

-> Operator

The -> operator combines pointer dereferencing and member access.

```
expr1 -> expr2
```

Where:

expr1
A pointer expression.
expr2
An expression.

Remarks

An expression of the form

```
x->y
```

(where `x` is a pointer of type `T*` and `y` is a member of `T`) is equivalent to

```
(*x).y
```

The -> operator can be used only in unmanaged code.

The -> operator cannot be overloaded.

Example

```
// cs_operator_dereferencing.cs
// compile with: /unsafe
using System;
struct Point
{
   public int x, y;
}

class Test
{
   public unsafe static void Main()
   {
      Point pt = new Point();
      Point* pp = &pt;
      pp->x = 123;
      pp->y = 456;
      Console.WriteLine ( "{0} {1}", pt.x, pt.y );
   }
}
```

Output

```
123 456
```

C# Attributes

This section contains an introduction to attributes and descriptions of the following reserved attributes.

AttributeUsage	Describes how a custom attribute class can be used.
Conditional	Marks a conditional method, a method whose execution depends on a specified preprocessing identifier.
Obsolete	Marks a program entity that should not be used.

See Also

C# Programmer's Reference | 17. Attributes | Attributes Tutorial | Introduction to Attributes | B. Interoperability | Platform Invoke Tutorial

Introduction to Attributes

C# provides a mechanism for defining declarative tags, called attributes, which you can place on certain entities in your source code to specify additional information. The information that attributes contain can be retrieved at run time through reflection. You can use predefined attributes or you can define your own custom attributes. This section provides a general introduction to attributes in C#; for more detailed information, refer to 17. Attributes.

- Using Attributes
- Attribute Targets and Global Attributes
- Creating Custom Attributes
- Retrieving Attribute Information

See Also

C# Attributes | 17. Attributes | Attributes Tutorial | Platform Invoke Tutorial

Using Attributes

Attributes can be placed on most any declaration (though a specific attribute might restrict the types of declarations on which it is valid). Syntactically, an attribute is specified by placing the name of the attribute, enclosed in square brackets, in front of the declaration of the entity to which it applies. For example, a class with the attribute **DllImport** is declared like this:

```
[DllImport] public class MyDllimportClass { ... }
```

For more information, see DllImportAttribute Class.

Many attributes have parameters, which can be either positional (unnamed) or named. Any positional parameters must be specified in a certain order and cannot be omitted; named parameters are optional and can be specified in any order. Positional parameters are specified first. For example, these three attributes are equivalent:

```
[DllImport("user32.dll", SetLastError=false, ExactSpelling=false)]
[DllImport("user32.dll", ExactSpelling=false, SetLastError=false)]
[DllImport("user32.dll")]
```

The first parameter, the DLL name, is positional and always comes first; the others are named. In this case, both named parameters default to false, so they can be omitted (refer to the individual attribute's documentation for information on default parameter values).

More than one attribute can be placed on a declaration, either separately or within the same set of brackets:

```
bool AMethod([In][Out]ref double x);
bool AMethod([Out][In]ref double x);
bool AMethod([In,Out]ref double x);
```

Some attributes can be specified more than once for a given entity. An example of such a multiuse attribute is Conditional:

```
[Conditional("DEBUG"), Conditional("TEST1")] void TraceMethod() {...}
```

> **Note** By convention, all attribute names end with the word "Attribute" to distinguish them from other items in the .NET Framework. However, you do not need to specify the attribute suffix when using attributes in code. For example, `[DllImport]` is equivalent to `[DllImportAttribute]`, but **DllImportAttribute** is the attribute's actual name in the .NET Framework.

See Also

Introduction to Attributes | Attribute Targets | Global Attributes | Creating Custom Attributes | Retrieving Attribute Information

Attribute Targets

In certain situations, the target of an attribute (that is, the entity to which the attribute applies) appears to be ambiguous. For example, in the following method declaration, the `SomeAttr` attribute could apply to the method or to the method's return value:

```
[SomeAttr] int Method1( string s )
```

This sort of situation arises frequently when marshaling. To resolve the ambiguity, C# has a set of default targets for each kind of declaration, which can be overridden by explicitly specifying attribute targets.

```
[method: SomeAttr] int Method1( string s ) // applies to method
[return: SomeAttr] int Method1( string s ) // applies to return value
[SomeAttr] int Method1( string s ) // default: applies to method
```

Note that this is independent of the targets on which `SomeAttr` is defined to be valid (see AttributeUsage); that is, even if `SomeAttr` were defined to apply only to return values, the **return** target would still have to be specified. In other words, the compiler will not use **AttributeUsage** information to resolve ambiguous attribute targets.

The syntax for attribute targets is as follows:

```
[target : attribute-list]
```

where:

target
One of the following: assembly, field, event, method, module, param, property, return, type.
attribute-list
A list of applicable attributes.

The table below lists all declarations where attributes are allowed; for each declaration, the possible targets for attributes on the declaration are listed in the second column. Targets in bold are the defaults.

Declaration	Possible targets
assembly	assembly
module	module
class	**type**
struct	**type**
interface	**type**
enum	**type**
delegate	**type**, return
method	**method**, return
parameter	**param**
field	**field**
property — indexer	**property**
property — get accessor	**method**, return
property — set accessor	**method**, param, return
event — field	**event**, field, method
event — property	**event**, property
event — add	**method**, param
event — remove	**method**, param

Note that assembly- and module-level attributes have no default target. For more information, see Global Attributes.

Example

```
// cs_attribute_targets.cs
// compile with: /target:library
using System.Runtime.InteropServices;
```

```
[Guid("12345678-1234-1234-1234-123456789abc"),
InterfaceType(ComInterfaceType.InterfaceIsIUnknown)]
interface IMyInterface
{
   [DispId(17)]                  // set the DISPID of the method
   // the following attribute sets the marshaling on the return type
   [return : MarshalAs(UnmanagedType.Interface)]
   object MyInterfaceMethod();
}
```

Introduction to Attributes | 17.2 Attribute specification | Global Attributes | Creating Custom Attributes | Retrieving Attribute Information

Global Attributes

Most attributes are attached to specific language elements, such as classes or methods; however, some attributes are global — they apply to an entire assembly or module. Assembly-level attributes are specified as follows:

```
[assembly: attribute-list]
```

Module-level attributes are specified as follows:

```
[module: attribute-list]
```

where:

attribute-list
A list of applicable global attributes.

Global attributes appear in the source code after any top-level using directives and before any type or namespace declarations. Global attributes can appear in multiple source files in a single compilation.

Of the .NET Framework assembly-level attributes, the following let you modify the information in an assembly:

- System.Reflection.AssemblyConfigurationAttribute
- System.Reflection.AssemblyCultureAttribute
- System.Reflection.AssemblyDescriptionAttribute
- System.Reflection.AssemblyKeyFileAttribute
- System.Reflection.AssemblyKeyNameAttribute
- System.Reflection.AssemblyDelaySignAttribute
- System.Reflection.AssemblyTitleAttribute
- System.Reflection.AssemblyVersionAttribute

Use the file created by Strong Name Utility (SN.exe) as the parameter to **AssemblyKeyFileAttribute**, **AssemblyKeyNameAttribute**, or **AssemblyDelaySignAttribute** to sign (or give a strong name to) your assembly.

See the file AssemblyInfo.cs, which is added to all C# projects created in Visual Studio, to see those attributes in use.

Use /target:module to create an output file that does not contain an Assembly.

> **Note** Assembly-level attributes are ignored if you are not creating an assembly.

Example

The CLSCompliant attribute indicates whether all types defined in the assembly comply with the .NET Framework common language specification.

```
[assembly: System.CLSCompliant(true)]
```

See Also

Introduction to Attributes | Using Attributes | Attribute Targets | Creating Custom Attributes | Retrieving Attribute Information

Creating Custom Attributes

You can create your own custom attributes by defining an attribute class, a class that derives directly or indirectly from **System.Attribute** (which makes identifying attribute definitions in metadata fast and easy). Suppose you want to tag classes and structs with the name of the programmer who wrote the class or struct. You might define a custom `Author` attribute class:

```
using System;
[AttributeUsage(AttributeTargets.Class|AttributeTargets.Struct)]
public class Author : Attribute
{
   public Author(string name) { this.name = name; version = 1.0; }
   public double version;
   string name;
}
```

The class name is the attribute's name, `Author`. It is derived from **System.Attribute**, so it is a custom attribute class. The constructor's parameters are the custom attribute's positional parameters (in this case, `name`), and any public read-write fields or properties are named parameters (in this case, `version` is the only named parameter). Note the use of the **AttributeUsage** attribute to make the `Author` attribute valid only on class and struct declarations.

You could use this new attribute as follows:

```
[Author("H. Ackerman", version=1.1)] class SomeClass{...}
```

AttributeUsage has a named parameter, **AllowMultiple**, with which you can make a custom attribute single-use or multiuse.

```
[AttributeUsage(AttributeTargets.Class|AttributeTargets.Struct,
   AllowMultiple=true)] // multiuse attribute
public class Author : Attribute
{
   ...
}
```

See Also

Introduction to Attributes | Using Attributes | Attribute Targets | Global Attributes | Retrieving Attribute Information | AttributeUsage

Retrieving Attribute Information

The fact that you can define custom attributes and place them in your source code would be of little value without some way of retrieving that information and acting on it. Fortunately, C# has a reflection system that allows you to do just that. The key method is **GetCustomAttributes**, which returns an array of objects that are the run-time equivalents of the source code attributes.

An attribute specification such as:

```
[Author("H. Ackerman", version=1.1)] class AClass {...}
```

is conceptually equivalent to this:

```
Author anonymousAuthorObject = new Author("H. Ackerman");
anonymousAuthorObject.version = 1.1;
```

However, the code is not executed until `AClass` is queried for attributes. Calling **GetCustomAttributes** on `AClass` causes an `Author` object to be constructed and initialized as above. If the class has other attributes, other attribute objects are constructed similarly. **GetCustomAttributes** then returns the `Author` object and any other attribute objects in an array. You can then iterate over this array, determine what attributes were applied based on the type of each array element, and extract information from the attribute objects.

Example

Here is a complete example. A custom attribute is defined, applied to several entities, and retrieved via reflection.

```
// cs_attributes_retr.cs
using System;
[AttributeUsage(AttributeTargets.Class|AttributeTargets.Struct,
   AllowMultiple=true)]
public class Author : Attribute
{
   public Author(string name)
   {
      this.name = name; version = 1.0;
   }
   public double version;
   string name;
   public string GetName()
   {
      return name;
   }
}

[Author("H. Ackerman")]
class FirstClass
{
   /*...*/
}

class SecondClass  // no Author attribute
{
   /*...*/
}

[Author("H. Ackerman"), Author("M. Knott", version=1.1)]
class Steerage
{
   /*...*/
}

class AuthorInfo
{
   public static void Main()
```

```
    {
       PrintAuthorInfo(typeof(FirstClass));
       PrintAuthorInfo(typeof(SecondClass));
       PrintAuthorInfo(typeof(Steerage));
    }
    public static void PrintAuthorInfo(Type t)
    {
       Console.WriteLine("Author information for {0}", t);
       Attribute[] attrs = Attribute.GetCustomAttributes(t);
       foreach(Attribute attr in attrs)
       {
          if (attr is Author)
          {
             Author a = (Author)attr;
             Console.WriteLine("   {0}, version {1:f}",
a.GetName(), a.version);
          }
       }
    }
}
```

Output

```
Author information for FirstClass
   H. Ackerman, version 1.00
Author information for SecondClass
Author information for Steerage
   H. Ackerman, version 1.00
   M. Knott, version 1.10
```

See Also

Introduction to Attributes | Using Attributes | Attribute Targets | Global Attributes | Creating Custom Attributes | Discovering Type Information at Runtime

AttributeUsage

Describes how a custom attribute class can be used.

```
[AttributeUsage(
   validon,
   AllowMultiple=allowmultiple,
   Inherited=inherited
)]
```

Parameters

validon
Specifies the language elements on which the attribute can be placed; a combination of AttributeTargets values. Default value is **AttributeTargets.All**.

allowmultiple (optional)
A bool; if **true**, the attribute is multiuse. Default is **false** (single-use).

inherited (optional)
A **bool**; if **true**, the attribute is inherited by derived classes. Default is **false** (not inherited).

Applies To

Class declarations.

Remarks

The **AttributeUsage** attribute is a single-use attribute. **AttributeUsage** is an alias for **System.AttributeUsageAttribute**.

Example

See the example in Retrieving Attribute Information.

See Also

C# Attributes | Attributes Tutorial

Conditional

Marks a conditional method whose execution depends on a specified preprocessing identifier.

```
[Conditional(
   conditionalSymbol
)]
```

Parameters

conditionalSymbol
A string representing the name of a preprocessing identifier.

Applies To

Method declarations.

Remarks

The **Conditional** attribute is a multiuse attribute. **Conditional** is an alias for **System.Diagnostics.ConditionalAttribute**.

Wherever a conditional method is called, the presence or absence of the preprocessing symbol specified by *conditionalSymbol* at the point of the call determines whether the call is included or omitted. If the symbol is defined, the call is included; otherwise, the call is omitted. Conditional methods provide a cleaner, more elegant alternative to enclosing the method call in #if *conditionalSymbol*...#endif preprocessor directives.

A conditional method must be a method in a class or struct declaration and must have a return type of void (for other restrictions, see 17.4.2 The Conditional attribute).

If a method has multiple **Conditional** attributes, a call to the method is included if at least one of the conditional symbols is defined (in other words, the symbols are logically ORed together).

```
[Conditional("A"), Conditional("B")] public static void IfAorB( )
{
   ...
}
```

To achieve the effect of logically ANDing symbols, you can define serial conditional methods:

```
[Conditional("A")] public static void IfAandB( )
{
   AandBPrivate( );
}
[Conditional("B")] static void AandBPrivate( )
{
   /* Code to execute when both A and B are defined... */
}
```

Call `IfAandB`; if both `A` and `B` are defined, `AandBPrivate` will execute.

Example

```
// cs_attribute_conditional.cs
#define DEBUG
using System;
using System.Diagnostics;
public class Trace
{
   [Conditional("DEBUG")] public static void Msg(string msg)
   {
      Console.WriteLine(msg);
```

```
    }
}
class Test
{
    static void A( )
    {
        Trace.Msg("Now in A.");
        B( );
    }
    static void B( )
    {
        Trace.Msg("Now in B.");
    }
    public static void Main( )
    {
        Trace.Msg("Now in Main.");
        A( );
        Console.WriteLine("Done.");
    }
}
```

Output

```
Now in Main.
Now in A.
Now in B.
Done.
```

If you compile the sample with first line omitted (or changed to `#undef DEBUG`), the output will be: `Done`..

See Also

C# Attributes | Conditional Methods Tutorial | C# Preprocessor Directives

Obsolete

Marks a program entity that should not be used.

```
[Obsolete(
   message
)]
[Obsolete(
   message,
   iserror
)]
```

Parameters

message
A string; ideally, a human-readable explanation of why the item is obsolete and what to use instead.
iserror
A bool; if **true**, the compiler should treat the use of the item as an error. Default value is **false** (compiler generates a warning).

Applies To

Any declaration that allows attributes.

Remarks

The **Obsolete** attribute is a single-use attribute. **Obsolete** is an alias for **System.ObsoleteAttribute**.

When an entity marked **Obsolete** is used in a program, the compiler issues either an error or a warning (depending on *iserror*) and prints out *message*.

Example

```
// cs_attribute_obsolete.cs
// CS0619 expected
using System;
public class MyClass
{
   [Obsolete("Don't use OldWay; use NewWay instead", true)]
   static void OldWay( ) { Console.WriteLine("Silly me!"); }
   static void NewWay( ) { Console.WriteLine("D'oh!"); }
   public static void Main( )
   {
      OldWay( );
   }
}
```

C# Preprocessor Directives

This section discusses the C# language's preprocessor directives:

- #if
- #else
- #elif
- #endif
- #define
- #undef
- #warning
- #error
- #line
- #region
- #endregion

While the compiler does not have a separate preprocessor, the directives described in this section are processed as if there was one; these directives are used to aid in conditional compilation. Unlike C and C++ directives, you cannot use these directives to create macros.

A preprocessor directive must be the only instruction on a line.

For more information, see 2.5 Pre-processing directives.

See Also

C# Programmer's Reference | Conditional Methods Tutorial

#if

#if lets you begin a conditional directive, testing a symbol or symbols to see if they evaluate to **true**. If they do evaluate to **true**, the compiler evaluates all the code between the **#if** and the next directive.

```
#if symbol [operator symbol]...
```

where:

symbol
The name of the symbol you want to test. You can also use **true** and **false**. *symbol* can be prefaced with the negation operator. For example, **!true** will evaluate to **false**.

operator (optional)
You can use the following operators to evaluate multiple symbols:

== (equality)

!= (inequality)

&& (and)

|| (or)

You can group symbols and operators with parentheses.

Remarks

#if, along with the **#else**, **#elif**, **#endif**, **#define**, and **#undef** directives, lets you include or exclude code based on the condition of one or more symbols. This can be most useful when compiling code for a debug build or when compiling for a specific configuration.

A conditional directive beginning with a **#if** directive must explicitly be terminated with a **#endif** directive.

Example

```
// preprocessor_if.cs
#define DEBUG
#define VC_V7
using System;
public class MyClass
{
   public static void Main()
   {

      #if (DEBUG && !VC_V7)
         Console.WriteLine("DEBUG is defined");
      #elif (!DEBUG && VC_V7)
         Console.WriteLine("VC_V7 is defined");
      #elif (DEBUG && VC_V7)
         Console.WriteLine("DEBUG and VC_V7 are defined");
      #else
         Console.WriteLine("DEBUG and VC_V7 are not defined");
      #endif
   }
}
```

Output

```
DEBUG and VC_V7 are defined
```

See Also

#else

#else lets you create a compound conditional directive, such that, if none of the expressions in the preceding #if or (optional) #elif directives did not evaluate to **true**, the compiler will evaluate all code between **#else** and the subsequent **#endif**.

```
#else
```

Remarks

#endif must be the next preprocessor directive after **#else**.

Example

See #if for an example of how to use **#else**.

See Also

C# Preprocessor Directives

#elif

#elif lets you create a compound conditional directive. The **#elif** expression will be evaluated if neither the preceding #if nor any preceding (optional) #elif directive expressions evaluate to **true**. If a **#elif** expression evaluates to **true**, the compiler evaluates all the code between the **#elif** and the next directive.

```
#elif symbol [operator symbol]...
```

where:

symbol
The name of the symbol you want to test. You can also use **true** and **false**. *symbol* can be prefaced with the negation operator. For example, **!true** will evaluate to **false**.

operator (optional)
You can use the following operators to evaluate multiple symbols:

== (equality)

!= (inequality)

&& (and)

|| (or)

You can group symbols and operators with parentheses.

Remarks

#elif is equivalent to using:

```
#else
#if
```

But using **#elif** is simpler because each **#if** requires a #endif, whereas a **#elif** can be used without a matching **#endif**.

Example

See #if for an example of how to use **#elif**.

See Also

C# Preprocessor Directives

#endif

#endif specifies the end of a conditional directive, which began with the #if directive.

```
#endif
```

Remarks

A conditional directive, beginning with a **#if** directive, must explicitly be terminated with a **#endif** directive.

Example

See #if for an example of how to use **#endif**.

See Also

C# Preprocessor Directives

#define

#define lets you define a symbol, such that, by using the symbol as the expression passed to the #if directive, the expression will evaluate to **true**.

```
#define symbol
```

where:

symbol
The name of the symbol to define.

Remarks

Symbols can be used to specify conditions for compilation. You can test for the symbol with either #if or #elif. You can also use the **conditional** attribute to perform conditional compilation.

You can define a symbol, but you cannot assign a value to a symbol. The **#define** directive must appear in the file before you use any instructions that are not also directives.

You can also define a symbol with the /define compiler option. You can undefine a symbol with #undef.

A symbol that you define with /define or with **#define** does not conflict with a variable of the same name. That is, a variable name should not be passed to a preprocessor directive and a symbol can only be evaluated by a preprocessor directive.

The scope of a symbol created with **#define** is the file in which it was defined.

Example

See #if for an example of how to use **#define**.

See Also

C# Preprocessor Directives | Conditional Methods Tutorial

#undef

#undef lets you undefine a symbol, such that, by using the symbol as the expression in a **#if** directive, the expression will evaluate to **false**.

```
#undef symbol
```

where:

symbol
The name of the symbol you want to undefine.

Remarks

A symbol can be defined either with the #define directive or the /define compiler option. The **#undef** directive must appear in the file before you use any statements that are not also directives.

Example

```
// preprocessor_undef.cs
// compile with: /d:DEBUG
#undef DEBUG
using System;
public class MyClass
{
   public static void Main()
   {
      #if DEBUG
         Console.WriteLine("DEBUG is defined");
      #else
         Console.WriteLine("DEBUG is not defined");
      #endif
   }
}
```

Output

```
DEBUG is not defined
```

See Also

C# Preprocessor Directives

#warning

#warning lets you generate a level one warning from a specific location in your code.

```
#warning text
```

where:

text
The text of the warning that should appear in the compiler's output.

Remarks

A common use of **#warning** is in a conditional directive. It is also possible to generate a user-defined error with #error.

Example

```
// preprocessor_warning.cs
// CS1030 expected
#define DEBUG
public class MyClass
{
   public static void Main()
   {
      #if DEBUG
      #warning DEBUG is defined
      #endif
   }
}
```

See Also

C# Preprocessor Directives

#error

#error lets you generate an error from a specific location in your code.

```
#error text
```

where:

text
The text of the error that should appear in the compiler's output.

Remarks

A common use of **#error** is in a conditional directive. It is also possible to generate a user-defined warning with #warning.

Example

```
// preprocessor_error.cs
// CS1029 expected
#define DEBUG
public class MyClass
{
   public static void Main()
   {
      #if DEBUG
      #error DEBUG is defined
      #endif
   }
}
```

See Also

C# Preprocessor Directives

#line

#line lets you modify the compiler's line number and (optionally) the file name output for errors and warnings.

```
#line [ number ["file_name"] | hidden | default ]
```

where:

number
The number you want to specify for the following line in a source code file.

"*file_name*" (optional)
The file name you want to appear in the compiler output. By default, the actual name of the source code file is used. The file name must be in double quotation marks ("").

hidden
Hides the successive lines from the debugger until another **#line** directive is encountered.

default
Resets the line numbering in a file.

Remarks

The **#line** directive might be used in an automated, intermediate step in the build process. For example, if lines were removed from the original source code file, but you still wanted the compiler to generate output based on the original line numbering in the file, you could remove lines and then simulate the original line numbering with **#line**.

The **#line hidden** directive hides the successive lines from the debugger, such that when the developer steps through the code, any lines between a **#line hidden** and the next **#line** directive (assuming that it is not another **#line hidden** directive) will be stepped over. This option can also be used to allow ASP.NET to differentiate between user-defined and machine-generated code. Although ASP.NET is the primary consumer of this feature, it is likely that more source generators will make use of it.

A **#line hidden** directive does not affect file names or line numbers in error reporting. That is, if an error is encountered in a hidden block, the compiler will report the current file name and line number of the error.

A source code file can have any number of **#line** directives.

Example 1

The following example shows how to report two warnings, associated with line numbers. The `#line 200` directive forced the line number to be 200 (although the default is #7). The other line (#9) follows the usual sequence as a result of the default `#line` directive.

```
// preprocessor_line.cs
public class MyClass2
{
   public static void Main()
   {
      #line 200
      int i;   // CS0168 on line 200
      #line default
      char c;   // CS0168 on line 9
   }
}
```

Example 2

The following example shows how the debugger ignores the hidden lines in the code. When you run the example, it will display three lines of text. However, when you set a break point, as shown in the example, and hit F10 to step through the code, you will notice that the debugger ignores the hidden line. Notice also that even if you set a break point at the hidden line, the debugger will still ignore it.

```
// preprocessor_linehidden.cs

using System;
```

```
class MyClass
{
   public static void Main()
   {
      Console.WriteLine("Normal line #1.");   // Set a break point here.
      #line hidden
      Console.WriteLine("Hidden line.");
      #line default
      Console.WriteLine("Normal line #2.");
   }
}
```

See Also

C# Preprocessor Directives

#region

#region lets you specify a block of code that you can expand or collapse when using the outlining feature of the Visual Studio Code Editor.

```
#region name
```

where:

name
The name you want to give to the region, which will appear in the Visual Studio Code Editor.

Remarks

A **#region** block must be terminated with a #endregion directive.

A **#region** block cannot overlap with a #if block. However, a **#region** block can be nested in a **#if** block, and a **#if** block can be nested in a **#region** block.

Example

```
// preprocessor_region.cs
#region MyClass definition
public class MyClass
{
   public static void Main()
   {
   }
}
#endregion
```

See Also

C# Preprocessor Directives

#endregion

#endregion marks the end of a #region block.

```
#endregion name
```

where:

name
A comment you want to pass to the `#endregion` directive.

Example

See #region for an example of how to use **#endregion**.

C# Preprocessor Directives

C# Language Features

This section of the *C# Programmer's Reference* provides information about the following language features:

- Arrays
- Constructors and Destructors
- Indexers
- Main
- Properties
- Passing Parameters
- XML Documentation

See Also

C# Programmer's Reference | C# Tutorials | Visual C# Samples

Arrays

An array is a data structure that contains a number of variables called the elements of the array. The array elements are accessed through computed indexes. C# arrays are zero indexed; that is, the array indexes start at zero. All of the array elements must be of the same type, which is called the element type of the array. Array elements can be of any type, including an array type. An array can be a single-dimensional array, or a multidimensional array. Array types are reference types derived from the abstract base type **System.Array**.

The following topics are discussed in this section:

- Single-Dimensional Arrays
- Multidimensional Arrays
- Jagged Arrays
- Passing Arrays Using ref and out

See Also

C# Language Features | Reference Types | 12. Arrays | Arrays Tutorial

Single-Dimensional Arrays

You can declare an array of five integers as in the following example:

```
int[] myArray = new int [5];
```

This array contains the elements from `myArray[0]` to `myArray[4]`. The **new** operator is used to create the array and initialize the array elements to their default values. In this example, all the array elements are initialized to zero.

An array that stores string elements can be declared in the same way. For example:

```
string[] myStringArray = new string[6];
```

Array Initialization

It is possible to initialize an array upon declaration, in which case, the rank specifier is not needed because it is already supplied by the number of elements in the initialization list. For example:

```
int[] myArray = new int[] {1, 3, 5, 7, 9};
```

A string array can be initialized in the same way. The following is a declaration of a string array where each array element is initialized by a name of a day:

```
string[] weekDays = new string[]
               {"Sun","Sat","Mon","Tue","Wed","Thu","Fri"};
```

When you initialize an array upon declaration, it is possible to use the following shortcuts:

```
int[] myArray = {1, 3, 5, 7, 9};
string[] weekDays = {"Sun","Sat","Mon","Tue","Wed","Thu","Fri"};
```

It is possible to declare an array variable without initialization, but you must use the **new** operator when you assign an array to this variable. For example:

```
int[] myArray;
myArray = new int[] {1, 3, 5, 7, 9};   // OK
myArray = {1, 3, 5, 7, 9};   // Error
```

Value Type and Reference Type Arrays

Consider the following array declaration:

```
MyType[] myArray = new MyType[10];
```

The result of this statement depends on whether `MyType` is a value type or a reference type. If it is a value type, the statement results in creating an array of 10 instances of the type `MyType`. If `MyType` is a reference type, the statement creates an array of 10 elements, each of which is initialized to a null reference.

For more information on value types and reference types, see Types.

Passing Arrays as Parameters

You can pass an initialized array to a method. For example:

```
PrintArray(myArray);
```

You can also initialize and pass a new array in one step. For example:

```
PrintArray(new int[] {1, 3, 5, 7, 9});
```

Example

In the following example, a string array is initialized and passed as a parameter to the `PrintArray` method, where its elements are displayed:

```
// cs_sd_arrays.cs
using System;
public class ArrayClass
{
   static void PrintArray(string[] w)
   {
      for (int i = 0 ; i < w.Length ; i++)
         Console.Write(w[i] + "{0}", i < w.Length - 1 ? " " : "");
      Console.WriteLine();
   }

   public static void Main()
   {
      // Declare and initialize an array:
      string[] WeekDays = new string []
         {"Sun","Sat","Mon","Tue","Wed","Thu","Fri"};

      // Pass the array as a parameter:
      PrintArray(WeekDays);
   }
}
```

Output

```
Sun Sat Mon Tue Wed Thu Fri
```

See Also

Arrays | Multidimensional Arrays | Jagged Arrays

Multidimensional Arrays

Arrays can have more than one dimension. For example, the following declaration creates a two-dimensional array of four rows and two columns:

```
int[,] myArray = new int[4,2];
```

Also, the following declaration creates an array of three dimensions, 4, 2, and 3:

```
int[,,] myArray = new int [4,2,3];
```

Array Initialization

You can initialize the array upon declaration as shown in the following example:

```
int[,] myArray = new  int[,] {{1,2}, {3,4}, {5,6}, {7,8}};
```

You can also initialize the array without specifying the rank:

```
int[,] myArray = {{1,2}, {3,4}, {5,6}, {7,8}};
```

If you choose to declare an array variable without initialization, you must use the **new** operator to assign an array to the variable. For example:

```
int[,] myArray;
myArray = new int[,] {{1,2}, {3,4}, {5,6}, {7,8}};   // OK
myArray = {{1,2}, {3,4}, {5,6}, {7,8}};   // Error
```

You can also assign a value to an array element, for example:

```
myArray[2,1] = 25;
```

Passing Arrays as Parameters

You can pass an initialized array to a method. For example:

```
PrintArray(myArray);
```

You can also initialize and pass a new array in one step. For example:

```
PrintArray(new int[,] {{1,2}, {3,4}, {5,6}, {7,8}});
```

Example

In this example, a two-dimensional array is initialized and passed to the `PrintArray` method, where its elements are displayed.

```
// cs_td_arrays.cs
using System;
public class ArrayClass
{
   static void PrintArray(int[,] w)
   {
      // Display the array elements:
      for (int i=0; i < 4; i++)
         for (int j=0; j < 2; j++)
            Console.WriteLine("Element({0},{1})={2}", i, j, w[i,j]);
```

```
    }

    public static void Main()
    {
       // Pass the array as a parameter:
       PrintArray(new int[,] {{1,2}, {3,4}, {5,6}, {7,8}});
    }
}
```

Output

```
Element(0,0)=1
Element(0,1)=2
Element(1,0)=3
Element(1,1)=4
Element(2,0)=5
Element(2,1)=6
Element(3,0)=7
Element(3,1)=8
```

Arrays | Single-Dimensional Arrays | Jagged Arrays

Jagged Arrays

A jagged array is an array whose elements are arrays. The elements of a jagged array can be of different dimensions and sizes. A jagged array is sometimes called an "array-of-arrays." This topic contains examples of declaring, initializing, and accessing jagged arrays.

The following is a declaration of a single-dimensional array that has three elements, each of which is a single-dimensional array of integers:

```
int[][] myJaggedArray = new int[3][];
```

Before you can use `myJaggedArray`, its elements must be initialized. You can initialize the elements like this example:

```
myJaggedArray[0] = new int[5];
myJaggedArray[1] = new int[4];
myJaggedArray[2] = new int[2];
```

Each of the elements is a single-dimensional array of integers. The first element is an array of 5 integers, the second is an array of 4 integers, and the third is an array of 2 integers.

It is also possible to use initializers to fill the array elements with values, in which case you don't need the array size, for example:

```
myJaggedArray[0] = new int[] {1,3,5,7,9};
myJaggedArray[1] = new int[] {0,2,4,6};
myJaggedArray[2] = new int[] {11,22};
```

You can also initialize the array upon declaration like this:

```
int[][] myJaggedArray = new int [][]
                        {
                           new int[] {1,3,5,7,9},
                           new int[] {0,2,4,6},
                           new int[] {11,22}
                        };
```

You can use the following shortcut (notice that you cannot omit the **new** operator from the elements initialization because there is no default initialization for the elements):

```
int[][] myJaggedArray = {
                           new int[] {1,3,5,7,9},
                           new int[] {0,2,4,6},
                           new int[] {11,22}
                        };
```

You can access individual array elements like these examples:

```
// Assign 33 to the second element of the first array:
myJaggedArray[0][1] = 33;
// Assign 44 to the second element of the third array:
myJaggedArray[2][1] = 44;
```

It is possible to mix jagged and multidimensional arrays. The following is a declaration and initialization of a single-dimensional jagged array that contains two-dimensional array elements of different sizes:

```
int[][,] myJaggedArray = new int [3][,]
                         {
                            new int[,] { {1,3}, {5,7} },
                            new int[,] { {0,2}, {4,6}, {8,10} },
                            new int[,] { {11,22}, {99,88}, {0,9} }
                         };
```

You can access individual elements like this example, which displays the value of the element `[1,0]` of the first array (value `5`):

```
Console.Write("{0}", myJaggedArray[0][1,0]);
```

Example

This example builds an array, `myArray`, whose elements are arrays. Each one of the array elements has a different size.

```
// cs_array_of_arrays.cs
using System;
public class ArrayTest
{
   public static void Main()
   {
      // Declare the array of two elements:
      int[][] myArray = new int[2][];

      // Initialize the elements:
      myArray[0] = new int[5] {1,3,5,7,9};
      myArray[1] = new int[4] {2,4,6,8};

      // Display the array elements:
      for (int i=0; i < myArray.Length; i++)
      {
         Console.Write("Element({0}): ", i);

         for (int j = 0 ; j < myArray[i].Length ; j++)
            Console.Write("{0}{1}", myArray[i][j],
                          j == (myArray[i].Length-1) ? "" : " ");

         Console.WriteLine();
      }
   }
}
```

Output

```
Element(0): 1 3 5 7 9
Element(1): 2 4 6 8
```

Passing Arrays Using ref and out

Like all out parameters, an **out** parameter of an array type must be assigned before it is used; that is, it must be assigned by the callee. For example:

```
public static void MyMethod(out int[] arr)
{
   arr = new int[10];   // definite assignment of arr
}
```

Like all ref parameters, a **ref** parameter of an array type must be definitely assigned by the caller. Therefore, there is no need to be definitely assigned by the callee. A **ref** parameter of an array type may be altered as a result of the call. For example, the array can be assigned the **null** value or can be initialized to a different array. For example:

```
public static void MyMethod(ref int[] arr)
{
   arr = new int[10];   // arr initialized to a different array
}
```

The following two examples demonstrate the difference between **out** and **ref** when used in passing arrays to methods.

Example 1

In this example, the array `myArray` is declared in the caller (the `Main` method), and initialized in the `FillArray` method. Then, the array elements are returned to the caller and displayed.

```
// cs_array_ref_and_out.cs
using System;
class TestOut
{
   static public void FillArray(out int[] myArray)
   {
      // Initialize the array:
      myArray = new int[5] {1, 2, 3, 4, 5};
   }

   static public void Main()
   {
      int[] myArray; // Initialization is not required

      // Pass the array to the callee using out:
      FillArray(out myArray);

      // Display the array elements:
      Console.WriteLine("Array elements are:");
      for (int i=0; i < myArray.Length; i++)
         Console.WriteLine(myArray[i]);
   }
}
```

Output

```
Array elements are:
1
2
3
4
5
```

Example 2

In this example, the array `myArray` is initialized in the caller (the `Main` method), and passed to the `FillArray` method by using the **ref** parameter. Some of the array elements are updated in the `FillArray` method. Then, the array elements are returned to the caller and displayed.

```
// cs_array_ref_and_out2.cs
using System;
class TestRef
{
   public static void FillArray(ref int[] arr)
   {
      // Create the array on demand:
      if (arr == null)
         arr = new int[10];
      // Otherwise fill the array:
      arr[0] = 123;
      arr[4] = 1024;
   }

   static public void Main ()
   {
      // Initialize the array:
      int[] myArray = {1,2,3,4,5};

      // Pass the array using ref:
      FillArray(ref myArray);

      // Display the updated array:
      Console.WriteLine("Array elements are:");
      for (int i = 0; i < myArray.Length; i++)
         Console.WriteLine(myArray[i]);
   }
}
```

Output

```
Array elements are:
123
2
3
4
1024
```

Constructors and Destructors

This section explains the process of creation, initialization, and destruction of objects. It introduces the following topics:

- Class Constructors
- Struct Constructors
- Destructors

See Also

C# Language Features

Class Constructors

In this section, three kinds of class constructors are discussed:

Type of class constructor	Comments
Instance	Used to create and initialize instances of the class.
Private	A special type of instance constructor that is not accessible outside the class. A class c annot be instantiated using a private constructor.
Static	Called automatically to initialize the class before the first instance is created or any st atic members are referenced. The constructor cannot be called directly.

See Also

Constructors and Destructors

Instance Constructors

Instance constructors are used to create and initialize instances. Constructors are declared using the following form:

```
[attributes] [modifiers] identifier([formal-parameter-list])
[initializer] { constructor-body }
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see C# Attributes.
modifiers (Optional)
The allowed modifiers are extern and the four access modifiers.
identifier
The *identifier* is the same as the class name.
formal-parameter-list (Optional)
The optional parameters passed to the constructor. The parameters must be as accessible as the constructor itself.
initializer (Optional)
Invoked before the execution of the constructor body. The *initializer* can be one of the following with an optional *argument-list*:
: base (*argument-list*)
: this (*argument-list*)
constructor-body
The block that contains the statements that initialize the class instance.

Remarks

The class constructor is invoked when you create a new object, for example:

```
Point myPoint = new Point();
```

A class can have more than one constructor. For example, you can declare a constructor without arguments, such as `Point()`, and another constructor with arguments, such as `Point(int x, int y)`.

If the class does not have a constructor, a default parameterless constructor is automatically generated for you and the default values are used to initialize the object fields (for example, an **int** is initialized to 0). For more information on default values, see Default Values Table.

The class constructor can invoke the constructor of the base class through the initializer, for example:

```
public Cylinder(double radius, double height): base(radius, height)
{
}
```

In the preceding example, the fields, `radius` and `height`, are initialized through the base class constructor. This is analogous to the C++ initialization list.

The class constructor can also invoke another constructor from the same class by using the keyword **this**, for example:

```
public Point(): this(0,20)
{
}
```

In the preceding example, the parameterless constructor `Point()` is invoking another constructor that has two arguments to initialize the default position at (0, 20).

Example 1

The following example demonstrates a class with two class constructors, one without arguments and one with two arguments.

```
// Constructor1.cs
```

```
using System;

class Point
{
   public int x, y;
   // Default constructor:
   public Point()
   {
      x = 0;
      y = 0;
   }
   // A constructor with two arguments:
   public Point(int x, int y)
   {
      this.x = x;
      this.y = y;
   }

   // Override the ToString method:
   public override string ToString()
   {
      return(String.Format("({0},{1})", x, y));
   }
}

class MainClass
{
   static void Main()
   {
      Point p1 = new Point();
      Point p2 = new Point(5,3);

      // Display the results using the overriden ToString method:
      Console.WriteLine("Point #1 at {0}", p1);
      Console.WriteLine("Point #2 at {0}", p2);
   }
}
```

Output

```
Point #1 at (0,0)
Point #2 at (5,3)
```

Example 2

In this example the class `Person` does not have any constructors, in which case, a default constructor is automatically provided and the fields are initialized to their default values.

```
// Constructor2.cs
using System;

public class Person
{
   public int age;
   public string name;
}

public class MainClass
{
   static void Main()
   {
      Person p = new Person();

      Console.Write("Name: {0}, Age: {1}",p.name, p.age);
   }
```

```
}
```

Output

```
Name: , Age: 0
```

Notice that the default value of `age` is `0` and the default value of `name` is **null**. For more information on default values, see Default Values Table.

Example 3

The following example demonstrates using the base class initializer. The `Circle` class is derived from the general class `Shape`, and the `Cylinder` class is derived from the `Circle` class. The constructor on each derived class is using its base class initializer.

```
// CtorInitializer.cs
using System;

abstract class Shape
{
   public const double pi = Math.PI;
   protected double x, y, z;

   public Shape (double x, double y, double z)
   {
      this.x = x;
      this.y = y;
      this.z = z;
   }

   public abstract double Area();
}

class Circle: Shape
{
   public Circle(double radius): base(radius,0,0)
   {
   }

   public override double Area()
   {
      return pi*x*x;
   }
}

class Cylinder: Circle
{
   public Cylinder(double radius, double height): base(radius)
   {
      y = height;
   }

   public override double Area()
   {
      return 2*(base.Area()) + 2*pi*x*y;
   }
}
class TestClass
{
   public static void Main()
   {
      double radius = 2.5, height = 3.0;
      Circle myCircle = new Circle(radius);
      Cylinder myCylinder = new Cylinder(radius, height);

      Console.WriteLine("Area of the circle   = {0:F2}",
```

```
                                myCircle.Area());
        Console.WriteLine("Area of the cylinder = {0:F2}",
                                myCylinder.Area());
    }
}
```

Output

```
Area of the circle   = 19.63
Area of the cylinder = 86.39
```

For more examples on invoking the base class constructors, see virtual, override, and base.

See Also

10.10 Instance Constructors | Constructors and Destructors | Class Constructors

Private Constructors

A private constructor is a special instance constructor. It is commonly used in classes that contain static members only. If a class has one or more private constructors and no public constructors, then other classes (except nested classes) are not allowed to create instances of this class. For example:

```
class NLog
{
   // Private Constructor:
   private NLog() {}

   public static double e = 2.71828;
}
```

The declaration of the empty constructor prevents the automatic generation of a default constructor. Note that if you don't use an access modifier with the constructor it will still be private by default. However, the **private** modifier is usually used explicitly to make it clear that the class cannot be instantiated.

Private constructors are useful to prevent creation of a class when there are no instance fields or methods, such as the Math class, or when a method is called to obtain an instance of a class.

Example

The following is an example of a class using a private constructor.

```
// PrivateCtor1.cs
using System;

public class MyClass
{
   private MyClass() {}
   public static int counter;
   public static int IncrementCounter()
   {
      return ++counter;
   }
}

class MainClass
{
   static void Main()
   {
      // If you uncomment the following statement, it will generate
      // an error because the constructor is inaccessible:
      // MyClass myObject = new MyClass();   // Error
      MyClass.counter = 100;
      MyClass.IncrementCounter();
      Console.WriteLine("New count: {0}", MyClass.counter);
   }
}
```

Output

```
New count: 101
```

Notice that if you uncomment the following statement from the example, it will generate an error because the constructor is inaccessible due to its protection level:

```
// MyClass myObject = new MyClass();   // error
```

See Also

static | 10.10.5 Private constructors | Constructors and Destructors | Class Constructors

Static Constructors

A static constructor is used to initialize a class. It is called automatically to initialize the class before the first instance is created or any static members are referenced. It is declared using the following form:

```
[attributes] static identifier( ) { constructor-body }
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see C# Attributes.
identifier
The *identifier* is the same as the class name.
constructor-body
The block that contains the statements that initialize the class.

Remarks

A static constructor does not take access modifiers or have parameters.

A static constructor is called automatically to initialize the class before the first instance is created or any static members are referenced.

A static constructor cannot be called directly.

The user has no control on when the static constructor is executed in the program.

A typical use of static constructors is when the class is using a log file and the constructor is used to write entries to this file.

Example

In this example, the class `MyClass` has a static constructor and one static member, `MyMethod()`. When `MyMethod()` is called, the static constructor is invoked to initialize the class.

```
// StaticCtor1.cs
using System;
class MyClass
{
   // Static constructor:
   static MyClass()
   {
      Console.WriteLine("The static constructor invoked.");
   }

   public static void MyMethod()
   {
      Console.WriteLine("MyMethod invoked.");
   }
}

class MainClass
{
   static void Main()
   {
      MyClass.MyMethod();
   }
}
```

Output

```
The static constructor invoked.
MyMethod invoked.
```

For more information and examples of static constructors, see 1.7.10 Static constructors and 10.11 Static constructors.

See Also

static | Constructors and Destructors | Class Constructors

Struct Constructors

Struct constructors are similar to class constructors, except for the following differences:

- Structs cannot contain explicit parameterless constructors. Struct members are automatically initialized to their default values.
- A struct cannot have an initializer in the form: **base** (*argument-list*).

Example

The following is an example of a constructor using two arguments for the `Point` struct.

```
// Structctor1.cs
using System;

public struct Point
{
   public int x, y;
   // Constructor:
   public Point(int x, int y)
   {
      this.x = x;
      this.y = y;
   }
   // Override the ToString method:
   public override string ToString()
   {
      return(String.Format("({0},{1})", x, y));
   }
}

class MainClass
{
   static void Main()
   {
      // Initialize two points:
      Point p1 = new Point();
      Point p2 = new Point(10,15);

      // Display the results using the overriden ToString method:
      Console.WriteLine("Point #1 (default initialization): {0}", p1);
      Console.WriteLine("Point #2 (explicit initialization): {0}", p2);
   }
}
```

Output

```
Point #1 (default initialization): (0,0)
Point #2 (explicit initialization): (10,15)
```

For more information on structs, see struct and the Structs Tutorial.

For a complete comparison between structs and classes, see 11.3 Class and struct differences.

See Also

Constructors and Destructors | Class Constructors

Destructors

Destructors are used to destruct instances of classes. A destructor is declared using the following form:

```
[attributes] ~ identifier( ) { destructor-body }
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see C# Attributes.
identifier
The *identifier* is the same as the class name.
destructor-body
The block that contains the statements that destruct the instance of the class.

Remarks

Destructors cannot be used with structs. They are only used with classes.

A class can only have one destructor.

Destructors cannot be inherited or overloaded.

Destructors cannot be called. They are invoked automatically.

A destructor does not take modifiers or have parameters. For example, the following is a declaration of a destructor for the class `MyClass`:

```
~ MyClass()
{
   // Cleanup statements.
}
```

The destructor implicitly calls the Object.Finalize method on the object's base class. Therefore, the preceding destructor code is implicitly translated to:

```
protected override void Finalize()
{
   try
   {
      // Cleanup statements.
   }
   finally
   {
      base.Finalize();
   }
}
```

This means that the **Finalize** method is called recursively for all of the instances in the inheritance chain, from the most derived to the least derived.

The programmer has no control on when the destructor is called because this is determined by the garbage collector. The garbage collector checks for objects that are no longer being used by the application. It considers these objects eligible for destruction and reclaims their memory. Destructors are also called when the program exits.

It is possible to force garbage collection by calling the GC.Collect method, but in most cases, this should be avoided because it may result in performance issues. For more information, see Forcing a Garbage Collection.

Example

The following example creates three classes that make a chain of inheritance. The class `First` is the base class, `Second` is derived from `First`, and `Third` is derived from `Second`. All three have destructors. In `Main()`, an instance of the most derived class is created. When the program runs, notice that the destructors for the three classes are called automatically, and in order, from the

most derived to the least derived.

```
// Destructors1.cs
using System;

class First
{
   ~First()
   {
      Console.WriteLine("First's destructor is called");
   }
}

class Second: First
{
   ~Second()
   {
      Console.WriteLine("Second's destructor is called");
   }
}

class Third: Second
{
   ~Third()
   {
      Console.WriteLine("Third's destructor is called");
   }
}

public class MainClass
{
   public static void Main()
   {
      Third myObject = new Third();
   }
}
```

Output

```
Third's destructor is called
Second's destructor is called
First's destructor is called
```

Using Destructors to Release Resources

In general, you should not be as concerned about memory management as you would with C++. This is because the .NET Framework garbage collector implicitly manages the allocation and release of memory for your objects. However, when your application encapsulates unmanaged resources such as windows, files, and network connections, you should use destructors to free those resources. When the object is eligible for destruction, the garbage collector runs the object's **Finalize** method.

Explicit Release of Resources

If your application is using an expensive external resource, it is also recommended that you provide a way to explicitly release the resource before the garbage collector frees the object. You do this by implementing a **Dispose** method (from the IDisposable interface) that performs the necessary cleanup for the object. This can considerably improve the performance of the application. Even with this explicit control over resources, the destructor becomes a safeguard to clean up resources if the call to the **Dispose** method failed.

For more details on cleaning up resources, see the following topics:

- Cleaning Up Unmanaged Resources
- Implementing a Dispose Method
- using Statement

See Also

Programming Essentials for Garbage Collection | 8.13 The using statement | Constructors and Destructors

Indexers

Indexers permit instances of a class or struct to be indexed in the same way as arrays. Indexers are similar to properties except that their accessors take parameters.

In this section, the following topics are introduced:

- Indexer Declaration
- Comparison Between Properties and Indexers
- Interface Indexers

For information on associated arrays, see the .NET Framework Hashtable Class.

See Also

Properties | Indexers Tutorial | C# Language Features

Indexer Declaration

Indexers allow you to index a class or a struct instance in the same way as an array. To declare an indexer, use the following:

```
[attributes] [modifiers] indexer-declarator {accessor-declarations}
```

The *indexer-declarator* takes one of the forms:

```
type this [formal-index-parameter-list]
type interface-type.this [formal-index-parameter-list]
```

The *formal-index-parameter* takes the form:

```
[attributes] type identifier
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see C# Attributes.

modifiers (Optional)
Allowed modifiers are **new**, **virtual**, **sealed**, **override**, **abstract**, **extern**, and a valid combination of the four access modifiers. For details, see Access Modifiers.

indexer-declarator
Includes the *type* of the element introduced by the indexer, **this**, and the *formal-index-parameter-list*. If the indexer is an explicit interface member implementation, the *interface-type* is included.

type
A type name.

interface-type
The interface name.

formal-index-parameter-list
Specifies the parameters of the indexer. The parameter includes optional *attributes*, the index *type*, and the index *identifier*. At least one parameter must be specified. The parameter modifiers **out** and **ref** are not allowed.

accessor-declarations
The indexer accessors, which specify the executable statements associated with reading and writing indexer elements.

identifier
The parameter name.

get Accessor

The **get** accessor body of an indexer is similar to a method body. It returns the type of the indexer. The **get** accessor uses the same *formal-index-parameter-list* as the indexer. For example:

```
get
{
   return myArray[index];
}
```

set Accessor

The **set** accessor body of an indexer is similar to a method body. It uses the same *formal-index-parameter-list* as the indexer, in addition to the **value** implicit parameter. For example:

```
set
{
   myArray[index] = value;
}
```

Remarks

The type of an indexer and each of the types referenced in the *formal-index-parameter-list* must be at least as accessible as the indexer itself. For more information on accessibility levels, see Access Modifiers.

The signature of an indexer consists of the number and types of its formal parameters. It does not include the indexer type or the names of the formal parameters.

If you declare more than one indexer in the same class, they must have different signatures.

An indexer value is not classified as a variable; therefore, it is not possible to pass an indexer value as a **ref** or **out** parameter.

To provide the indexer with a name that other languages can use for the default indexed property, use a **name** attribute in the declaration. For example:

```
[System.Runtime.CompilerServices.CSharp.IndexerName("MyItem")]
public int this [int index]   // Indexer declaration
{
}
```

This indexer will have the name `MyItem`. Without providing the **name** attribute, the default name will be `Item`.

Example

The following example shows how to declare a private array field, `myArray`, and an indexer. Using the indexer allows direct access to the instance `b[i]`. The alternative to using the indexer is to declare the array as a **public** member and access its members, `myArray[i]`, directly.

```
// cs_keyword_indexers.cs
using System;
class IndexerClass
{
   private int [] myArray = new int[100];
   public int this [int index]   // Indexer declaration
   {
      get
      {
         // Check the index limits.
         if (index < 0 || index >= 100)
            return 0;
         else
            return myArray[index];
      }
      set
      {
         if (!(index < 0 || index >= 100))
            myArray[index] = value;
      }
   }
}

public class MainClass
{
   public static void Main()
   {
      IndexerClass b = new IndexerClass();
      // Call the indexer to initialize the elements #3 and #5.
      b[3] = 256;
      b[5] = 1024;
      for (int i=0; i<=10; i++)
      {
         Console.WriteLine("Element #{0} = {1}", i, b[i]);
      }
   }
}
```

Output

```
Element #0 = 0
Element #1 = 0
Element #2 = 0
Element #3 = 256
Element #4 = 0
Element #5 = 1024
Element #6 = 0
Element #7 = 0
Element #8 = 0
Element #9 = 0
Element #10 = 0
```

Notice that when an indexer's access is evaluated (for example, in a **Console.Write** statement) the **get** accessor is invoked. Therefore, if no **get** accessor exists, a compile-time error occurs.

For an additional example, see 10.8 Indexers.

Indexers | Properties | Accessors | Indexers Tutorial

Comparison Between Properties and Indexers

Indexers are similar to properties. Except for the differences shown in the following table, all of the rules defined for property accessors apply to indexer accessors as well.

Property	**Indexer**
Identified by its name.	Identified by its signature.
Accessed through a simple name or a member access.	Accessed through an element access.
Can be a static or an instance member.	Must be an instance member.
A **get** accessor of a property has no parameters.	A **get** accessor of an indexer has the same formal parameter list as the indexer.
A **set** accessor of a property contains the implicit **value** parameter.	A **set** accessor of an indexer has the same formal parameter list as the indexer, in addition to the **value** parameter.

See Also

Indexers | Properties | Accessors

Interface Indexers

Indexers can be declared on interfaces. The declaration takes the following form:

```
[attributes] [new] type this [formal-index-parameter-list] {interface-accessors}
```

where:

attributes (Optional)
Same as indexers on classes.
type
Same as indexers on classes.
formal-index-parameter-list
Same as indexers on classes.
interface-accessors
The indexer accessors.

Remarks

Accessors of interface indexers differ from the accessors of class indexers in the following ways:

- Interface accessors do not use modifiers.
- An interface accessor does not have a body.

Thus, the purpose of the accessor is to indicate whether the indexer is read-write, read-only, or write-only.

The following is an example of an interface indexer accessor:

```
public interface IMyInterface
{
   ...
   // Indexer declaration:
   string this[int index]
   {
      get;
      set;
   }
}
```

The signature of an indexer must differ from the signatures of all other indexers declared in the same interface.

Example

The following example shows how to implement interface indexers.

```
// cs_interface_indexers.cs
using System;
// Indexer on an interface:
public interface IMyInterface
{
   // Indexer declaration:
   int this[int index]
   {
      get;
      set;
   }
}

// Implementing the interface.
class IndexerClass : IMyInterface
{
   private int [] myArray = new int[100];
   public int this [int index]   // indexer declaration
```

```
    {
       get
       {
          // Check the index limits.
          if (index < 0 || index >= 100)
             return 0;
          else
             return myArray[index];
       }
       set
       {
          if (!(index < 0 || index >= 100))
             myArray[index] = value;
       }
    }
}

public class MainClass
{
   public static void Main()
   {
      IndexerClass b = new IndexerClass();
      // Call the indexer to initialize the elements #3 and #5.
      b[2] = 4;
      b[5] = 32;
      for (int i=0; i<=10; i++)
      {
         Console.WriteLine("Element #{0} = {1}", i, b[i]);
      }
   }
}
```

Output

```
Element #0 = 0
Element #1 = 0
Element #2 = 4
Element #3 = 0
Element #4 = 0
Element #5 = 32
Element #6 = 0
Element #7 = 0
Element #8 = 0
Element #9 = 0
Element #10 = 0
```

In the preceding example, you could use the explicit interface member implementation by using the fully qualified name of the interface member. For example:

```
public string IMyInterface.this
{
}
```

However, the fully qualified name is only needed to avoid ambiguity when the class is implementing more than one interface with the same indexer signature. For example, if the `Employee` class is implementing two interfaces, `ICitizen` and `IEmployee`, and both interfaces have the same indexer signature, the explicit interface member implementation is necessary. That is, the following indexer declaration:

```
public string IEmployee.this
{
}
```

implements the indexer on the `IEmployee` interface, while the following declaration:

```
public string ICitizen.this
{
}
```

implements the indexer on the `ICitizen` interface.

For more information, see 13.4.1 Explicit interface member implementations.

Indexers | interface

Main

The `Main` method is the entry point of your program, where the program control starts and ends. It is declared inside a class or struct. It must be static. It can either have a **void** or **int** return type. The `Main` method is where you create objects and invoke other methods. The `Main` method can be declared without parameters or with parameters. The latter form allows your program to read command-line arguments.

See the following topics for more information and examples on using the `Main` method:

- Return Values
- Command-Line Arguments

See Also

C# Language Features

Return Values

The `Main` method can be of the type **void**:

```
static void Main()
{
}
```

It can also return an **int**:

```
static int Main()
{
   return 0;
}
```

Example

In this example, the program contains two classes, `Factorial` and `MainClass`. The `Main` method, which resides in the `MainClass` class, is used to read a number from the keyboard, invoke the `Fac` method from the `Factorial` class, and calculate and display the factorial of the input number.

```
// cs_main.cs
using System;
public class Factorial
{
   public static long Fac(long i)
   {
      return ((i <= 1) ? 1 : (i * Fac(i-1)));
   }
}

class MainClass
{
   public static void Main()
   {
      // Read a string from the keyboard:
      Console.Write("Enter an integer: ");

      string s = Console.ReadLine();

      // Convert the string to long:

      try
      {
         long num = Int64.Parse(s);
         Console.WriteLine("The Factorial of {0} is {1}.",
                           num, Factorial.Fac(num));
      }
      catch (System.FormatException)
      {
         Console.WriteLine("Invalid input specified");
      }
   }
}
```

Input

```
5
```

Sample Output

```
Enter an integer: 5
The Factorial of 5 is 120.
```

See Also

Command-Line Arguments | Main

Command-Line Arguments

The `Main` method can use arguments, in which case, it takes one of the following forms:

```
static int Main(string[] args)
static void Main(string[] args)
```

The parameter of the `Main` method is a `string` array that represents the command-line arguments. Usually you check for the existence of the arguments by testing the `Length` property, for example:

```
if (args.Length == 0)
{
   Console.WriteLine("Please enter a numeric argument.");
   return 1;
}
```

You can also convert the string arguments to numeric types by using the `Convert` class or the `Parse` method. For example, the following statement converts the string to a long number by using the `Parse` method on the `Int64` class:

```
long num = Int64.Parse(args[0]);
```

It is also possible to use the C# type `long`, which aliases `Int64`:

```
long num = long.Parse(args[0]);
```

You can also use the `Convert` class method `ToInt64` to do the same thing:

```
long num = Convert.ToInt64(s);
```

For more information see Parse Method and Convert Class.

Example

In this example, the program takes one argument at run time, converts the argument to a long number, and calculates the factorial of the number. If no arguments are supplied, the program issues a message that explains the correct usage of the program.

```
// Factorial_main.cs
// arguments: 3
using System;
public class Factorial
{
   public static long Fac(long i)
   {
      return ((i <= 1) ? 1 : (i * Fac(i-1)));
   }
}

class MainClass
{
   public static int Main(string[] args)
   {
      // Test if input arguments were supplied:
      if (args.Length == 0)
      {
         Console.WriteLine("Please enter a numeric argument.");
         Console.WriteLine("Usage: Factorial <num>");
         return 1;
      }
```

```
        // Convert the input arguments to numbers:
        try
        {
             long num = long.Parse(args[0]);
             Console.WriteLine("The Factorial of {0} is {1}.",
                          num, Factorial.Fac(num));
             return 0;
        }
        catch (System.FormatException)
        {
           Console.WriteLine("Please enter a numeric argument.");
           Console.WriteLine("Usage: Factorial <num>");
           return 1;
        }
    }
}
```

Output

```
The Factorial of 3 is 6.
```

The following are two sample runs of the program assuming that the program name is Factorial.exe.

Run #1:

```
Enter the following command line:
Factorial 10
You get the following result:
The Factorial of 10 is 3628800.
```

Run #2:

```
Enter the following command line:
Factorial
You get the following result:
Please enter a numeric argument.
Usage: Factorial <num>
```

For more examples on using command-line arguments, see the example in Creating and Using C# DLLs.

Main | Return Values | General Structure of a C# Program | Command Line Parameters Tutorial

Properties

Properties are named members of classes, structs, and interfaces. They provide a flexible mechanism to read, write, or compute the values of private fields through accessors.

In this section, the following topics are introduced:

- Property Declaration
- Accessors
- Interface Properties
- value

See Also

Indexers | Properties Tutorial | C# Language Features

Property Declaration

Properties are an extension of fields and are accessed using the same syntax. Unlike fields, properties do not designate storage locations. Instead, properties have accessors that read, write, or compute their values.

Property declaration takes one of the following forms:

```
[attributes] [modifiers] type identifier {accessor-declaration}
[attributes] [modifiers] type interface-type.identifier {accessor-declaration}
```

where:

attributes (Optional)
Additional declarative information. For more information on attributes and attribute classes, see C# Attributes.
modifiers (Optional)
The allowed modifiers are new, static, virtual, abstract, override, and a valid combination of the four access modifiers.
type
The property type, which must be at least as accessible as the property itself. For more information on accessibility levels, see Access Modifiers.
identifier
The property name. For more information on interface member implementation, see interface.
accessor-declaration
Declaration of the property accessors, which are used to read and write the property.
interface-type
The interface in a fully qualified property name. See Interface Properties.

Remarks

Unlike fields, properties are not classified as variables. Therefore, it is not possible to pass a property as a ref or out parameter.

A property declared using the **static** modifier is classified as a static property; otherwise, it is classified as an instance property. Like other static members, a static property is not associated with a specific instance and cannot be referenced through an instance. Instead, it is associated with the type and can only be referenced through the type name. For example, in the following statements:

```
Button okButton = new Button();
// Using an instance property:
string s = okButton.Caption;
```

the `Caption` property is associated with the instance `okButton`. If `Caption` is declared as a static property, the class name (`Button`) must be used instead:

```
// Using a static property:
string s = Button.Caption;
```

An instance of a class can be accessed using this in the accessors of an instance property, but it is an error to use **this** in the accessors of a static property.

It is an error to use a virtual, abstract, or override modifier on an accessor of a static property.

Example

This example demonstrates instance, static, and read-only properties. It accepts the name of the employee from the keyboard, increments `numberOfEmployees` by 1, and displays the Employee name and number.

```
// property.cs
// Properties
using System;
public class Employee
{
   public static int numberOfEmployees;
```

```
    private static int counter;
    private string name;

    // A read-write instance property:
    public string Name
    {
       get
       {
          return name;
       }
       set
       {
          name = value;
       }
    }

    // A read-only static property:
    public static int Counter
    {
       get
       {
          return counter;
       }
    }

    // Constructor:
    public Employee()
    {
       // Calculate the employee's number:
       counter = ++counter + numberOfEmployees;
    }
 }

 public class MainClass
 {
    public static void Main()
    {
       Employee.numberOfEmployees = 100;
       Employee e1 = new Employee();
       e1.Name = "Claude Vige";
       Console.WriteLine("Employee number: {0}", Employee.Counter);
       Console.WriteLine("Employee name: {0}", e1.Name);
    }
 }
```

Output

```
Employee number: 101
Employee name: Claude Vige
```

Properties | Accessors | Indexers | Properties Tutorial

Accessors

The accessor of a property contains the executable statements associated with getting (reading or computing) or setting (writing) the property. The accessor declarations can contain a **get** accessor, a **set** accessor, or both. The declarations take the following forms:

```
set {accessor-body}
get {accessor-body}
```

where:

accessor-body
The block that contains the statements to be executed when the accessor is invoked.

The get Accessor

The body of the **get** accessor is similar to that of a method. It must return a value of the property type. The execution of the **get** accessor is equivalent to reading the value of the field. The following is a **get** accessor that returns the value of a private field `name`:

```
private string name;   // the name field
public string Name   // the Name property
{
   get
   {
      return name;
   }
}
```

When you reference the property, except as the target of an assignment, the **get** accessor is invoked to read the value of the property. For example:

```
Employee e1 = new Employee();
...
Console.Write(e1.Name);   // The get accessor is invoked here
```

The **get** accessor must terminate in a **return** or **throw** statement, and control cannot flow off the accessor body.

The set Accessor

The **set** accessor is similar to a method that returns **void**. It uses an implicit parameter called **value**, whose type is the type of the property. In the following example, a **set** accessor is added to the `Name` property:

```
public string Name
{
   get
   {
      return name;
   }
   set
   {
      name = value;
   }
}
```

When you assign a value to the property, the **set** accessor is invoked with an argument that provides the new value. For example:

```
e1.Name = "Joe";   // The set accessor is invoked here
```

It is an error to use the implicit parameter name (**value**) for a local variable declaration in a **set** accessor.

Remarks

A property is classified according to the accessors used as follows:

- A property with a **get** accessor only is called a read-only property. You cannot assign a value to a read-only property.
- A property with a **set** accessor only is called a write-only property. You cannot reference a write-only property except as a target of an assignment.
- A property with both **get** and **set** accessors is a read-write property.

In a property declaration, both the **get** and **set** accessors must be declared inside the body of the property.

It is a bad programming style to change the state of the object by using the **get** accessor. For example, the following accessor produces the side effect of changing the state of the object each time the `number` field is accessed.

```
public int Number
{
   get
   {
      return number++;   // Don't do this
   }
}
```

The **get** accessor can either be used to return the field value or to compute it and return it. For example:

```
public string Name
{
   get
   {
      return name != null ? name : "NA";
   }
}
```

In the preceding code segment, if you don't assign a value to the `Name` property, it will return the value `NA`.

Example 1

This example demonstrates how to access a property in a base class that is hidden by another property with the same name in a derived class.

```
// property_hiding.cs
// Property hiding
using System;
public class BaseClass
{
   private string name;
   public string Name
   {
      get
      {
         return name;
      }
      set
      {
         name = value;
      }
   }
}

public class DerivedClass : BaseClass
{
   private string name;
   public new string Name   // Notice the use of the new modifier
   {
      get
```

```
        {
           return name;
        }
        set
        {
           name = value;
        }
    }
}

public class MainClass
{
    public static void Main()
    {
        DerivedClass d1 = new DerivedClass();
        d1.Name = "John";  // Derived class property
        Console.WriteLine("Name in the derived class is: {0}",d1.Name);
        ((BaseClass)d1).Name = "Mary"; // Base class property
        Console.WriteLine("Name in the base class is: {0}",
           ((BaseClass)d1).Name);
    }
}
```

Output

```
Name in the derived class is: John
Name in the base class is: Mary
```

The following are important points shown in the preceding example:

- The property `Name` in the derived class hides the property `Name` in the base class. In such a case, the **new** modifier is used in the declaration of the property in the derived class:

  ```
  public new string Name
  {
  ...
  ```

- The cast `(BaseClass)` is used to access the hidden property in the base class:

  ```
  ((BaseClass)d1).Name = "Mary";
  ```

For more information on hiding members, see the new modifier.

Example 2

In this example, two classes, `Cube` and `Square`, implement an abstract class, `Shape`, and override its abstract `Area` property. Note the use of the override modifier on the properties. The program accepts the side as an input and calculates the areas for the square and cube. It also accepts the area as an input and calculates the corresponding side for the square and cube.

```
// overridding_properties.cs
// Overriding properties
using System;
abstract class Shape
{
    public abstract double Area
    {
        get;
        set;
    }
}

class Square: Shape
{
```

```
      public double side;

      // Constructor:
      public Square(double s)
      {
         side = s;
      }

   // The Area property
   public override double Area
   {
      get
      {
         return side*side ;
      }
      set
      {
         // Given the area, compute the side
         side = Math.Sqrt(value);
      }
   }
}

class Cube: Shape
{
      public double side;

      // Constructor:
      public Cube(double s)
      {
         side = s;
      }

      // The Area property
      public override double Area
      {
         get
         {
            return 6*side*side;
         }
         set
         {
            // Given the area, compute the side
            side = Math.Sqrt(value/6);
         }
      }
}

public class MainClass
{
   public static void Main()
   {
      // Input the side:
      Console.Write("Enter the side: ");
      string sideString = Console.ReadLine();
      double side = double.Parse(sideString);

      // Compute areas:
      Square s = new Square(side);
      Cube c = new Cube(side);

      // Display results:
      Console.WriteLine("Area of a square = {0:F2}",s.Area);
      Console.WriteLine("Area of a cube = {0:F2}", c.Area);

      // Input the area:
      Console.Write("Enter the area: ");
      string areaString = Console.ReadLine();
```

```
        double area = double.Parse(areaString);

        // Compute sides:
        s.Area = area;
        c.Area = area;

        // Display results:
        Console.WriteLine("Side of a square = {0:F2}", s.side);
        Console.WriteLine("Side of a cube = {0:F2}", c.side);
    }
}
```

Input

```
4
24
```

Sample Output

```
Enter the side: 4
Area of a square = 16.00
Area of a cube = 96.00
Enter the area: 24
Side of a square = 4.90
Side of a cube = 2.00
```

Interface Properties

Properties can be declared on interfaces. The declaration takes the following form:

```
[attributes] [new] type identifier {interface-accessors}
```

where:

attributes (Optional)
  Same as properties on classes.
type
  Same as properties on classes.
identifier
  The property name.
interface-accessors
  The property accessors. See the Remarks section below.

Remarks

The accessor of an interface property does not have a body.

Thus, the purpose of the accessors is to indicate whether the property is read-write, read-only, or write-only.

The following is an example of an interface indexer accessor:

```
public interface IMyInterface
{
   // Property declaration:
   string Name
   {
      get;
      set;
   }
}
```

Example

In this example, the interface `IEmployee` has a read-write property, `Name`, and a read-only property, `Counter`. The class `Employee` implements the `IEmployee` interface and uses these two properties. The program reads the name of a new employee and the current number of employees and displays the employee name and the computed employee number.

```
// cs_interface_properties.cs
// Interface Properties
using System;
interface IEmployee
{
   string Name
   {
      get;
      set;
   }

   int Counter
   {
      get;
   }
}

public class Employee: IEmployee
{
   public static int numberOfEmployees;
   private int counter;
   private string name;
```

```
      // Read-write instance property:
      public string Name
      {
         get
         {
            return name;
         }
         set
         {
            name = value;
         }
      }
      // Read-only instance property:
      public int Counter
      {
         get
         {
            return counter;
         }
      }
      // Constructor:
      public Employee()
      {
         counter = ++counter + numberOfEmployees;
      }
   }

   public class MainClass
   {
      public static void Main()
      {
         Console.Write("Enter number of employees: ");
         string s = Console.ReadLine();
         Employee.numberOfEmployees = int.Parse(s);
         Employee e1 = new Employee();
         Console.Write("Enter the name of the new employee: ");
         e1.Name = Console.ReadLine();
         Console.WriteLine("The employee information:");
         Console.WriteLine("Employee number: {0}", e1.Counter);
         Console.WriteLine("Employee name: {0}", e1.Name);
      }
   }
```

Input

```
210
Hazem Abolrous
```

Sample Output

```
Enter number of employees: 201
Enter the name of the new employee: Hazem Abolrous
The employee information:
Employee number: 202
Employee name: Hazem Abolrous
```

In the preceding example, you could use the fully qualified name of the property, which references the interface in which the member is declared. For example:

```
public string IEmployee.Name
{
}
```

However, the fully qualified name is only needed to avoid ambiguity when the class is implementing more than one interface with the same property signature. For example, if the class `Employee` is implementing two interfaces `ICitizen` and `IEmployee` and both interfaces have the `Name` property, the explicit interface member implementation will be necessary. That is, the following property declaration:

```
public string IEmployee.Name
{
}
```

implements the `Name` property on the `IEmployee` interface, while the following declaration:

```
public string ICitizen.Name
{
}
```

implements the `Name` property on the `ICitizen` interface.

For more information, see 13.4.1 Explicit interface member implementations.

Indexers Tutorial | Properties Tutorial

Passing Parameters

In C#, parameters can be passed either by value or by reference. Passing parameters by reference allows function members (methods, properties, indexers, operators, and constructors) to change the value of the parameters and have that change persist. To pass a parameter by reference, use the **ref** or **out** keyword. For simplicity, only the **ref** keyword is used in the examples of this topic. For information on the difference between **ref** and **out**, see ref, out, and Passing Arrays Using ref and out.

This topic includes the following sections:

- Passing Value-Type Parameters
- Passing Reference-Type Parameters

It also includes the following examples:

Example	Demonstrates	Uses ref or out
1	Passing value types by value	No
2	Passing value types by reference	Yes
3	Swapping value types (two integers)	Yes
4	Passing reference types by value	No
5	Passing reference types by reference	Yes
6	Swapping reference types (two strings)	Yes

Passing Value-Type Parameters

A value-type variable contains its data directly as opposed to a reference-type variable, which contains a reference to its data. Therefore, passing a value-type variable to a method means passing a copy of the variable to the method. Any changes to the parameter that take place inside the method have no affect on the original data stored in the variable. If you want the called method to change the value of the parameter, you have to pass it by reference, using the **ref** or **out** keyword. For simplicity, the following examples use **ref**.

Example 1: Passing Value Types by Value

The following example demonstrates passing value-type parameters by value. The variable `myInt` is passed by value to the method `SquareIt`. Any changes that take place inside the method have no affect on the original value of the variable.

```
// PassingParams1.cs
using System;
class PassingValByVal
{
    static void SquareIt(int x)
    // The parameter x is passed by value.
    // Changes to x will not affect the original value of myInt.
    {
        x *= x;
        Console.WriteLine("The value inside the method: {0}", x);
    }
    public static void Main()
    {
        int myInt = 5;
        Console.WriteLine("The value before calling the method: {0}",
           myInt);
        SquareIt(myInt);   // Passing myInt by value.
        Console.WriteLine("The value after calling the method: {0}",
           myInt);
    }
}
```

Output

```
The value before calling the method: 5
The value inside the method: 25
The value after calling the method: 5
```

Code Discussion

The variable `myInt`, being a value type, contains its data (the value `5`). When `SquareIt` is invoked, the contents of `myInt` are copied into the parameter `x`, which is squared inside the method. In Main, however, the value of `myInt` is the same, before and after calling the `SquareIt` method. In fact, the change that takes place inside the method only affects the local variable `x`.

Example 2: Passing Value Types by Reference

The following example is the same as Example 1, except for passing the parameter using the **ref** keyword. The value of the parameter is changed after calling the method.

```
// PassingParams2.cs
using System;
class PassingValByRef
{
    static void SquareIt(ref int x)
    // The parameter x is passed by reference.
    // Changes to x will affect the original value of myInt.
    {
        x *= x;
        Console.WriteLine("The value inside the method: {0}", x);
    }
    public static void Main()
    {
        int myInt = 5;
        Console.WriteLine("The value before calling the method: {0}",
           myInt);
        SquareIt(ref myInt);   // Passing myInt by reference.
        Console.WriteLine("The value after calling the method: {0}",
           myInt);
    }
}
```

Output

```
The value before calling the method: 5
The value inside the method: 25
The value after calling the method: 25
```

Code Discussion

In this example, it is not the value of `myInt` that is passed; rather, a reference to `myInt` is passed. The parameter `x` is not an **int**; it is a reference to an **int** (in this case, a reference to `myInt`). Therefore, when `x` is squared inside the method, what actually gets squared is what `x` refers to: `myInt`.

Example 3: Swapping Value Types

A common example of changing the values of the passed parameters is the `Swap` method, where you pass two variables, `x` and `y`, and have the method swap their contents. You must pass the parameters to the `Swap` method by reference; otherwise, you will be dealing with a local copy of the parameters inside the method. The following is an example of the `Swap` method that uses reference parameters:

```
static void SwapByRef(ref int x, ref int y)
{
    int temp = x;
    x = y;
    y = temp;
}
```

When you call this method, use the **ref** keyword in the call, like this:

```
SwapByRef (ref i, ref j);
```

Passing Reference-Type Parameters

A variable of a reference type does not contain its data directly; it contains a reference to its data. When you pass a reference-type parameter by value, it is possible to change the data pointed to by the reference, such as the value of a class member. However, you cannot change the value of the reference itself; that is, you cannot use the same reference to allocate memory for a new class and have it persist outside the block. To do that, pass the parameter using the **ref** (or **out**) keyword. For simplicity, the following examples use **ref**.

Example 4: Passing Reference Types by Value

The following example demonstrates passing a reference-type parameter, `myArray`, by value, to a method, `Change`. Because the parameter is a reference to `myArray`, it is possible to change the values of the array elements. However, the attempt to reassign the parameter to a different memory location only works inside the method and does not affect the original variable, `myArray`.

```
// PassingParams4.cs
// Passing an array to a method without the ref keyword.
// Compare the results to those of Example 5.
using System;
class PassingRefByVal
{
   static void Change(int[] arr)
   {
      arr[0]=888;   // This change affects the original element.
      arr = new int[5] {-3, -1, -2, -3, -4};   // This change is local.
      Console.WriteLine("Inside the method, the first element is: {0}", arr[0]);
   }

   public static void Main()
   {
      int[] myArray = {1,4,5};
      Console.WriteLine("Inside Main, before calling the method, the first element is: {0}",
myArray [0]);
      Change(myArray);
      Console.WriteLine("Inside Main, after calling the method, the first element is: {0}", m
yArray [0]);
   }
}
```

Output

```
Inside Main, before calling the method, the first element is: 1
Inside the method, the first element is: -3
Inside Main, after calling the method, the first element is: 888
```

Code Discussion

In the preceding example, the array, `myArray`, which is a reference type, is passed to the method without the **ref** parameter. In such a case, a copy of the reference, which points to `myArray`, is passed to the method. The output shows that it is possible for the method to change the contents of an array element (from `1` to `888`). However, allocating a new portion of memory by using the **new** operator inside the `Change` method makes the variable `arr` reference a new array. Thus, any changes after that will not affect the original array, `myArray`, which is created inside `Main`. In fact, two arrays are created in this example, one inside `Main` and one inside the `Change` method.

Example 5: Passing Reference Types by Reference

This example is the same as Example 4, except for using the **ref** keyword in the method header and call. Any changes that take place in the method will affect the original variables in the calling program.

```
// PassingParams5.cs
// Passing an array to a method with the ref keyword.
// Compare the results to those of Example 4.
using System;
class PassingRefByRef
{
   static void Change(ref int[] arr)
   {
      // Both of the following changes will affect the original variables:
      arr[0]=888;
      arr = new int[5] {-3, -1, -2, -3, -4};
      Console.WriteLine("Inside the method, the first element is: {0}", arr[0]);
   }

   public static void Main()
   {
      int[] myArray = {1,4,5};
      Console.WriteLine("Inside Main, before calling the method, the first element is: {0}",
myArray [0]);
      Change(ref myArray);
      Console.WriteLine("Inside Main, after calling the method, the first element is: {0}", m
yArray [0]);
   }
}
```

Output

```
Inside Main, before calling the method, the first element is: 1
Inside the method, the first element is: -3
Inside Main, after calling the method, the first element is: -3
```

Code Discussion

All of the changes that take place inside the method affect the original array in Main. In fact, the original array is reallocated using the **new** operator. Thus, after calling the `Change` method, any reference to `myArray` points to the five-element array, which is created in the `Change` method.

Example 6: Swapping Two Strings

Swapping strings is a good example of passing reference-type parameters by reference. In the example, two strings, `str1` and `str2`, are initialized in Main and passed to the `SwapStrings` method as parameters modified by the **ref** keyword. The two strings are swapped inside the method and inside Main as well.

```
// PassingParams6.cs
using System;
class SwappinStrings
{
    static void SwapStrings(ref string s1, ref string s2)
    // The string parameter x is passed by reference.
    // Any changes on parameters will affect the original variables.
    {
        string temp = s1;
        s1 = s2;
        s2 = temp;
        Console.WriteLine("Inside the method: {0}, {1}", s1, s2);
    }
    public static void Main()
    {
        string str1 = "John";
        string str2 = "Smith";
        Console.WriteLine("Inside Main, before swapping: {0} {1}",
           str1, str2);
        SwapStrings(ref str1, ref str2);   // Passing strings by reference
```

```
        Console.WriteLine("Inside Main, after swapping: {0}, {1}",
           str1, str2);
    }
}
```

Output

```
Inside Main, before swapping: John Smith
Inside the method: Smith, John
Inside Main, after swapping: Smith, John
```

Code Discussion

In this example, the parameters need to be passed by reference to affect the variables in the calling program. If you remove the **ref** keyword from both the method header and the method call, no changes will take place in the calling program.

For more information on strings, see the string keyword.

XML Documentation

In Visual C# you can document the code you write using XML. C# is the only programming language in Visual Studio .NET with this feature. For details on creating an XML file with documentation comments, see the following topics.

For information about	See
The C# compiler option to use	/doc (Process Documentation Comments)
Tags you can use to provide commonly used functionality in documentation	Recommended Tags for Documentation Comments
The ID strings that the compiler produces to identify the constructs in your code	Processing the XML File
How to delimit documentation tags	Delimiters for Documentation Tags
How to document a type	XML Documentation Tutorial
Links to information about XML as it relates to Visual Studio feature areas	XML in Visual Studio

See Commenting Code for information on how Visual Studio will display a report on the structure of your code, to include XML Documentation comments.

C# Language Features

Recommended Tags for Documentation Comments

The C# compiler will process documentation comments in your code to an XML file. Processing the XML file to create documentation is a detail that needs to be implemented at your site.

Tags are processed on code constructs such as types and type members.

> **Note** Tags are not processed on namespaces.

The compiler will process any tag that is valid XML. The following tags provide commonly used functionality in user documentation:

<c>	<para>	<see>[1]
<code>	<param>[1]	<seealso>[1]
<example>	<paramref>[1]	<summary>
<exception>[1]	<permission>[1]	<value>
<include>[1]	<remarks>	
<list>	<returns>	

1. Compiler verifies syntax.

See Also

/doc (Process Documentation Comments) | XML Documentation

<c>

```
<c>text</c>
```

where:

text
The text you would like to indicate as code.

Remarks

The <c> tag gives you a way to indicate that text within a description should be marked as code. Use <code> to indicate multiple lines as code.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_c_tag.cs
// compile with: /doc:xml_c_tag.xml

/// text for class MyClass
public class MyClass
{
   /// <summary><c>MyMethod</c> is a method in the <c>MyClass</c> class.
   /// </summary>
   public static void MyMethod(int Int1)
   {
   }
   /// text for Main
   public static void Main ()
   {
   }
}
```

See Also

Recommended Tags for Documentation Comments

<code>

```
<code>content</code>
```

where:

content
The text you want marked as code.

Remarks

The <code> tag gives you a way to indicate multiple lines as code. Use <c> to indicate that text within a description should be marked as code.

Compile with /doc to process documentation comments to a file.

Example

See the <example> topic for an example of how to use the <code> tag.

See Also

Recommended Tags for Documentation Comments

<example>

```
<example>description</example>
```

where:

description
A description of the code sample.

Remarks

The <example> tag lets you specify an example of how to use a method or other library member. Commonly, this would involve use of the <code> tag.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_example_tag.cs
// compile with: /doc:xml_ctag.xml

/// text for class MyClass
public class MyClass
{
   /// <summary>
   /// The GetZero method.
   /// </summary>
   /// <example> This sample shows how to call the GetZero method.
   /// <code>
   ///   class MyClass
   ///   {
   ///      public static int Main()
   ///      {
   ///         return GetZero();
   ///      }
   ///   }
   /// </code>
   /// </example>
   public static int GetZero()
   {
      return 0;
   }
   /// text for Main
   public static void Main ()
   {
   }
}
```

See Also

Recommended Tags for Documentation Comments

<exception>

```
<exception cref="member">description</exception>
```

where:

cref = "*member*"
A reference to an exception that is available from the current compilation environment. The compiler checks that the given exception exists and translates *member* to the canonical element name in the output XML. *member* must appear within double quotation marks (" ").

description
A description.

Remarks

The <exception> tag lets you specify which exceptions can be thrown. This tag is applied to a method definition.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_exception_tag.cs
// compile with: /doc:xml_exception_tag.xml
using System;

/// comment for class
public class EClass : Exception
{
   // class definition ...
}

/// <exception cref="System.Exception">Thrown when... .</exception>
class TestClass
{
   public static void Main()
   {
      try
      {
      }
      catch(EClass)
      {
      }
   }
}
```

See Also

Recommended Tags for Documentation Comments

<include>

```
<include file='filename' path='tagpath[@name="id"]' />
```

where:

filename
The name of the file containing the documentation. The file name can be qualified with a path. Enclose *filename* in single quotation marks (' ').

tagpath
The path of the tags in *filename* that leads to the tag *name*. Enclose the path in single quotation marks (' ').

name
The name specifier in the tag that precedes the comments; *name* will have an *id*.

id
The ID for the tag that precedes the comments. Enclose the ID in double quotation marks (" ").

Remarks

The <include> tag lets you refer to comments in another file that describe the types and members in your source code. This is an alternative to placing documentation comments directly in your source code file.

The <include> tag uses the XML XPath syntax. Refer to XPath documentation for ways to customize your <include> use.

Example

This is a multifile example. The first file, which uses <include>, is listed below:

```
// xml_include_tag.cs
// compile with: /doc:xml_include_tag.xml
/// <include file='xml_include_tag.doc' path='MyDocs/MyMembers[@name="test"]/*' />
class Test
{
   public static void Main()
   {
   }
}

/// <include file='xml_include_tag.doc' path='MyDocs/MyMembers[@name="test2"]/*' />
class Test2
{
   public void Test()
   {
   }
}
```

The second file, xml_include_tag.doc, contains the following documentation comments:

```
<MyDocs>

<MyMembers name="test">
<summary>
The summary for this type.
</summary>
</MyMembers>

<MyMembers name="test2">
<summary>
The summary for this other type.
</summary>
</MyMembers>

</MyDocs>
```

Program Output

```
<?xml version="1.0"?>
<doc>
    <assembly>
        <name>t2</name>
    </assembly>
    <members>
        <member name="T:Test">
            <summary>
The summary for this type.
</summary>
        </member>
        <member name="T:Test2">
            <summary>
The summary for this other type.
</summary>
        </member>
    </members>
</doc>
```

Recommended Tags for Documentation Comments

<list>

```
<list type="bullet" | "number" | "table">
   <listheader>
      <term>term</term>
      <description>description</description>
   </listheader>
   <item>
      <term>term</term>
      <description>description</description>
   </item>
</list>
```

where:

term
A term to define, which will be defined in *text*.

description
Either an item in a bullet or numbered list or the definition of a *term*.

Remarks

The <listheader> block is used to define the heading row of either a table or definition list. When defining a table, you only need to supply an entry for term in the heading.

Each item in the list is specified with an <item> block. When creating a definition list, you will need to specify both *term* and *text*. However, for a table, bulleted list, or numbered list, you only need to supply an entry for *text*.

A list or table can have as many <item> blocks as needed.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_list_tag.cs
// compile with: /doc:xml_list_tag.xml

/// text for class MyClass
public class MyClass
{
   /// <remarks>Here is an example of a bulleted list:
   /// <list type="bullet">
   /// <item>
   /// <description>Item 1.</description>
   /// </item>
   /// <item>
   /// <description>Item 2.</description>
   /// </item>
   /// </list>
   /// </remarks>
   public static void Main ()
   {
   }
}
```

See Also

Recommended Tags for Documentation Comments

<para>

```
<para>content</para>
```

where:

content
The text of the paragraph.

Remarks

The <para> tag is for use inside a tag, such as <summary>, <remarks>, or <returns>, and lets you add structure to the text.

Compile with /doc to process documentation comments to a file.

Example

See <summary> for an example of using <para>.

See Also

Recommended Tags for Documentation Comments

<param>

```
<param name='name'>description</param>
```

where:

name
The name of a method parameter. Enclose the name in single quotation marks (' ').
description
A description for the parameter.

Remarks

The <param> tag should be used in the comment for a method declaration to describe one of the parameters for the method.

The text for the <param> tag will be displayed in IntelliSense, the Object Browser, and in the Code Comment Web Report.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_param_tag.cs
// compile with: /doc:xml_param_tag.xml

/// text for class MyClass
public class MyClass
{
   /// <param name="Int1">Used to indicate status.</param>
   public static void MyMethod(int Int1)
   {
   }
   /// text for Main
   public static void Main ()
   {
   }
}
```

See Also

Recommended Tags for Documentation Comments

<paramref>

```
<paramref name="name"/>
```

where:

name
The name of the parameter to refer to. Enclose the name in double quotation marks (" ").

Remarks

The <paramref> tag gives you a way to indicate that a word is a parameter. The XML file can be processed to format this parameter in some distinct way.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_paramref_tag.cs
// compile with: /doc:xml_paramref_tag.xml
/// text for class MyClass
public class MyClass
{
   /// <remarks>MyMethod is a method in the MyClass class.
   /// The <paramref name="Int1"/> parameter takes a number.
   /// </remarks>
   public static void MyMethod(int Int1)
   {
   }

   /// text for Main
   public static void Main ()
   {
   }
}
```

See Also

Recommended Tags for Documentation Comments

<permission>

```
<permission cref="member">description</permission>
```

where:

cref = "*member*"
A reference to a member or field that is available to be called from the current compilation environment. The compiler checks that the given code element exists and translates *member* to the canonical element name in the output XML. *member* must appear within double quotation marks (" ").

description
A description of the access to the member.

Remarks

The <permission> tag lets you document the access of a member. The **System.Security.PermissionSet** lets you specify access to a member.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_permission_tag.cs
// compile with: /doc:xml_permission_tag.xml
using System;
class TestClass
{
   /// <permission cref="System.Security.PermissionSet">Everyone can access this method.</per
mission>
   public static void Test()
   {
   }
   public static void Main()
   {
   }
}
```

See Also

Recommended Tags for Documentation Comments

<remarks>

```
<remarks>description</remarks>
```

where:

description
A description of the member.

Remarks

The <remarks> tag is used to add information about a type, supplementing the information specified with <summary>. This information is displayed in the Object Browser and in the Code Comment Web Report.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_remarks_tag.cs
// compile with: /doc:xml_remarks_tag.xml
/// <summary>
/// You may have some primary information about this class.
/// </summary>
/// <remarks>
/// You may have some additional information about this class.
/// </remarks>
public class MyClass
{
   /// text for Main
   public static void Main ()
   {
   }
}
```

See Also

Recommended Tags for Documentation Comments

<returns>

```
<returns>description</returns>
```

where:

description
A description of the return value.

Remarks

The <returns> tag should be used in the comment for a method declaration to describe the return value.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_returns_tag.cs
// compile with: /doc:xml_returns_tag.xml

/// text for class MyClass
public class MyClass
{
   /// <returns>Returns zero.</returns>
   public static int GetZero()
   {
      return 0;
   }

   /// text for Main
   public static void Main ()
   {
   }
}
```

Recommended Tags for Documentation Comments

<see>

```
<see cref="member"/>
```

where:

cref = "*member*"
A reference to a member or field that is available to be called from the current compilation environment. The compiler checks that the given code element exists and passes *member* to the element name in the output XML. *member* must appear within double quotation marks (" ").

Remarks

The <see> tag lets you specify a link from within text. Use <seealso> to indicate text that you might want to appear in a See Also section.

Compile with /doc to process documentation comments to a file.

Example

See <summary> for an example of using <see>.

See Also

Recommended Tags for Documentation Comments

<seealso>

```
<seealso cref="member"/>
```

where:

cref = "*member*"
A reference to a member or field that is available to be called from the current compilation environment. The compiler checks that the given code element exists and passes *member* to the element name in the output XML. *member* must appear within double quotation marks (" ").

Remarks

The <seealso> tag lets you specify the text that you might want to appear in a See Also section. Use <see> to specify a link from within text.

Compile with /doc to process documentation comments to a file.

Example

See <summary> for an example of using <seealso>.

See Also

Recommended Tags for Documentation Comments

<summary>

```
<summary>description</summary>
```

where:

description
A summary of the object.

Remarks

The <summary> tag should be used to describe a type or a type member. Use <remarks> to add supplemental information to a type description.

The text for the <summary> tag is the only source of information about the type in IntelliSense, and is also displayed in the Object Browser and in the Code Comment Web Report.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_summary_tag.cs
// compile with: /doc:xml_summary_tag.xml

/// text for class MyClass
public class MyClass
{
   /// <summary>MyMethod is a method in the MyClass class.
   /// <para>Here's how you could make a second paragraph in a description. <see cref="System
.Console.WriteLine"/> for information about output statements.</para>
   /// <seealso cref="MyClass.Main"/>
   /// </summary>
   public static void MyMethod(int Int1)
   {
   }

   /// text for Main
   public static void Main ()
   {
   }
}
```

See Also

Recommended Tags for Documentation Comments

<value>

```
<value>property-description</value>
```

where:

property-description
A description for the property.

Remarks

The <value> tag lets you describe a property. Note that when you add a property via code wizard in the Visual Studio .NET development environment, it will add a <summary> tag for the new property. You should then manually add a <value> tag to describe the value that the property represents.

Compile with /doc to process documentation comments to a file.

Example

```
// xml_value_tag.cs
// compile with: /doc:xml_value_tag.xml
using System;
/// text for class Employee
public class Employee
{
   private string name;
   /// <value>Name accesses the value of the name data member</value>
   public string Name
   {
      get
      {
         return name;
      }
      set
      {
         name = value;
      }
   }
}

/// text for class MainClass
public class MainClass
{
   /// text for Main
   public static void Main()
   {
   }
}
```

Recommended Tags for Documentation Comments

Processing the XML File

The compiler generates an ID string for each construct in your code that is tagged to generate documentation. (For information on how to tag your code, see Recommended Tags for Documentation Comments.) The ID string uniquely identifies the construct. Programs that process the XML file can use the ID string to identify the corresponding .NET Framework metadata/reflection item that the documentation applies to.

The XML file is not a hierarchical representation of your code, it is a flat list with a generated ID for each element.

The compiler observes the following rules when it generates the ID strings:

- No whitespace is placed in the string.
- The first part of the ID string identifies the kind of member being identified, via a single character followed by a colon. The following member types are used:

Character	Description
N	namespace You cannot add documentation comments to a namespace, but you can make cref references to them, where supported.
T	type: class, interface, struct, enum, delegate
F	field
P	property (including indexers or other indexed properties)
M	method (including such special methods as constructors, operators, and so forth)
E	event
!	error string The rest of the string provides information about the error. The C# compiler generates error informati on for links that cannot be resolved.

- The second part of the string is the fully qualified name of the item, starting at the root of the namespace. The name of the item, its enclosing type(s), and namespace are separated by periods. If the name of the item itself has periods, they are replaced by the hash-sign ('#'). It is assumed that no item has an hash-sign directly in its name. For example, the fully qualified name of the String constructor would be "System.String.#ctor".
- For properties and methods, if there are arguments to the method, the argument list enclosed in parentheses follows. If there are no arguments, no parentheses are present. The arguments are separated by commas. The encoding of each argument follows directly how it is encoded in a .NET Framework signature:
    - Base types. Regular types (ELEMENT_TYPE_CLASS or ELEMENT_TYPE_VALUETYPE) are represented as the fully qualified name of the type.
    - Intrinsic types (for example, ELEMENT_TYPE_I4, ELEMENT_TYPE_OBJECT, ELEMENT_TYPE_STRING, ELEMENT_TYPE_TYPEDBYREF. and ELEMENT_TYPE_VOID) are represented as the fully qualified name of the corresponding full type. For example, System.Int32 or System.TypedReference.
    - ELEMENT_TYPE_PTR is represented as a '*' following the modified type.
    - ELEMENT_TYPE_BYREF is represented as a '@' following the modified type.
    - ELEMENT_TYPE_PINNED is represented as a '^' following the modified type. The C# compiler never generates this.
    - ELEMENT_TYPE_CMOD_REQ is represented as a '|' and the fully qualified name of the modifier class, following the modified type. The C# compiler never generates this.
    - ELEMENT_TYPE_CMOD_OPT is represented as a '!' and the fully qualified name of the modifier class, following the modified type.
    - ELEMENT_TYPE_SZARRAY is represented as "[]" following the element type of the array.
    - ELEMENT_TYPE_GENERICARRAY is represented as "[?]" following the element type of the array. The C# compiler never generates this.
    - ELEMENT_TYPE_ARRAY is represented as [*lowerbound*:*size*,*lowerbound*:*size*] where the number of commas is the rank - 1, and the lower bounds and size of each dimension, if known, are represented in decimal. If a lower bound or size is not specified, it is simply omitted. If the lower bound and size for a particular dimension are omitted, the ':' is omitted as well. For example, a 2-dimensional array with 1 as the lower bounds and unspecified sizes is [1:,1:].
    - ELEMENT_TYPE_FNPTR is represented as "=FUNC:*type*(*signature*)", where *type* is the return type, and *signature* is the arguments of the method. If there are no arguments, the parentheses are omitted. The C# compiler never generates this.

The following signature components are not represented because they are never used for differentiating overloaded methods:

- calling convention
- return type
- ELEMENT_TYPE_SENTINEL

- For conversion operators only (op_Implicit and op_Explicit), the return value of the method is encoded as a '~' followed by the return type, as encoded above.

Examples

The following examples show how the ID strings for a class and its members would be generated:

```
///
///
namespace N  // "N:N"
{
   ///
   ///
   public unsafe class X    // "T:N.X"
   {
      /// <summary>
      ///
      /// </summary>
      public X(){}   // "M:N.X.#ctor"
      // public X(){} // "M:N.X.#cctor", a class constructor
      /// <summary>
      ///
      /// </summary>
      /// <param name="i"></param>
      public X(int i){}  // "M:N.X.#ctor(System.Int32)"
      /// <summary>
      ///
      /// </summary>
      ~X(){}  // "M:N.X.Finalize", destructor's representation in metadata

      /// <summary>
      ///
      /// </summary>
      public string q;  // "F:N.X.q"
      /// <summary>
      ///
      /// </summary>
      /// <returns></returns>
      public const double PI = 3.14;  // "F:N.X.PI"
      /// <summary>
      ///
      /// </summary>
      /// <param name="s"></param>
      /// <param name="y"></param>
      /// <param name="z"></param>
      /// <returns></returns>
      public int f(){return 1;}  // "M:N.X.f"
      /// <summary>
      ///
      /// </summary>
      /// <param name="array1"></param>
      /// <param name="array"></param>
      /// <returns></returns>
      public int bb(string s, ref int y, void * z){return 1;}
      // "M:N.X.bb(System.String,System.Int32@,=System.Void*)"
      /// <summary>
      ///
      /// </summary>
      /// <param name="x"></param>
      /// <param name="xx"></param>
```

```
        /// <returns></returns>
        public int gg(short[] array1, int[,] array){return 0;}
        // "M:N.X.gg(System.Int16[], System.Int32[0:,0:])"
        /// <summary>
        ///
        /// </summary>
        public static X operator+(X x, X xx){return x;} // "M:N.X.op_Addition(N.X,N.X)"
        /// <summary>
        ///
        /// </summary>
        public int prop {get{return 1;} set{}} // "P:N.X.prop"
        /// <summary>
        ///
        /// </summary>
        ///
        public event D d; // "E:N.X.d"
        /// <summary>
        ///
        /// </summary>
        public int this[string s]{get{return 1;}} // "P:N.X.Item(System.String)"
        /// <summary>
        ///
        /// </summary>
        public class Nested{} // "T:N.X.Nested"
        /// <summary>
        ///
        /// </summary>
        public delegate void D(int i); // "T:N.X.D"
        /// <summary>
        ///
        /// </summary>
        /// <param name="x"></param>
        /// <returns></returns>
        public static explicit operator int(X x){return 1;}
        // "M:N.X.op_Explicit(N.X)~System.Int32"
    }
}
```

Delimiters for Documentation Tags

The use of documentation tags requires delimiters, which indicate to the compiler where a documentation comment begins and ends. You can use the following kinds of delimiters with the XML documentation tags:

`///`
This is the form that is shown in documentation examples and used by the Visual C# project templates.

> **Note** The Visual Studio IDE has a feature called Smart Comment Editing that automatically inserts the <summary> and </summary> tags and moves your cursor within these tags after you type the `///` delimiter in the Code Editor. Access this feature from the Formatting, C#, Text Editor, Options Dialog Box in your project property pages.

`/** */`
Added after the Visual Studio .NET release. These are multiline delimiters.

There are some formatting rules when using the `/** */` delimiters:

- For the line that contains the `/**` delimiter, if the remainder of the line is white space, the line is not processed for comments. If the first character is white space, that white space character is ignored and the rest of the line is processed. Otherwise, the entire text of the line after the `/**` delimiter is processed as part of the comment.
- For the line that contains the `*/` delimiter, if there is only white space up to the `*/` delimiter, that line is ignored. Otherwise, the text on the line up to the `*/` delimiter is processed as part of the comment, subject to the pattern-matching rules described in the following bullet.
- For the lines after the one that begins with the `/**` delimiter, the compiler looks for a common pattern at the beginning of each line that consists of optional white space and an asterisk (`*`), followed by more optional white space. If the compiler finds a common set of characters at the beginning of each line, it will ignore that pattern for all lines after the `/**` delimiter, up to and possibly including the line that contains the `*/` delimiter.

Some examples:

- The only part of the following comment that will be processed is the line that begins with `<summary>`. The following two tag formats will produce the same comments:

```
/**
<summary>text</summary>
*/
```

```
/** <summary>text</summary> */
```

- The compiler applies a pattern of " * " to ignore at the beginning of the second and third lines.

```
/**
 * <summary>
 *  text </summary>*/
```

- The compiler finds no pattern in this comment because there is no asterisk on the second line. Therefore, all text on the second and third lines, up till the `*/`, will be processed as part of the comment.

```
/**
 * <summary>
   text </summary>*/
```

- The compiler finds no pattern in this comment for two reasons. First, there is no line that begins with a consistent number of spaces before the asterisk. Second, the fifth line begins with a tab, which does not match spaces. Therefore, all text from the second line until the `*/` will be processed as part of the comment.

```
/**
  * <summary>
  * text
```

```
 *  text2
   *  </summary>
*/
```

.NET Framework Reference Information

This topic links you to information on working with the .NET Framework class library.

In the Visual Basic and Visual C# Documentation

Introduction to the .NET Framework Class Library in Visual Studio
Provides links to Visual Studio topics that support the development of features based on classes in the .NET Framework.

In the .NET Framework Documentation

Reference (.NET Framework)
Contains a complete set of reference topics for the .NET Framework, including the class library and ASP.NET syntax.
Class Library (.NET Framework)
Contains a complete set of reference topics for the .NET Framework.
Introduction to the .NET Framework Class Library
Introduces the classes, interfaces, and value types that help expedite and optimize the development process and provide access to system functionality.
Inside the .NET Framework
Contains description of key features of the .NET Framework, including the common language runtime.
Samples (.NET Framework)
Contains a list of sample programs that demonstrate how to write applications and components that use the .NET Framework technologies.

Upgrading Reference for Visual Basic and Visual C#

This section links you to topics on upgrading your applications from other languages to Visual Basic .NET and Visual C# .NET.

In This Section

Visual Basic 6.0 Upgrading Reference
Contains topics about errors, warnings, and issues generated while upgrading a Visual Basic 6.0 project to the new version of Visual Basic.

Java Language Conversion Assistant
Describes the tool for converting Visual J++ projects to Visual C#. Includes diagnostic messages for the conversion process.

Related Sections

Reference (Visual Basic and Visual C#)
Links you to reference information on various aspects of Visual Basic and Visual C# programming.

Visual Basic 6.0 Upgrading Reference

The topics in the following section of the Table of Contents relate to errors, warnings, and issues generated while upgrading a Visual Basic 6.0 project to Visual Basic .NET. These topics should only be accessed from links in the upgraded project in order to provide the proper context.

Upgrading Applications Created in Previous Versions of Visual Basic

Upgrade Wizard

The Upgrade Wizard is used to upgrade Visual Basic 6.0 projects to Visual Basic .NET. The wizard creates a new project, copies each file from the original project into the new project and modifies it as necessary, and generates a report detailing what was done and what you need to do to finish the upgrade.

To access the Upgrade Wizard, open any Visual Basic 6.0 project file (.vbp) in Visual Basic .NET.

The following options are available in the Upgrade Wizard:

What type of project would you like this to be upgraded to?
If the Visual Basic 6.0 project was an ActiveX EXE or ActiveX Document EXE project, you can choose to upgrade it to either an .exe or a .dll file. For all other project types, the correct option is already selected and cannot be changed.

Where do you want your new project created?
Specifies the location of the new project. By default, the project will be placed in a directory directly beneath the Visual Basic 6.0 project. The new project will be named *ProjectName*.NET, where *ProjectName* is the name of the project being upgraded.

Upgrading Applications Created in Previous Versions of Visual Basic | Visual Basic Upgrade Wizard

A string cannot be used to index a control collection

In Visual Basic 6.0 the variable representing the name of a control could be used as the index value in the controls collection, as follows:

```
Form1.Controls (stringVariable)
```

In Visual Basic .NET, the index must be numeric.

What to do next

- Replace the control name with its index value from the **Controls** collection. The index value indicates the order in which the controls were added to the collection, with the first control being 0.

See Also

Controls Collection Changes in Visual Basic .NET

Add a delegate for AddressOf operator

In Visual Basic 6.0, the **AddressOf** operator was used to pass the address in memory of a function to an API procedure that takes a function pointer as an argument.

In Visual Basic .NET, the **AddressOf** operator must be used with a **Delegate** type. Delegates allow Visual Basic .NET to maintain a pointer to a function even if the function itself has already been garbage-collected.

The following example illustrates how a callback function that uses **AddressOf** is upgraded:

```
' Visual Basic 6.0
Declare Function SetWindowLong Lib "USER32.DLL" Alias "SetWindowLongA" (ByVal hwnd As Long, B
yVal attr As Long, ByVal lVal As Long) As Long
Sub SubClassWindow(ByVal hwnd As Long)
   If PrevProcPtr = 0 Then
      PrevProcPtr = SetWindowLong(hwnd, GWL_WNDPROC, AddressOf SubClassProc)
   End If
End Sub

' After upgrade to Visual Basic .NET
Declare Function SetWindowLong Lib "USER32.DLL"  Alias "SetWindowLongA"(ByVal hwnd As Integer
, ByVal attr As Integer, ByVal lVal As Integer) As Integer
Sub SubClassWindow(ByVal hwnd As Integer)
   If PrevProcPtr = 0 Then
      ' UPGRADE_WARNING: Add a delegate for AddressOf SubClassProc.
      PrevProcPtr = SetWindowLong(hwnd, GWL_WNDPROC, AddressOf SubClassProc)
   End If
End Sub
```

What to do next

- Add a delegate for the **AddressOf** operator, and change the parameter of the function declaration to the **Delegate** type:

```
Delegate Function SubClassProcDelegate(ByVal hwnd As Integer, ByVal msg As Integer, ByVal
wParam As Integer, ByVal lParam As Integer) As Integer
Declare Function SetWindowLong Lib "USER32.DLL" Alias "SetWindowLongA" (ByVal hwnd As Int
eger, ByVal attr As Integer, ByVal lVal As SubClassProcDelegate) As Integer
Sub SubClassWindow(ByVal hwnd As Integer)
   If PrevProcPtr = 0 Then
      PrevProcPtr = SetWindowLong(hwnd, GWL_WNDPROC, AddressOf SubClassProc)
   End If
End Sub
```

See Also

Delegates and the AddressOf Operator | AddressOf Operator | Delegate Statement

Application will terminate when Sub Main() finishes

In Visual Basic 6.0, an application would terminate only after every object that has been created was destroyed. Many applications set the startup object to **Sub_Main** in order to execute initialization code.

In Visual Basic .NET, the application terminates when the startup object is destroyed. If **Sub_Main** is set as the startup object, the application will terminate immediately after running the code in **Sub_Main**.

What to do next

- Set a form to be the startup object.
- Either move the code from **Sub_Main** to the form's **Load** event, or call **Sub_Main** from the **Load** event.

See Also

Choosing the Startup Form in Your Windows Application

Array may need to have individual elements initialized

In Visual Basic 6.0, all members of a user-defined type (UDT) were initialized when they were declared inside the **Type** statement block.

In Visual Basic .NET, user-defined types are replaced by structures. Members that require parameterless constructors (such as fixed-length strings, fixed-size arrays, and variables declared with the **New** keyword) require initialization. During upgrade, an Initialize() subroutine is added to the structure. Calls to the Initialize subroutine must be added whenever the structure is declared.

When an array of structures is declared or redimensioned, the Initialize() subroutine has to be called for each element of the array, or some members of the structures will not be initialized as they were in Visual Basic 6.0.

What to do next

- Add a call to the Initialize() subroutine wherever the array is declared or redimensioned:

```
' After upgrade to Visual Basic .NET
Private Structure MyStruct
   Dim MyClass1 As Class1

   ' UPGRADE_TODO: "Initialize" must be called to initialize instances of this structure.
   Public Sub Initialize()
      MyClass1 = New Class1
   End Sub
End Structure

Private Structure StructArray
   Dim MyArray As MyStruct

   ' UPGRADE_TODO: "Initialize" must be called to initialize instances of this structure.
   Public Sub Initialize()
      MyArray.Initialize
   End Sub
End Structure

Private Sub Form1_Load(ByVal eventSender As System.Object, ByVal eventArgs As System.Even
tArgs) Handles MyBase.Load
   ' UPGRADE_WARNING: Array MyStructArray may need to have individual elements initialize
d.
   Dim MyStructArray(1) as StructArray
   MyStructArray(0).MyArray.Initialize()
   MyStructArray(1).MyArray.Initialize()
End Sub
```

See Also

Initialize must be called to initialize instances of this structure

Array variables cannot be declared with New

In Visual Basic 6.0, array variables could be declared with the **New** keyword; this would automatically initialize all members of the array.

In Visual Basic .NET the **New** keyword is no longer supported for arrays; members within an array must be explicitly initialized.

The following example shows an array declared with the **New** keyword:

```
' Visual Basic 6.0
Dim MyArray(1) As New Class1
MyArray(0).Text = "Hello"
MyArray(1).Text = "world"

' After upgrade to Visual Basic .NET
' UPGRADE_WARNING: Arrays can't be declared with New.
Dim MyArray(1) As New Class1
MyArray(0).Text = "Hello"
MyArray(1).Text = "world"
```

What to do next

- Remove the **New** keyword.
- Initialize all members of the array when the array is declared:

  ```
  ' Modified code
  Dim MyArray(1) As Class1
  MyArray(0) = New Class1
  MyArray(1) = New Class1
  MyArray(0).Text = "Hello"
  MyArray(1).Text = "world"
  ```

- Alternatively, you can initialize the members of the array when they are used; however, if you do so, you should test to ensure that they are not already initialized:

  ```
  If IsNothing(MyArray(1)) Then
     MyArray(1) = New Class1
  End If
  MyArray(1).Text = "world"
  ```

See Also

Array Size Declaration Changes in Visual Basic

Arrays in a structure may need to be initialized

In Visual Basic .NET, fixed-size arrays in structures are not supported. Fixed-size arrays that are members of structures defined in COM interfaces will need to be initialized before they can be used.

The following example illustrates a structure in a COM object named TypeLibTest that contains a fixed-size array:

```
' Visual Basic 6.0
Dim xx As tlStructArrays
xx.m_tlUSHORT(3) = 55

' After upgrade to Visual Basic .NET
' UPGRADE_WARNING: Arrays in structure xx may need to be initialized before they can be used.

Dim xx As TypeLibTest.tlStructArrays
xx.m_tlUSHORT(3) = System.Convert.ToUInt16(55)
```

What to do next

- Add a line of code to initialize the array:

```
Dim xx As TypeLibTest.tlStructArrays
xx.m_tlUSHORT = New Uint16(4) {}
xx.m_tlUSHORT(3) = System.Convert.ToUInt16(55)
```

See Also

Array Size Declaration Changes in Visual Basic

As clause removed from variant ReDim

In Visual Basic 6.0, a variable of the **Variant** data type could be changed to an array of a different data type using the **ReDim** keyword with an **As** clause.

When a Visual Basic 6.0 project is upgraded to Visual Basic .NET, any **Variant** variables are converted to the **Object** data type; you cannot define an object as a different data type using the **As** clause.

The following example shows the usage of the **ReDim** keyword:

```
' Visual Basic 6.0
Dim V As Variant
ReDim V(10) As Integer

' After upgrade to Visual Basic .NET
Dim V As Object
' UPGRADE_WARNING: As Integer was removed from ReDim V statement.
ReDim V(10)
```

What to do next

- Modify your code so that the variable is initially declared as an array of the correct data type:

  ```
  ' Modified code
  Dim V() As Integer
  ReDim V(10)
  ```

- Search your code to see if the variable is used anywhere else, and make sure that the data type is correct for each occurrence. Assign new variables if necessary for any additional data types.

See Also

ReDim Statement Changes in Visual Basic

Assignment not supported

In Visual Basic 6.0, an integer or variant value could be assigned to the **KeyAscii** parameter of a **KeyPress** event in order to override the **KeyAscii** value passed to the event. The most common usage was to assign a value of 0 to cancel the keystroke.

In Visual Basic .NET, you cannot assign any value other than 0 to **KeyAscii**. The following example shows the effect of upgrading the **KeyPress** event:

```
' Visual Basic 6.0
Private Sub Text1_KeyPress(KeyAscii As Integer)
   Dim MyValue As Variant
   KeyAscii = MyValue
   KeyAscii = 0
   KeyAscii = 1
End Sub

' After upgrade to Visual Basic .NET
Private Sub Text1_KeyPress(ByVal eventSender As System.Object, ByVal eventArgs As System.Wind
ows.Forms.KeyPressEventArgs)
   Dim KeyAscii As Short = Asc(eventArgs.KeyChar)
   ' UPGRADE_WARNING: Assignment not supported: KeyAscii to a non-zero value.
   KeyAscii = MyValue
   KeyAscii = 0
   ' UPGRADE_WARNING: Assignment not supported: KeyAscii to a non-zero value.
   KeyAscii = 1
   If KeyAscii = 0 Then
      eventArgs.Handled = True
   End If
End Sub
```

What to do next

- You cannot assign key values in the **KeyPress** event. Instead, create your own function to assign the key value outside of the **KeyPress** event.

See Also

Control.KeyPress Event

Behavior of Null has changed

In Visual Basic 6.0, the **Null** keyword indicated that a variable contained no valid data, and the **IsNull** function was used to test for **Null**. In Visual Basic .NET, the **Null** keyword is still a reserved word, but it has no syntactical value; the **IsNull** function is no longer supported. In addition, Visual Basic 6.0 supported **Null** propagation — when **Null** was used in an expression, the result of the expression would also be **Null**. **Null** propagation is no longer supported in Visual Basic .NET.

During upgrade, **Null** is converted to **DBNull**, and **IsNull** is converted to **IsDBNull**. The behavior of **DBNull** is slightly different than that of **Null**. **Null** could be used in functions and assignments; **DBNull** cannot.

Where **Null** was used with a **Variant** data type, the **Variant** is converted to **Object** during upgrade; it may be more appropriate to use the **Nothing** keyword or the **IsNothing** function.

What to do next

- Review the use of **Null** in your code. In some cases, functions that worked with **Null** will cause an exception with **DBNull**; you will need to test for **DBNull** in these cases:

```
' Visual Basic 6.0
' Assumes that rs!Field1 is null.
x = Left(rs!Field1, 1)

' After upgrade to Visual Basic .NET
x = VB.Left(rs.Fields("Field1").Value, 1)

' Modified code
If Not IsDbNull rs.Fields("Field1").Value Then
   x = VB.Left(rs.Fields("Field1").Value, 1)
End If
```

  In other cases, code can be simplified:

```
' Visual Basic 6.0 code
If Not IsNull (rs!Field1, 1) Then
   x = rs!Field1
End If

' After upgrade to Visual Basic .NET
x = VB.Left(rs.Fields("Field1").Value, 1)

' Modified code.
' UPGRADE_WARNING: Use of Null/IsNull() detected.
If Not IsDbNull(rs.Fields("Field1").Value) Then
   x = rs.Field1("Field1").Value
End If

' Modified code - If statement no longer needed.
x = rs.Field1("Field1").Value & " "
```

See Also

IsDbNull Function | DBNull Class

Cannot resolve the name of a control

The index of an **HScrollBar** or **VScrollBar** control in a control array could not be resolved because it is not a constant value. The actual index of the control is required in order to resolve the control in the **Change** or **Scroll** events.

What to do next

- Replace the variable with the actual index of the control if possible.
- If the index is not known at design time, remove the controls from the control array and add code to handle the **Change** and **Scroll** events for each individual control.

See Also

Introduction to the Windows Forms HScrollBar and VScrollBar Controls

Cannot set a custom MousePointer

In Visual Basic 6.0, you could specify a custom mouse pointer by assigning an image to the **MouseIcon** property of a form or control and setting the **MousePointer** property to **vbCustom** or **99**. Custom mouse pointers are not supported at design time in Visual Basic .NET; the **MousePointer** property is replaced by the **Cursor** property, and the **MouseIcon** property no longer exists.

> **Note** The **Cursor** property can be set at run time to any value of type **System.Windows.Forms.Cursor**.

The following code set a custom mouse pointer in Visual Basic 6.0:

```
' Visual Basic 6.0
PictureBox1.Mousepointer = vbCustom
```

What to do next

- If the custom mouse pointer was set at design time, choose a new mouse pointer by selecting the **Cursor** property in the Properties window for the form or control.
- If the custom mouse pointer was set in code, modify your code to use the **Cursor** property. You can view a list of available cursors in the Properties window by selecting the **Cursor** property for any form or control.

  For example, to use the Hand cursor in a **PictureBox** control, enter the following code:

  ```
  ' Visual Basic .NET
  PictureBox1.Cursor = System.Windows.Forms.Cursors.Hand
  ```

Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

Class instancing was changed to Public

In Visual Basic 6.0, instance creation was controlled by the **Instancing** property of a class, which set both the access level (**Public**, **Private**, **Friend**) of a class and the way an object could be created.

In Visual Basic .NET, the **Instancing** property is no longer supported; you control the way that an object can be created by setting the access level of the constructor (**Sub New**). For more information, see Component Instancing Changes in Visual Basic.

There is no direct equivalent for **SingleUse**, **GlobalSingleUse**, or **GlobalMultiUse** instancing in Visual Basic .NET; when the **Instancing** property is set to one of these values, the access level of both the class and the constructor are set to **Public** during upgrade.

What to do next

- Review your code. The behavior may be slightly different than it was in Visual Basic 6.0, and you may need to change the access level of the class and/or the constructor.

See Also

Component Instancing Changes in Visual Basic

Code could not be parsed

In some cases, code that was syntactically incorrect did not cause compilation errors in Visual Basic 6.0. For example, the following code would not cause a compilation error:

```
Private Sub Form_Click()
   ' Note misspelling of DoEvents.
   DoEventss
End Sub
```

Visual Basic 6.0 performed incremental compilation; because the code in the **Form_Click** event would not be compiled until the event was triggered, the syntax error would only be encountered at run time.

In Visual Basic .NET, all code is compiled before the application is run, so syntax errors will always cause a compilation error.

What to do next

- Modify the code to use the correct syntax.

  Note If you run your application in Visual Basic 6.0 prior to upgrading using the **Start With Full Compile** option, you will get compilation errors for any syntax problems.

See Also

Preparing a Visual Basic 6.0 Application for Upgrading

Code was changed from an event to a procedure

During upgrade some events are changed to procedures in the code with an extra parameter and called from a different event. This is usually necessary because the sequence of events in Visual Basic .NET is different than in Visual Basic 6.0.

For example, in Visual Basic 6.0, when the **Scroll** or **Change** event of a **VScrollBar** control was raised, the current scroll value was assigned to the **Value** property. When the **Scroll** or **Change** event is raised in Visual Basic .NET, the control's value has not yet been updated with the new scroll value. During upgrade, the event is changed to a procedure, and the signature of the original subroutine is changed to include a parameter named **NewScrollValue**. When the **Scroll** event is raised, the procedure is called and the value is passed to the **NewScrollValue** parameter.

The following example shows how the code is upgraded.

```
' Visual Basic 6.0
Private Sub VScroll1_Change()
   Debug.Print "change " & VScroll1.Value
End Sub

Private Sub VScroll1_Scroll()
   Debug.Print "scroll " & VScroll1.Value
End Sub
```

```
' After upgrade to Visual Basic .NET
' UPGRADE NOTE: Vscroll1.Change was changed from an event to a procedure.
Private Sub VScroll1_Change(ByVal NewScrollValue As Integer)
   System.Diagnostics.Debug.WriteLine("change " & NewScrollValue)
End Sub

' UPGRADE NOTE: Vscroll1.Scroll was changed from an event to a procedure.
Private Sub VScroll1_Scroll_Renamed(ByVal NewScrollValue As Integer)
   System.Diagnostics.Debug.WriteLine("scroll " & NewScrollValue)
End Sub

Private Sub VScroll1_Scroll(ByVal eventSender As System.Object, _
ByVal eventArgs As System.Windows.Forms.ScrollEventArgs) Handles _
Vscroll1.Scroll
   Select Case eventArgs.type
      Case System.Windows.Forms.ScrollEventType.ThumbTrack
         VScroll1_Scroll_Renamed(eventArgs.newValue)
      Case System.Windows.Forms.ScrollEventType.EndScroll
         VScroll1_Change(eventArgs.newValue)
   End Select
End Sub
```

What to do next

- No further action is necessary — this note was added to make you aware of the changes made to your code.

See Also

Introduction to the Windows Forms HScrollBar and VScrollBar Controls | Event Changes in Visual Basic .NET

Code was upgraded to use a function which may not have the same behavior

During upgrade, some Visual Basic 6.0 functions are upgraded to different Visual Basic .NET functions with different behavior. In many cases, this will not have an effect on your code; however, you should be aware of these differences and review your code to make sure that your usage of these functions is still appropriate.

Assigning a Byte array to a string

In Visual Basic 6.0, you could assign a **Byte** array to a string with direct assignment. When upgraded to Visual Basic .NET, this assignment is replaced by a function in the **System.Text.UnicodeEncoding** namespace. Because it is Unicode based, it expects an even number of bytes; an odd number of bytes will cause an exception.

The following example illustrates how this is upgraded:

```
' Visual Basic 6.0
Dim B() As Byte
Dim S As String
S = B()

' After upgrade to Visual Basic .NET
Dim B() As Byte
Dim S As String
' UPGRADE_TODO: Code was upgraded to use GetString, which may not have the same behavior.
S = System.Text.UnicodeEncoding.Unicode.GetString(B)
```

What to do next

- Review the documentation for the Visual Basic .NET version of the function, and modify your code as necessary. In the above example, you would need to make sure that an even number of bytes are being passed when you assign to B().

Preparing a Visual Basic 6.0 Application for Upgrading

COM expression not supported

In Visual Basic 6.0, all methods of a COM object were supported whether they were exposed as methods on a class or methods on a module. Most COM objects only expose class methods; however, some objects such as the DirectX library also expose module methods.

In Visual Basic .NET, only the methods on a class are exposed to COM interop; Visual Basic 6.0 code that accesses methods on a module cannot be upgraded.

What to do next

- Review your code and determine how this method was used. In some cases, there may be objects in the .NET Framework that provide the same functionality. If your code absolutely depends on module methods of a COM object, you will need to keep the application in Visual Basic 6.0.

See Also

Preparing a Visual Basic 6.0 Application for Upgrading

Conditional block not upgraded because an expression evaluates to False

Visual Basic 6.0 supported conditional compilation using the **#If**...**#EndIf** statement syntax and conditional compilation constants. During compilation, only the code block that evaluated to **true** would be compiled; other code blocks within the **#If**...**#EndIf** construct would be ignored.

When a project is upgraded to Visual Basic .NET, only those blocks that evaluate to **true** will be upgraded; other code blocks within the **#If**...**#EndIf** construct will not be upgraded.

The following example shows a conditional block:

```
' Visual Basic 6.0
#If True Then
   Dim x As TextBox
#Else
   Dim x As Label
#End If

' After upgrade to Visual Basic .NET
#If True Then
   Dim x As System.Windows.Forms.TextBox
#Else
   ' UPGRADE_NOTE: #If #EndIf block was not upgraded because the expression Else did not eval
uate to True.
   Dim x As Label
#End If
```

What to do next

- Evaluate your project in Visual Basic 6.0 and make sure that the correct conditional compilation constants are being set. If you want to upgrade the code within a conditional block, remove it from the conditional block in Visual Basic 6.0, then add the conditional statements back after upgrading.

See Also

Conditional Compilation Overview

Constant was not upgraded

In some cases, constants used in Visual Basic 6.0 have no equivalent in Visual Basic .NET. During upgrade, constants are converted to their .NET equivalent where possible. If the property, method, or function to which the constant applies was not upgraded, the constant cannot be upgraded. For example, **Drag** constants are not upgraded because drag-and-drop code is not upgraded.

What to do next

- Check your code to determine how the constant is being used. If it applies to a property, method, or function that could not be upgraded, remove the line of code.
- If the context for the constant is still valid, check the value for the constant in your Visual Basic 6.0 application, and replace the constant with the value.

Constant Changes in Visual Basic .NET

Control was not upgraded

Due to differences between Visual Basic 6.0 and Visual Basic .NET, some controls cannot be upgraded, or some controls can only be upgraded under certain conditions. For example, the **Data** control cannot be upgraded because it depends on DAO, which is not supported in Visual Basic .NET.

What to do next

Select a control from the list below to see a topic listing changes and issues for that control.

Data Control Changes in Visual Basic .NET

Line Control Changes in Visual Basic .NET (diagonal lines only)

OLE Container Control Changes in Visual Basic .NET

RDO Data Control Changes in Visual Basic .NET

Shape Control Changes in Visual Basic .NET (circles or ovals only)

UpDown Control

The **UpDown** control that was included in the Microsoft Windows Common Controls 2 (Mscomct2.ocx) cannot be upgraded. There is no direct equivalent in Visual Basic .NET; however, the **DomainUpDown** control or the **NumericUpDown** control can be used to achieve similar functionality. For more information, see Introduction to the Windows Forms DomainUpDown Control or Introduction to the Windows Forms NumericUpDown Control.

UserControl Changes in Visual Basic .NET

Things to Consider Before Upgrading

Could not find a project file

The referenced file or files could not be found. The file(s) may have been moved, the media containing the file(s) may have been removed, or a network connection may have failed.

What to do next

- Restore the missing file(s) to the proper directories before upgrading. If the file(s) were not in the same directory as the project file (.vbp), you can open the project file in a text editor to determine the path to the file.

See Also

Upgrading a Project with the Upgrade Wizard

Could not load referenced component

A component referenced in the Visual Basic 6.0 project could not be loaded during the upgrade process. In most cases this occurs because the component does not exist on the upgrade computer, is not registered, or is referenced with an invalid path.

What to do next

Make sure that the project can be successfully compiled and run using Visual Basic 6.0 on the upgrade computer. If the project cannot be run successfully, check the component references in the Visual Basic 6.0 project and correct the path.

Alternatively, you can make sure that the correct version of the component is installed on the target computer in the location specified in the Visual Basic 6.0 .vbp file, then run the upgrade tool again.

Data binding for ComboBox or ListBox is read-only

In Visual Basic 6.0, a **ComboBox** or **ListBox** control could be bound to a database using ADO; when a value in the control was changed, the database was updated. In Visual Basic .NET, data binding for the ComboBox Control (Windows Forms) and ListBox Control (Windows Forms) controls is read-only when a user changes the value by selecting an item from the list. When the value in the database changes, the control is updated, but when the value in the control is changed, the database is not updated.

> **Note** For the **ComboBox** control, changing the value by typing in the **TextBox** portion of the control does update the database.

What to do next

Add code to the ListControl.SelectedValueChanged Event event for the **ComboBox** or **ListBox** controls to update the database.

See Also

ComboBox Control Changes in Visual Basic .NET | ListBox Control Changes in Visual Basic .NET | Data Changes in Visual Basic .NET

Declaration changed from Constant to Variable

In Visual Basic 6.0, constants were primitive types. In Visual Basic .NET, some values that were formerly represented as constants are now reference types within the .NET Framework.

For example, in Visual Basic 6.0 color constants such as `vbBlack` were used to refer to colors. In Visual Basic .NET, colors are reference types within the System.Drawing namespace: `System.Drawing.Color.Black`.

The following example shows a constant that is upgraded to a variable:

```
' Visual Basic 6.0
Const ConstColor = vbBlack

' After upgrade to Visual Basic .NET
' UPGRADE_NOTE: ConstColor was changed from a Constant to a Variable.
Dim ConstColor As System.Drawing.Color = System.Drawing.Color.Black
```

What to do next

- No further action is necessary. This upgrade note was added to make you aware of the new reference type that replaces your constant.

See Also

Declaration type not supported | NewEnum property was commented out

Declaration type not supported

Some variable declarations that were allowed in Visual Basic 6.0 are no longer allowed in Visual Basic .NET.

Arrays of fixed-length strings

In Visual Basic 6.0, you could declare an array of fixed-length strings as follows:

```
Dim x(10) As String * 10
```

Arrays of fixed-length strings are not supported in Visual Basic .NET.

What to do next

- Modify the declaration to use variable length strings:

  ```
  Dim x(10) As String
  ```

- If fixed-length strings are necessary, you can manage the length of strings before assigning them to the array using the **Len** function, **Left** function and the **PadRight** method:

  ```
  Public Function FixedLength10(ByVal S As String) As String
     Dim l As Long
     L = Len(s)
     If l > 10 Then
        FixedLength10 = Microsoft.VisualBasic.Left(s, 10)
     ElseIf l < 10 Then
        FixedLength10 = s.PadRight(10)
     End If
  End Function
  ```

Arrays with more than 32 dimensions

In Visual Basic 6.0, the maximum number of dimensions for an array was 60. In Visual Basic .NET, the maximum number of dimensions is 32.

What to do next

- Rethink the design of your application. Arrays with large number of dimensions are very memory-intensive and are likely to produce an out-of-memory error on most computers.

Arrays with a negative upper bounds

In Visual Basic 6.0, arrays could be declared with negative upper bounds. For example, the declaration `Dim MyArray(-15 To -10)` was valid.

What to do next

- In Visual Basic 6.0, change the bounds of arrays so that upper bounds are not negative and modify any code that uses the arrays prior to upgrading.

References to a Private Enum

In Visual Basic 6.0, it was possible to reference a Private Enum from a Public Enum within the same module. In Visual Basic .NET, this is no longer allowed.

What to do next

- Change the Enum to Public, or use the actual value of the Private Enum instead.

Color constants in an Enum

In Visual Basic 6.0, it was possible to define enumerations for colors using the VB Color constants:

```
' Visual Basic 6.0
Enum MyColors
   Red = vbRed
End Enum
```

In Visual Basic .NET, colors are reference types in the System.Drawing namespace; color constants are unnecessary.

What to do next

- Find any code that uses the Enum and replace it with code that sets the color using System.Drawing.Color:

```
' After upgrade to Visual Basic .NET
Me.BackColor = MyColors.Red

' Modified code
Me.BackColor = System.Drawing.Color.Red
```

See Also

Left Function | Len Function | String.PadRight Method | System.Drawing Namespace |
Declaration changed from Constant to Variable

Declare statement does not support parameters of type As Any

In Visual Basic 6.0, you could declare a reference to an external procedure with the **Declare** statement and specify **As Any** for the data type of an argument or return type. The **As Any** keyword disabled type checking and allowed any data type to be passed in or returned.

In Visual Basic .NET, the **As Any** keyword is no longer supported. To ensure type safety, you must specifically declare the data type of all arguments and return values.

For example, the following declaration accepted either a string or a long data type as the second argument:

```
' Visual Basic 6.0
Declare Function LoadCursor Lib "user32" Alias "LoadCursorA"(ByVal hInstance As Long, ByVal l
pCursorName As Any) As Long

' After upgrade to Visual Basic .NET
' UPGRADE_ISSUE: Declaring a parameter 'As Any' is not supported.
Declare Function LoadCursor Lib "user32" Alias "LoadCursorA"(ByVal hInstance As Integer, ByVa
l lpCursorName As Any) As Integer
```

What to do next

- Determine where the declared function is being used in your code and what data type is being passed. If all occurrences pass the same data type, change the declaration to include that data type instead of **As Any**:

  ```
  Declare Function LoadCursor Lib "user32" Alias "LoadCursorA"(ByVal hInstance As Integer,
  ByVal lpCursorName As String) As Integer
  ```

- If you need to support multiple data types, create an overloaded version of the declaration for each data type:

  ```
  Declare Function LoadCursor Lib "user32" Alias "LoadCursorA"(ByVal hInstance As Integer,
  ByVal lpCursorName As String) As Integer
  Declare Function LoadCursor Lib "user32" Alias "LoadCursorA"(ByVal hInstance As Integer,
  ByVal lpCursorName As Integer) As Long
  ```

See Also

Declaration Syntax Changes in Visual Basic

DoEvents no longer returns a value

In previous versions of Visual Basic, the **DoEvents** function returned an **Integer** value representing the number of open forms. In Visual Basic .NET, the **DoEvents** function is replaced by the **DoEvents** method; consequently, it has no return value. Attempting to call **DoEvents** as a function will cause the compiler error "No accessible overloaded method 'DoEvents' produces a value".

> **Note** The more common use of **DoEvents** was to yield execution to allow the system to process messages. In this case it was treated as a method with no return value. Code using **DoEvents** in this manner will migrate successfully to Visual Basic .NET.

```
' Visual Basic 6.0
Dim i As Integer
' Returns the number of open forms.
i = DoEvents
' Yields processing; no return value.
DoEvents

' After upgrade to Visual Basic .NET
Dim i as Short
' Causes a compiler error.
i = System.Windows.Forms.Application.DoEvents()
' Compiles successfully.
System.Windows.Forms.Application.DoEvents()
```

What to do next

- Change the **DoEvents** function to a method as in the above example.
- Review your code to determine how the return value of the **DoEvents** function was being used and modify your code as necessary.

> **Note** There is no equivalent function in Visual Basic .NET that returns the number of open forms.

See Also

Programming Element Support Changes Summary

Event is not supported

Some events that were supported in Visual Basic 6.0 are no longer supported in Visual Basic .NET or do not map directly to a Visual Basic .NET event. In these cases, code in the Visual Basic 6.0 event procedure will be preserved as is; however, the code will not execute in Visual Basic .NET and must be replaced. For example, the **DblClick** event for a **ListBox** control has no equivalent; depending on how it was used you might replace it with either the **SelectedIndexChanged** or **TextChanged** event.

What to do next

Select an object or control from the list below to see a topic listing changes and issues for that object.

Event Changes in Visual Basic .NET | Form Event Changes in Visual Basic .NET | Change Event Changes in Visual Basic .NET | TopIndex Property and Scroll Event Changes in Visual Basic .NET

Event may fire when form is initialized

In Visual Basic 6.0, events for a form or control were not raised until the form was finished loading. In Visual Basic .NET, the **InitializeComponent** method handles the initialization of the form and its controls; the order in which objects are initialized cannot be modified. In some cases, this may cause events to be raised during initialization. If the event handler references other components that have not yet been initialized, this could cause a run-time error.

For example, if the **Click** event handler for a **CheckBox** control sets a value in a **TextBox** control, an error may occur if the **TextBox** control is not yet initialized:

```
' Visual Basic 6.0
Private Sub Check1_Click()
   TextBox1.Text = "Check1 was clicked"
End Sub

' After upgrade to Visual Basic .NET
' UPGRADE_WARNING: Event CheckStateChanged may fire when form is initialized.
Private Sub Check1_CheckStateChanged(ByVal sender As System.Object, ByVal e As System.EventAr
gs) Handles Check1.CheckStateChanged
   ' The following line will cause an error if TextBox1 is not
   ' initialized.
   TextBox1.Text = "Check1 was clicked"
End Sub
```

What to do next

1. Add an **IsInitializing** property to the form.
2. Set the property to **true** in the form's constructor just prior to the **InitializeComponent** call; set it to **false** immediately following the call.
3. Add the following logic to the event procedure to check the value of the property before running the code:

```
Private Sub Check1_CheckStateChanged(ByVal sender As System.Object, ByVal e As System.Eve
ntArgs) Handles Check1.CheckStateChanged
   If Form1.DefInstance.IsInitializing = True Then
      Exit Sub
   Else
      TextBox1.Text = "Check1 was clicked"
   End If
End Sub
```

Property Statement | Forms Changes in Visual Basic .NET

Event parameter was not upgraded

Some event parameters that were supported in Visual Basic 6.0 are no longer supported in Visual Basic .NET.

- The **Cancel** parameter of the **Form_Unload** event is no longer supported. The **Unload** event is upgraded to the **Closed** event; when this event raises, garbage collection has already been initiated and it is too late to cancel.
- The **UnloadMode** parameter of the **Form_QueryUnload** event is no longer supported. The **QueryUnload** event is upgraded to the **Closing** event; this event has no mechanism for determining why it was called.

What to do next

- Move any code that is dependent on the **Cancel** parameter into the **Closing** event.
- If it is necessary to determine why the form is closing, you will need to create an overloaded version of the **Closing** event with custom code to determine the caller.

See Also

Form.Closed Event | Form.Closing Event

Function has a new behavior

Several functions in Visual Basic .NET behave differently than their equivalent Visual Basic 6.0 functions. In most cases, this will not have an effect on your code; however, you should be aware of these differences and review your code to make sure that your usage of these functions is still appropriate.

Array function

In Visual Basic 6.0, the **Array** statement was used to return a variant containing an array, assigning values to array elements in a single step. The **Array** function is no longer supported in Visual Basic .NET.

When a Visual Basic 6.0 project is upgraded to Visual Basic .NET, any **Variant** variables are converted to the **Object** data type, so the upgraded code will return an object containing an array.

What to do next

- Review your code. In most cases, you will probably want to create an array to replace the upgraded object and assign the values as you would with any other array.

Dir function

In Visual Basic 6.0, the **Dir** function was used to return the name of a file, folder, or directory. The "." and ".." strings could be used in the path argument to represent the current directory or the encompassing directory, respectively.

In Visual Basic .NET, the **Dir** function is essentially the same, but the "." and ".." syntax has a different behavior.

What to do next

- Code that returned files or directories was often written with the assumption that the "." and ".." would be returned as the first two entries; this is no longer true in Visual Basic .NET. Because of the difference in behavior, the upgraded code may not return the first two files or directories.

Get#, Put# Functions

In Visual Basic 6.0, the **Get#** and **Put#** functions were used to read and write data to a file.

In Visual Basic .NET, these are upgraded to the **FilePut** and **FileGet** functions. When these functions are used to pass dynamic arrays or strings to a file opened in **Random** mode, a two-byte length descriptor is added, resulting in a different file length.

What to do next

- To achieve the same results as in Visual Basic 6.0, use the optional **ArrayIsDynamic** argument to the **FilePut** and **FileGet** functions.
- When opening a file in Random mode, use the **StringIsFixedLength** argument.

IsObject function

In Visual Basic 6.0, the **IsObject** function was used to determine if a **Variant** variable was of type vbObject. If the variable was empty, the **IsObject** function would return **true** for an object, but **false** for a variant. Likewise, if the variable contained a string, it would return **false**.

When a Visual Basic 6.0 project is upgraded to Visual Basic .NET, any **Variant** variables are converted to the **Object** data type. The Visual Basic .NET **IsObject** function is used to determine if a variable contains an object. If an object is empty, the function will still return **true** because it is an object. In addition, strings in Visual Basic .NET are objects and will return **true**.

What to do next

- Find the variable(s) being evaluated by the **IsObject** function and make sure that the logic is still valid.

MOD operator

In Visual Basic 6.0, the MOD operator accepted any numeric expression and the result was always returned as an integer.

In Visual Basic .NET, the MOD operator no longer accepts variants, and if either operand is a floating-point number, the result will be a floating-point number.

What to do next

- If a variant has been converted to an object during upgrade, convert it to the appropriate numeric data type.
- If either of the operands is a floating-point number, modify the data type of the result, or modify your code to convert the operand(s) using the **CShort** function before using the **MOD** operator.

Return statement

In Visual Basic 6.0, the **Return** statement was used to branch back to the code following a **GoSub** statement.

In Visual Basic .NET, the **GoSub** statement is not supported. The **Return** statement is used to return control to a calling procedure from a **Function** or **Sub** procedure.

What to do next

- Remove any lines of code that use **Return** in conjunction with a **GoSub** statement.

SavePicture statement

In Visual Basic 6.0, the **SavePicture** statement was used to save a graphic from the **Picture** or **Image** property of an object to a file. If the format of the graphic for the **Picture** property was either GIF or JPEG, it was saved as a bitmap file (BMP). Graphics for the **Image** property were always saved as bitmaps regardless of their original format.

In Visual Basic .NET, the default behavior of the **Image.Save** method saves the files in different formats than in Visual Basic 6.0. **Image.Save** takes an **ImageFormat** class as an optional parameter that allows you to specify the format to use.

What to do next

- Modify the upgraded code to use the **ImageFormat** method, as in the following example:

```
' Default, will save as a PNG (Portable Network Graphics) file
Picture1.Image.Save("MyPicture.bmp")
' Using the optional parameter, will save as a bitmap
Picture1.Image.Save("MyPicture.bmp", System.Drawing.Imaging.ImageFormat.Bmp)
```

Str function

In Visual Basic 6.0, the **Str** function took a **Long** data type containing any valid numeric expression as an argument; date variables or literals were treated as valid numeric expressions.

In Visual Basic .NET, the **Str** function takes an object containing any valid numeric expression; date variables and literals are no longer treated as valid numeric expressions.

What to do next

- If the **Str** function uses a date variable or date literal as an argument, use the **Format** function instead. For more information, see Format Function.

TypeName function

In Visual Basic 6.0, the **TypeName** function was used to return a string describing the underlying data type of a variable.

The data types returned by the **TypeName** function may have different values in Visual Basic .NET. For example, any **Variant** variables are converted to the **Object** data type, strings are objects in Visual Basic .NET, and controls return a different type (**TreeView** is now **AXTreeView**). For more information, see TypeName Function.

What to do next

- Compare the result of the **TypeName** function with the result in the Visual Basic 6.0 to determine if they are the same, and modify your code if necessary.

TypeOf function

In Visual Basic 6.0, the **TypeOf** function was used in an **If...Then...Else** statement to determine whether an object reference was of a specified object type. In this context, a user-defined type was considered to be an object type.

In Visual Basic .NET, user-defined types (now known as structures) are not object types and cannot be evaluated by the **TypeOf** function.

The following example demonstrates the use of **TypeOf** with a user-defined type:

```
' Visual Basic 6.0
Private Type MyType
   a As Integer
End Type
Private Sub Form_Load()
   Dim m As MyType
   If TypeOf m Is MyType Then
      MsgBox "MyType"
   End If
End Sub

' After upgrade to Visual Basic .NET
Private Structure MyType
   Dim a As Short
End Structure
Private Sub Form_Load(ByVal eventSender As System.Object, ByVal eventArgs As System.EventArgs
) Handles MyBase.Load
   Dim m As MyType
   ' UPGRADE_WARNING: TypeOf has a new behavior.
   If TypeOf m Is MyType Then
      MsgBox "MyType"
   End If
End Sub
```

What to do next

- Modify your code to do a type comparison without the **TypeOf** function:

```
' Modified code
Dim m As MyType
Dim mTest As MyType
If m.GetType Is mTest.GetType Then...
```

VarType function

In Visual Basic 6.0, the **VarType** function was used to return an enumeration representing the underlying data type of a variable declared as a variant.

When a Visual Basic 6.0 project is upgraded to Visual Basic .NET, any **Variant** variables are converted to the **Object** data type. In Visual Basic 6.0, an unassigned variant returned 0 (Empty); in Visual Basic .NET, an unassigned object returns 9 (object).

What to do next

- Determine if the **VarType** function is returning 9 and, if so, modify your code to correctly interpret the new result.

Programming Element Support Changes Summary | Language Changes in Visual Basic

Function is not supported

Some Visual Basic 6.0 functions are no longer supported in Visual Basic .NET. The functionality that these functions provided can be accomplished using new functions in the .NET Framework; however, the differences in implementation make it too difficult to upgrade automatically.

The following functions are not upgraded:

CVErr function

The **CVErr** function in Visual Basic 6.0 returned a Variant of the subtype Error that contained an error number. Variants are no longer supported in Visual Basic .NET, so this function is no longer useful.

Error handling in general has changed significantly in Visual Studio .NET. For more information, see Event Handlers in Visual Basic and Visual C#.

IMEStatus function

The **IMEStatus** function in Visual Basic 6.0 was used to return the status of the Input Method Editor (IME) mode, available only on Chinese, Japanese, and Korean versions of Windows.

In Visual Basic .NET, this functionality is replaced by the **IMEMode** property of most controls and by the **IMEMode** enumeration, both in the System.Windows.Forms namespace. For more information, see Control.DefaultImeMode Property or ImeMode Enumeration.

AscB, ChrB, InstrB, LeftB, LenB, MidB, RightB functions

The **AscB**, **ChrB**, **InstrB**, **LeftB**, **LenB**, **MidB**, and **RightB** functions in Visual Basic 6.0 were string-handling functions that returned their results in bytes. They were used primarily for converting strings for use by double-byte character set languages.

In Visual Basic .NET, encoding and decoding functions in the System.Text namespace replace this functionality. For more information, see Globalizing and Localizing Applications.

VarPtr, ObjPtr, StrPtr, VarPtrArray, and VarPtrStringArray functions

The **VarPtr**, **ObjPtr**, **StrPtr**, **VarPtrArray**, and **VarPtrStringArray** functions in Visual Basic 6.0 were undocumented and unsupported functions that could be used to return a pointer to a memory address. Although unsupported, these functions were sometimes used when working with Windows API calls that would have otherwise been inaccessible from Visual Basic.

These functions are not supported in Visual Studio .NET; however, most of the scenarios where they were used can be addressed through new functionality in the .NET Framework. Many of the Windows API calls that were necessary in Visual Basic 6.0 are now encapsulated in the framework; pointer references are no longer necessary.

What to do next

- Review your code to determine what was being accomplished with this function, search the .NET Framework documentation for suitable replacements, and modify your code as necessary.

See Also

What's New in Visual Basic and Visual C# | Programming with the .NET Framework

Function parameter is not supported in Visual Basic .NET

Some function signatures are different in Visual Basic .NET than they were in Visual Basic 6.0, and some parameters are no longer supported.

In Visual Basic 6.0 the **MsgBox** and **InputBox** functions supported optional arguments to specify a Help topic that would be displayed when the user pressed F1. Because the mechanism for displaying Help topics has changed significantly in Visual Basic .NET, the **HelpFile** and **Context** arguments have been eliminated.

> **Note** Visual Basic .NET does not support calling Help from a message box or input box; you can duplicate this functionality by using a modal form instead and adding a Help button.

In Visual Basic 6.0, the **AppActivate** statements supported an optional **Wait** parameter that specified whether a specified application should be activated immediately, or wait until the calling application has focus. There is no equivalent functionality in Visual Basic .NET; the specified application is always activated immediately.

What to do next

- If Help support is required, replace the message box or input box with a modal form.
- Review your application's run-time behavior to make sure that removing the **Wait** parameter does not cause unexpected behavior. If necessary, modify your code so that **AppActivate** is only called when your application has focus.

Providing Help in a Windows Application

Initialize must be called to initialize instances of this structure

In Visual Basic 6.0, all members of a user-defined type (UDT) were initialized when they were declared inside the **Type** statement block.

In Visual Basic .NET, user-defined types are replaced by structures. Members that require parameterless constructors (such as fixed-length strings, fixed-size arrays, and variables declared with the **New** keyword) require initialization. During upgrade, an Initialize() subroutine is added to the structure. Calls to the Initialize subroutine must be added whenever the structure is declared.

The following code illustrates the upgrade of code that contains a fixed-size array in a user-defined type:

```
' Visual Basic 6.0
Public Type DriveInfo
   DriveNumber(25) As Integer
   DriveType As String
End Type

Function AddDrive(DriveNumber As Integer, DriveLabel As String)
   Dim Drives As DriveInfo
   Drives.DriveNumber(0) = 123
   Drives.DriveType = "Fixed"
End Function

' After upgrade to Visual Basic .NET
Public Structure DriveInfo
   ' Note that the fixed size was removed.
   Dim DriveNumber() As Short
   Dim DriveType As String
   ' UPGRADE_TODO: "Initialize" must be called to initialize instances of this structure.
   Public Sub Initialize()
      ReDim DriveNumber(25)
   End Sub
End Structure

Function AddDrive(ByRef Number As Short, ByRef DriveLabel As String) As Object
   Dim Drives As DriveInfo
   ' This will fail; the array has not been initialized.
   Drives.DriveNumber(0) = 123
   Drives.DriveType = "Fixed"
End Function
```

What to do next

- Find each occurrence in your code where an instance of the user-defined type is declared.
- Add a call to the Initialize() subroutine. In the example above, the **AddDrive** function would look like the following.

```
Function AddDrive(ByRef Number As Short, ByRef DriveLabel As String) As Object
   Dim Drives As DriveInfo
   Drives.Initialize()
   Drives.DriveNumber(0) = 123
   Drives.DriveType = "Fixed"
End Function
```

See Also

Array Size Declaration Changes in Visual Basic

IsMissing function was changed to IsNothing

In previous versions of Visual Basic the **IsMissing** function was used to test for optional arguments passed to user-defined function procedures as variants. Default values were not required for optional arguments; if no value was passed then **IsMissing** returned **true**. It was also possible to specify a default value of a primitive type to pass to the **Variant** argument.

In Visual Basic .NET, the **IsMissing** function has been removed from the language, and default values are now required for all optional arguments. During upgrade, variants are replaced with objects, and an object's default value of **Nothing** is added to all optional arguments.

The following code illustrates the upgrade of code that uses the **IsMissing** function:

```
' Visual Basic 6.0
Function DoThis(Optional X As Variant)
   If IsMissing(X) Then
      ' Do something here.
   End If
End Function

' After upgrade to Visual Basic .NET
Function DoThis(Optional ByRef X As Object = Nothing) As Object
   ' UPGRADE_WARNING: IsMissing function was changed to IsNothing.
   If IsNothing(X) Then
      ' Do something here.
   End If
End Function
```

In most cases this code should execute properly; however, in some cases it may not give the expected result. If X in the above example is an object being passed as a variant and the object has been set to **Nothing**, in Visual Basic 6.0 **IsMissing** would have returned **false**. In Visual Basic .NET, the value of X would be **Nothing** and **IsNothing** would return **true**.

What to do next

- Search for any code that calls this function. Step through the function call and inspect the value of the optional arguments that are being passed.
- If a value is being passed and **IsNothing** returns **true**, modify your code to add an additional test for **IsNothing** in the calling procedure:

```
' Visual Basic 6.0
Dim X As Object
' Do something with the object.
Set X = Nothing
' IsMissing in the DoThis function returns false.
DoThis(X)

' Visual Basic .NET
Dim X As Object
' Do something with the object.
X = Nothing
If Not IsNothing(X) Then
   DoThis(X)
End If
```

See Also

Procedure Declaration Changes in Visual Basic

ItemData property cannot be upgraded

In Visual Basic 6.0 the **ItemData** property for a **ListBox** or **ComboBox** control could be set at design time in the Properties window. In Visual Basic .NET the **ItemData** property no longer exists; list items are of type **Object** rather than **String** and can contain any type of data.

When a Visual Basic 6.0 project is upgraded, any values in the **ItemData** property are discarded.

What to do next

1. In your Visual Basic 6.0 project, check the **List** and **ItemData** properties for the **ListBox** or **ComboBox** controls in the Properties window to see the values that were entered at design time.
2. In the upgraded project, add code to the Sub New() procedure to assign the **ItemData** property at run time using the **SetItemData** function from the Visual Basic Compatibility library.

```
' Visual Basic .NET
' In the original project, values of 123, 456, and 789 were set at     ' design time for
the first three items in a ListBox.
VB6.SetItemData(List1, 0, 123)
VB6.SetItemData(List1, 1, 456)
VB6.SetItemData(List1, 2, 789)
```

See Also

ComboBox Control Changes in Visual Basic .NET | ListBox Control Changes in Visual Basic .NET

Late-bound default property reference could not be resolved

In Visual Basic 6.0, objects had a default property that could be used as a shortcut in code. For example, the default property of a **TextBox** control was the **Text** property; you could type `TextBox1 = "Hello"` instead of `TextBox1.Text = "Hello"`.

In Visual Basic .NET, default properties are no longer supported; all property references must be fully qualified. During upgrade, default properties for early-bound objects are resolved to the property name; however, late-bound objects cannot be resolved because it is impossible to determine a default property without knowing what the object is.

In addition, Visual Basic 6.0 allowed late-bound calls to implemented interfaces of classes; this is no longer allowed in Visual Basic .NET.

The following example shows late-bound code that cannot be resolved:

```
' Visual Basic 6.0
   Dim x As String
   Dim y As Object
   x = "Hello"
   Set y = Form1.Controls(0)
   y = x
   Debug.Print y

' After upgrade to Visual Basic .NET
   Dim x As String
   Dim y As Object
   x = "Hello"
   'UPGRADE_WARNING: VB.Controls method Controls.Item has a new behavior.
   y = Form1.DefInstance.Controls(0)
   ' UPGRADE_WARNING: Couldn't resolve default property of object 'y'.
   y = x
   System.Diagnostics.Debug.WriteLine(y)
```

What to do next

- In many cases, nothing needs to be done. If the warning is given for a primitive type rather than an object, nothing needs to be done.
- If possible, modify your code to use early binding before upgrading to Visual Basic .NET.
- If late binding is necessary, determine the default property for the object and add it to your code. The following example shows how to modify the above code, assuming that `Controls(0)` refers to a **TextBox** control:

  ```
  Dim x As String
  Dim y As Object
  x = "Hello"
  y = Me.Controls(0).Text
  y = x
  Console.WriteLine y
  ```

Preparing a Visual Basic 6.0 Application for Upgrading

LoadResStrings method may need to be replaced

In Visual Basic 6.0, applications created with the **VB Application Wizard** could optionally store string resources in an external resource file. If the **Would you like to use a Resource file for the strings in your application?** option was selected, a function named **LoadResStrings** was created in the .bas module for the project. This function used the Visual Basic 6.0 **LoadResString** function to extract string resources at run time.

In Visual Basic .NET, resources are handled differently than they were in Visual Basic 6.0. The Visual Basic Compatibility library contains a **VB6.LoadResString** function to duplicate Visual Basic 6.0 functionality.

During upgrade, if the **LoadResStrings** function is detected, the code within the function is not upgraded. This is because if the code generated by the wizard was subsequently modified, the upgrade tool cannot determine the correct replacement code. You will need to manually modify the code within this function in order to correctly load the string resources in Visual Basic .NET.

What to do next

- If the code generated by the **VB Application Wizard** was not modified, you can perform a cut-and-paste operation on the following code and place it into your Visual Basic .NET application to replace the **LoadResStrings** function:

```
' Visual Basic .NET
Sub LoadResStrings(ByRef frm As System.Windows.Forms.Form)
   On Error Resume Next
   Dim ctl As System.Windows.Forms.Control
   Dim obj As Object
   Dim fnt As System.Drawing.Font
   Dim sCtlType As String
   Dim nVal As Short

   ' Set the form's caption.
   frm.Text = VB6.LoadResString(CShort(frm.Tag))

   ' Set the font.
   Dim FontName As String, FontSize As Double
   FontName = VB6.LoadResString(20)
   FontSize = CShort(VB6.LoadResString(21))
   frm.Font = New System.Drawing.Font(FontName, FontSize)

   ' Set the controls' captions using the caption
   ' property for menu items and the Tag property
   ' for all other controls.
   For Each ctl In frm.Controls
      ctl.Font = fnt
      sCtlType = TypeName(ctl)
      If sCtlType = "Label" Then
         ctl.Text = VB6.LoadResString(CShort(ctl.Tag))
      ElseIf sCtlType = "AxTabStrip" Then
         For Each obj In CObj(ctl).Tabs
            obj.Caption = VB6.LoadResString(CShort(obj.Tag))
            obj.ToolTipText = VB6.LoadResString(CShort(obj.ToolTipText))
         Next obj
      ElseIf sCtlType = "AxToolbar" Then
         For Each obj In CObj(ctl).Buttons
            obj.ToolTipText = VB6.LoadResString(CShort(obj.ToolTipText))
         Next obj
      ElseIf sCtlType = "AxListView" Then
         For Each obj In CObj(ctl).ColumnHeaders
            obj.Text = VB6.LoadResString(CShort(obj.Tag))
         Next obj
      Else
         nVal = 0
```

```
            nVal = Val(ctl.Tag)
            If nVal > 0 Then ctl.Text = VB6.LoadResString(nVal)
            nVal = 0
            nVal = Val(CObj(frm).ToolTip1.GetToolTip(ctl))
            If nVal > 0 Then
               CObj(frm).ToolTip1.SetToolTip(ctl, VB6.LoadResString(nVal))
            End If
         End If
      Next ctl

      Dim mnu As System.Windows.Forms.MainMenu = CObj(frm).MainMenu1
      If Not mnu Is Nothing Then
         LoadMenuResStrings(mnu)
      End If
   End Sub

   Public Sub LoadMenuResStrings(ByVal mnu As System.Windows.Forms.Menu)
      Dim mnuItem As System.Windows.Forms.MenuItem
      For Each mnuItem In mnu.MenuItems
         On Error Resume Next
         mnuItem.Text = VB6.LoadResString(CInt(mnuItem.Text))
         On Error Goto 0
         If mnuItem.MenuItems.Count > 0 Then
            LoadMenuResStrings(mnuItem)
         End If
      Next
   End Sub
```

- If the code generated by the **VB Application Wizard** was modified, modify the above code to accommodate the changes, then perform a cut-and-paste operation on the code and place it into your Visual Basic .NET application to replace the **LoadResStrings** function. You can use the functions in the above code as an example of how to modify your own code.

See Also

Visual Basic 6.0 Compatibility Library

Lower bound of array was changed to 0

Previous versions of Visual Basic allowed you to set the lower bounds of an array to 1 using the **Option Base** statement, or to any valid number using the syntax MyArray(*lowerbounds* to *upperbounds*) where *upperbounds* and *lowerbounds* are numbers. Arrays in Visual Basic .NET are required to have lower bounds of 0.

During upgrade, the lower bounds of all arrays are changed to 0, as in the following example:

```
' Visual Basic 6.0
Dim x(1 To 10) As Integer
Dim z() As Integer
ReDim z(5 To 15) As Integer

' After upgrade to Visual Basic .NET
' UPGRADE_WARNING: Lower bound of array x was changed from 1 to 0.
Dim x(10) As Short
Dim z() As Short
' UPGRADE_WARNING: Lower bound of array z was changed from 5 to 0.
ReDim z(15)
```

What to do next

Review your code to see where and how the array is being used.

- If the original array had a lower bound greater than 0, the elements of the array remain the same:

```
' Visual Basic 6.0
Dim x(1 To 10) As Integer
' Assign a value to the first element.
x(1) = 100

' After upgrade to Visual Basic .NET
' UPGRADE_WARNING: Lower bound of array x was changed from 1 to 0.
Dim x(10) As Integer
' Assign a value to the first element (now the second element).
x(1) = 100
```

- If any code relies on the size of the array (for example, passing the array to an API function, writing to a file, or assigning to another array), it will be incorrect since the size of the array has changed:

```
' Visual Basic 6.0
Dim x(10 To 15) As Integer
Dim y As Integer
y = UBound(x) - LBound(x)
' Returns 4.
Debug.Print y

' After upgrade to Visual Basic .NET
' UPGRADE_WARNING: Lower bound of array x was changed from 10 to 0.
Dim x(15) As Short
Dim y As Short
y = UBound(x) - LBound(x)
' Returns 15.
System.Diagnostics.Debug.WriteLine(y)
```

See Also

Array Bound Changes in Visual Basic | Array Size Declaration Changes in Visual Basic

LSet may not be used to assign a UDT from one type to another

In Visual Basic 6.0, the **LSet** statement could optionally be used to copy a variable of one user-defined type into a variable of another user-defined type. The primary use for the **LSet** statement was to left align a string within a string variable; the use of **LSet** to copy user-defined types was not recommended.

Visual Basic .NET does not allow the use of **LSet** to assign one user-defined type (now structure) to another. When a Visual Basic 6.0 application is upgraded, code that uses **LSet** for assignment will be flagged as an upgrade issue.

The **LSet** method in Visual Basic .NET can still be used to left align strings; the new **PadLeft** method provides additional capabilities and may be a more suitable replacement.

The following code illustrates the use of the **LSet** statement:

```
' Visual Basic 6.0
Private Type typTypeA
   x As Integer
End Type
Private Type typTypeB
   x As Integer
End Type

Sub AssignType()
   Dim aType As typTypeA
   Dim bType As typTypeB
   LSet aType = bType
End Sub

Sub StringAlign()
   Dim strString1 As String
   Dim strString2 As String
   LSet strString1 = strString2
End Sub

' After upgrade to Visual Basic .NET
Private Structure typTypeA
   Dim x As Short
End Type
Private Structure typTypeB
   Dim x As Short
End Type

Sub AssignType()
   Dim aType As typTypeA
   Dim bType As typTypeB
   ' UPGRADE_ISSUE: LSet cannot assign one type to another.
   aType = LSet(bType)
End Sub

Sub StringAlign()
   Dim strString1 As String
   Dim strString2 As String
   ' The statement is replaced by a method.
   strString1 = LSet( strString2, Len(strString1) )
End Sub
```

What to do next

- Review your code to determine if the user-defined types contain the exact same types. Visual Basic 6.0 sometimes used type coercion to automatically convert a variable of one type to another; in Visual Basic .NET, type mismatches will cause a compilation error.
- If the user-defined types are an exact match, you can modify the above code as follows:

```
Private Structure typTypeA
   Dim x As Integer
```

```
End Type
Private Structure typTypeB
   Dim x As Integer
End Type

Sub AssignType()
   Dim aType As typTypeA
   Dim bType As typTypeB
   AType.x = bType.x
End Sub
```

For structures that contain multiple elements, you will need to assign each element individually.

String.PadLeft Method

MDI form Show behavior has changed

In Visual Basic 6.0 the **AutoShowChildren** property of an MDI form was used to automatically show an MDI child form when it was loaded. Standard forms did not have this behavior; calling the **Load** method did not show the form.

In Visual Basic .NET, the **AutoShowChildren** property no longer exists. To emulate the Visual Basic 6.0 behavior, a line of code is added during upgrade to show each child form if **AutoShowChildren** was set to **true** in the original application.

What to do next

- If you do not want to show the child form when the MDI form is loaded, remove the line of code containing the **Show** method.

See Also

MDIForm Object Changes in Visual Basic .NET | MDI Changes in Visual Basic .NET

MTS or COM+ objects were not upgraded

The project that you are attempting to upgrade has a reference to the COM+ Services Type Library (Comsvcs.dll) that cannot be upgraded. In Visual Basic 6.0, this library was used to access Microsoft Transaction Services (MTS). In Visual Basic .NET, MTS is replaced by transaction processing functionality in the .NET Framework.

What to do next

- Because of differences in the transaction processing models, existing code will need to be deleted and replaced by code that uses .NET transaction processing.

See Also

Processing Transactions

NewEnum property was commented out

In Visual Basic 6.0, collection classes created using the Class Builder add-in included a **NewEnum** property that allowed you to enumerate the collection using **For...Each** syntax.

Collections in Visual Basic .NET support enumeration through the **System.Collections.IEnumerator** class; the **NewEnum** property is no longer needed.

What to do next

- Remove the code for the **NewEnum** property that was commented out.
- Review the code that was added by the upgrade tool.

See Also

Uncomment and change the following line to return the collection enumerator | System.Collections Namespace

NewIndex property cannot be upgraded

In Visual Basic 6.0 the **NewIndex** property was used to retrieve the index of the item most recently added to a **ListBox** or **ComboBox** control. During upgrade, the value of **NewIndex** cannot be determined in some cases. The return value from the **Items.Add** method can be used instead of **NewIndex**.

What to do next

- Review the usage of the **NewIndex** property and modify your code as in the following example.

```
' Visual Basic 6.0
List1.AddItem "Hello"
List1.ListIndex = List1.NewIndex
```

```
' After upgrade to Visual Basic .NET
List1.Items.Add("Hello")
' UPGRADE_ISSUE: ListBox property Form1.List1.NewIndex was not upgraded.
List1.SelectedIndex = List1.NewIndex    ' Causes a compilation error.
```

The Visual Basic .NET code should then be modified as follows:

```
Dim x As Integer
x = List1.Items.Add("Hello")
List1.SelectedIndex = x
```

See Also

ComboBox Control Changes in Visual Basic .NET | ListBox Control Changes in Visual Basic .NET

Object could not be resolved because it was within a generic namespace

In Visual Basic 6.0 you could use the **ActiveForm** property of a **Forms** collection to refer to controls on the currently selected form; controls were actually treated as properties of the form. In Visual Basic .NET, **ActiveForm** is a generic type that has no controls. For example, the following code works in Visual Basic 6.0 but cannot compile after being upgraded to Visual Basic .NET:

```
' Visual Basic 6.0
MDIForm1.ActiveForm!Label1.Caption = "Active"

' After upgrade to Visual Basic .NET
' Causes a compilation error.
MDIForm1.DefInstance.ActiveMDIChild.Label1.Caption = "Active"
```

What to do next

- Modify your code to refer to the underlying form object:

```
' Modified Visual Basic .NET code
CType(MDIForm1.DefInstance.ActiveMDIChild, Form1).Label1.Text = "Active"
```

> **Note** Using the **CType** function makes this late bound. The original code in this example is problematic because it assumes that the **ActiveForm** property will always have a label named Label1 — if Label1 does not exist, a run-time error will occur.

Things to Consider Before Upgrading

Object was upgraded to a panel, and cannot be coerced to a PictureBox

When an application is upgraded from Visual Basic 6.0, if a **PictureBox** control is used as a container (that is, it contains child controls), it is upgraded to **Panel** control; otherwise, it is upgraded to a **PictureBox** control.

If a **PictureBox** control that has been upgraded to a **Panel** control is assigned to a variable of type **PictureBox**, the assignment will fail.

If a **PictureBox** control that was upgraded to a **Panel** control is passed as a parameter to a function, a run-time error will occur because the parameter is expecting a **PictureBox** control.

The following example shows code that would cause these errors:

```
' Visual Basic 6.0
Function PictureOrPanel()
   Dim p As PictureBox
   ' Not used as a container.
   Set p = Me.PictureBoxWithoutControls
   MyFunction Me.PictureBoxWithoutControls
   ' Used as a container.
   Set p = Me.PictureBoxWithControls
   MyFunction Me.PictureBoxWithControls
End Function

Function MyFunction( p As PictureBox )
   ' Do something here.
End Function

' After upgrade to Visual Basic .NET
Function PictureOrPanel() As Object
   Dim p As System.Windows.Forms.PictureBox
   ' Not used as a container.
   Set p = Me.PictureBoxWithoutControls
   MyFunction Me.PictureBoxWithoutControls
   ' Used as a container.
   ' UPGRADE_ISSUE: Form1.PictureBoxWithControls was upgraded to a Panel and cannot be coerce
d to a PictureBox.
   Set p = Me.PictureBoxWithControls
   ' UPGRADE_ISSUE: Form1.PictureBoxWithControls was upgraded to a Panel and cannot be coerce
d to a PictureBox.
   MyFunction Me.PictureBoxWithControls
End Function

Function MyFunction( p As PictureBox )
   ' Do something here.
End Function
```

What to do next

- If the **Panel** control is being assigned to a variable of type **PictureBox**, create a new variable of type **Panel** and assign to that. If the **Panel** control is being passed as a parameter to a function, create a second version of the function with a parameter of type **Panel**.

```
Function PictureOrPanel() As Object
   Dim p As System.Windows.Forms.PictureBox
   Dim q As System.Windows.Forms.Panel
   ' Not used as a container.
   Set p = Me.PictureBoxWithoutControls
   MyFunction Me.PictureBoxWithoutControls
   ' Used as a container.
   Set q = Me.PictureBoxWithControls
   MyFunction2 Me.PictureBoxWithControls
```

```
End Function

Function MyFunction( p As PictureBox )
   ' Do something here.
End Function

Function MyFunction2( p As Panel )
   ' Do something here.
End Function
```

Objects of type vbDataObject are not supported

In Visual Basic 6.0, objects created in C++ that did not support the IDispatch interface were treated as a **Variant** with a type of 13 (vbDataObject). In Visual Basic .NET, objects that do not support IDispatch are no longer allowed.

During upgrade, any reference in code to `VarType() = vbDataObject` or `VarType() = 13` will be flagged with a warning.

What to do next

- Remove the line of code, or modify it to use a different object.
- If you have access to the source code for the object, modify it to support IDispatch.

See Also

Preparing a Visual Basic 6.0 Application for Upgrading

Only OpenType and TrueType fonts are supported

Visual Basic 6.0 supported standard fonts for backward compatibility; Visual Basic .NET supports only TrueType and OpenType fonts. The font for this control or form has been changed to the default OpenType font Microsoft Sans Serif, and any formatting such as bold or italic has not been preserved.

What to do next

- Review the appearance of the font on your form or control.
  - If you are happy with it, do nothing.
  - If you are not happy with the selected font, change the font by selecting the **Font** property in the Properties window or by setting it in code.

    Note If the Visual Basic 6.0 application used formatting such as bold or italic, it may be easier to change the font in the original application to a TrueType or OpenType font, and then run the upgrade tool again.

See Also

Font Changes in Visual Basic .NET

ParamArray parameter has been changed from ByRef to ByVal

In Visual Basic, the **ParamArray** keyword could be used to specify an arbitrary number of parameters for a declaration, sub, or function. ParamArrays were always passed by reference (**ByRef**). In Visual Basic .NET, ParamArrays are always passed by value; the **ParamArray** keyword must be preceded by the **ByVal** keyword.

When a parameter is passed by value, a copy of the variable is passed; when passed by reference, a pointer to the variable is passed. When passing by value, it is possible that the value of the variable may have changed and that the copy is out of date.

During upgrade, **ParamArray** parameters are modified as follows:

```
' Visual Basic 6.0
Sub HasParameters(ParamArray X())

' After upgrade to Visual Basic .NET
' UPGRADE_WARNING: ParamArray X was changed from ByRef to ByVal.
Sub HasParameters(ParamArray ByVal X() As Object)
```

What to do next

- Review your code to make sure that the variables being passed as parameters are not being changed between the time that they are set and the time that they are used in a procedure. If necessary, modify your code so that the procedure executes before the variables are modified.

See Also

7.1.5.4 Paramarray Parameters

Picture will be tiled

When a Visual Basic 6.0 **PictureBox** control is used as a control container, it is upgraded to a Visual Basic .NET **Panel** control rather than a **PictureBox** control, because the Visual Basic .NET **PictureBox** control cannot be used as a container.

In Visual Basic 6.0, an image specified by the **Picture** property would be displayed in the upper left corner of the **PictureBox** control; the **AutoSize** property determined whether the picture box would be resized to match the dimensions of the image. The Visual Basic .NET **Panel** control does not have an **AutoSize** property, so any image assigned to the **BackgroundImage** property will be tiled and the panel will not be automatically resized.

What to do next

- Run the upgraded application and observe the behavior. If you are happy with the behavior, do nothing.
- If the intended behavior was to resize the picture box to match the size of the image, resize the panel at design time.
- If it is necessary to resize the panel when a new image is assigned at run time, add code similar to the following to the event handler that assigns the new image.

```
' Visual Basic .NET
Picture1.BackgroundImage = _ System.Drawing.Image.FromFile("C:\SomePicture.bmp")
Picture1.Height = Picture1.BackgroundImage.Height
Picture1.Width = Picture1.BackgroundImage.Width
```

PictureBox Control Changes in Visual Basic .NET

Project item has an invalid format

The referenced file is a Visual Basic 5.0 (or earlier) file. The upgrading tools in Visual Basic .NET do not support upgrading Visual Basic 5.0 files. While it is possible to upgrade a Visual Basic 5.0 file, doing so could cause unpredictable results in Visual Basic .NET.

What to do next

- Upgrade the referenced file to Visual basic 6.0 by opening and saving the file in Visual Basic 6.0, and then upgrade the project to Visual Basic .NET.

See Also

Preparing a Visual Basic 6.0 Application for Upgrading

Project item is not a Visual Basic 6.0 file

The referenced item does not match any known Visual Basic 6.0 file format and cannot be upgraded. It may not be a Visual Basic 6.0 file, it may be from an older version of Visual Basic, or it may have the wrong file extension (for example, a .bas module with an .frm extension).

What to do next

Make sure that the project can be successfully compiled and run using Visual Basic 6.0 on the upgrade computer.

See Also

Preparing a Visual Basic 6.0 Application for Upgrading | Working with Both Visual Basic 6.0 and Visual Basic .NET

Project item was not upgraded

An item in the Visual Basic 6.0 project could not be upgraded because it is of a type not supported by Visual Basic .NET. The item was copied into the new project directory; however, it cannot be opened in Visual Studio .NET.

What to do next

Review the help topic Things to Consider Before Upgrading, which contains a list of unsupported features.

- In some cases unsupported features can be used in Visual Basic .NET after some modification in Visual Basic 6.0.
- In most cases you should be able to duplicate the functionality of the project item using the new features of Visual Basic .NET.
- If the referenced item is critical to the project and cannot easily be duplicated, you may need to reconsider your upgrade decision.

Property, Method, or Event was upgraded to a different name and has a new behavior

Some Visual Basic 6.0 properties, methods, and events are upgraded to Visual Basic .NET equivalents that have different names and can have subtle differences in behavior. For example, in Visual Basic 6.0 the **Change** event for a **ComboBox** control was only raised when the text was changed in the text entry portion of the control; in Visual Basic .NET the **TextChanged** event will also be raised when an item is selected in the list portion of the control.

What to do next

Select an object or control from the list below to see a topic listing changes and issues for that object.

Control Changes in Visual Basic .NET

Property or statement is not supported

In Visual Basic 6.0, the **Calendar** property was a stand-alone property that determined the calendar (Gregorian or Hijri) to be used for date-related functions. In Visual Basic .NET, this property is no longer supported; the **Calendar** class in the System.Globalization namespace that supports several additional calendar types replaces it.

In Visual Basic 6.0, the **Load** statement could be used to load a form without displaying it. A form could also be loaded without displaying it by referencing any of its properties.

The **Load** statement is no longer supported in Visual Basic .NET. When an instance of a form is created using the **New** keyword, it is loaded but not displayed until the **Show** method is called.

The following code shows the usage of the **Load** statement:

```
' Visual Basic 6.0
Load Form2
Form2.Caption = "Hello"
MsgBox Form2.Caption

' After upgrade to Visual Basic .NET
'UPGRADE_ISSUE: Load statement is not supported.
Load(Form2)
Form2.DefInstance.Text = "Hello"
MsgBox (Form2.DefInstance.Text)
```

What to do next

- Remove the line of code that sets the **Calendar** property and add a reference to one of the following classes:

```
' If the Calendar property was 0 or vbCalGreg.
Public Class GregorianCalendar
   Inherits Calendar
' If the Calendar property was 1 or vbCalHijri.
Public Class Hijri Calendar
   Inherits Calendar
```

- Remove the line of code that contains the **Load** statement.
- If you need to load the form without showing it, use the **New** keyword, as in the following example:

```
' Modified code
Dim Form2 As New Form2
Form2.Text = "Hello"
MsgBox (Form2.Text)
```

See Also

Calendar Class | Programming Element Support Changes Summary

ScaleMode is not supported

In Visual Basic 6.0, the **ScaleMode** property could be used to change the coordinate system for a form or **PictureBox** control from the default scale of twips.

Visual Basic .NET does not support multiple coordinate systems; only pixels are supported. During upgrade, coordinates are automatically converted from twips to pixels; code that sets the **ScaleMode** property at run time will cause a compilation error and must be modified.

> **Note** The upgrade tool assumes that the design-time setting for the **ScaleMode** property was twips; if this is not the case, the conversion will be incorrect and must be fixed.

What to do next

1. Remove the line of code that sets the **ScaleMode** property.
2. Review any code that was based on the **ScaleMode** property and modify any calculations as necessary. For example, the following code shows how to modify a procedure that used a **ScaleMode** of inches.

```
' Visual Basic 6.0
Form1.ScaleMode = vbInches
Text1.Move 2, 1
```

The above procedure moves the text box 2 inches right and 1 inch down from the upper left corner of the form.

```
' After upgrade to Visual Basic .NET
'UPGRADE ISSUE: Constant vbInches was not upgraded.
'UPGRADE ISSUE: Form property Form1.ScaleMode is not supported.
' The next line must be removed in order to compile.
Form1.ScaleMode = vbInches
' Twips are converted to pixels, but the original inch values are used.
Text1.SetBounds(VB6.TwipsToPixelsX(2), VB6.TwipsToPixelsX(1),...
```

After upgrade, the procedure moves the text box right by 2 pixels and down by 1 pixel — not the desired result.

```
' Modified Visual Basic .NET code
' Removed the ScaleMode line.
' Convert the scale (1 inch = 1440 twips).
Text1.SetBounds(VB6.TwipsToPixelsX(2880), VB6.TwipsToPixelsX(1440),...
```

By multiplying the inches by 1440, the twips to pixel conversion now gives the same result as in the original Visual Basic 6.0 code.

See Also

Form Object Changes in Visual Basic .NET

Setting an object variable to Nothing does not destroy the object

In Visual Basic 6.0, setting an object to **Nothing** immediately destroyed the object. In Visual Basic .NET, setting an object to **Nothing** marks the object for garbage collection, but the object is not immediately destroyed. This could cause problems if other portions of your code depend on the object being destroyed.

For example, if an object is set to **Nothing** inside a procedure and the next line of code creates an object of the same name, the first object may not yet be destroyed and a reference to the new object might incorrectly return the first object.

What to do next

- Review your code and search for additional references to this object.
- If necessary, call the **Dispose** method to destroy the object immediately:

```
' Visual Basic .NET
Dim x As New Button
x.Text = "Goodbye"
x.Dispose()
```

See Also

Lifetime

Some run-time code needs to be commented out to give the same effect as VB6

In Visual Basic 6.0 it was possible to write code that had no effect at run time, but that did not cause a compilation error. For example, the following code attempts to set the read-only **BorderStyle** property for a form at run time.

```
' Visual Basic 6.0
Form1.Borderstyle = 2
Debug.Print Form1.Borderstyle
```

This gave the result of 2, indicating that the **BorderStyle** had been changed, when in fact it had not — the **BorderStyle** was still the default (1).

When this code is upgraded to Visual Basic .NET it may cause unexpected results, since the **BorderStyle** constants are different. In other cases, code that did nothing in Visual Basic 6.0 may cause compilation errors in Visual Basic .NET.

What to do next

- If you want your application to behave as it did in Visual Basic 6.0, comment out (or delete) the line of code.
- If you intended for the line of code to be executed, modify the code. In the above example, if your intent was to actually make the border sizable, modify the code as follows:

  ```
  ' Visual Basic .NET
  Me.Borderstyle = Windows.Forms.FormBorderStyle.Sizable
  System.Diagnostics.Debug.WriteLine(Me.Borderstyle)
  ```

See Also

Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

Statement is no longer supported

In Visual Basic .NET, the **GoSub...Return** and **On...GoSub** statements are no longer supported. These statements were supported in Visual Basic 6.0 for compatibility with earlier versions of the Basic language; they are not compatible with object-oriented programming practices.

What to do next

- Replace **GoSub** statements with **Call**, **Function**, or **Sub** statements. The **Return** keyword is no longer needed.
- Replace **On...GoSub** statements with **Select Case** statements, as shown in the following example:

```
' Visual Basic 6.0
On x GoSub 1000, 2000
1000:
   MyString = "Hello"
2000:
   MyString = "Goodbye"

' Visual Basic .NET
Select Case x
   Case 1000
      MyString = "Hello"
   Case 2000
      MyString = "Goodbye"
End Select
```

See Also

Control Statement Changes in Visual Basic

Structure may require marshalling attributes to be passed as an argument in this Declare statement

In Visual Basic 6.0, user-defined types could be passed as an argument in a **Declare** statement for a Windows API.

In Visual Basic .NET, a structure (user-defined type) passed as an argument in a **Declare** statement may require additional marshalling attributes in order to be passed correctly to the external function or subroutine. In particular, arrays and fixed-length strings may not function as expected without these attributes.

The following example shows a structure before and after upgrade:

```
' Visual Basic 6.0 code
Type MyType
   s As String * 100
End Type

' After upgrade to Visual Basic .NET
Structure MyType
   <VBFixedString(100), System.Runtime.InteropServices.MarshalAs(System.Runtime.InteropServic
es.UnmanagedType.ByValTStr, SizeConst:=100)> Public s As String
End Structure
```

What to do next

- Add an **Imports** statement to reference the **InteropServices** namespace:

  ```
  Imports System.Runtime.InteropServices
  ```

- Modify the structure and the string declaration to include marshalling attributes, as in the following example:

  ```
  ' Modified code
  <StructLayout( LayoutKind.Sequential, CharSet:=CharSet.ANSI)>Structure MyType
     <MarshalAs(UnmanagedType.ByValTStr, SizeConst:=100)> Public s As String
  End Structure
  ```

See Also

Applying Attributes | Passing Structures

Sub Main will not be called at component startup

In Visual Basic 6.0, any code in a **Sub_Main** procedure for a .dll or .ocx file would be run automatically on startup. In Visual Basic .NET, **Sub_Main** cannot be set as a startup object; any code in the **Sub_Main** procedure will not be run on startup.

What to do next

- Add code to the constructor (**Sub New**) to call the **Sub_Main** procedure whenever an instance of the object is created:

```
Public Sub New()
   Main()
End Sub
```

- Alternatively, move the code from the **Sub_Main** procedure to the **Sub_New** procedure.

See Also

What's New in Components and Component Authoring

The referenced component is missing a design-time license

The application that you are upgrading contains the referenced component, which requires a design-time license. The license file is missing, or may have been moved to a different location.

Some ActiveX controls or components require a license in order to be used in Visual Basic. At design time, when you add the control to a form, a check is made for a license file on the development computer; if not found, the control cannot be used.

> **Tip** You should always test your application in Visual Basic 6.0 on the development computer before upgrading. If it runs in Visual Basic 6.0, this upgrade error will not occur.

To correct this error

- Determine if the referenced component is actually required for your application; if not, you can remove the control and ignore this warning.
- If the component is required, you will need to install the license file on your development computer. The license file is usually installed into the same directory as the component.

> **Note** You may need to check the documentation for the component to determine how to install the license file. Licensing terms for some components restrict installation to a single computer.

See Also

Control Changes in Visual Basic .NET | UserControl Changes in Visual Basic .NET

The referenced project is either not compiled or out-of-date

The project that you are attempting to upgrade has a reference to an ActiveX EXE or ActiveX DLL project. The output of that project must be loaded in order for the upgrade to proceed. Either the referenced project has not been compiled, or the compiled output is missing.

What to do next

- Compile the referenced project in Visual Basic 6.0 by choosing **Make *Projectname*** from the **File** menu.

See Also

Preparing a Visual Basic 6.0 Application for Upgrading

There may be differences in data-binding behavior

When Visual Basic 6.0 applications that use data binding are upgraded to Visual Basic .NET, there are a few behavioral differences that you need to be aware of.

Dispose behavior for BindingCollection object has changed

When using a **BindingCollection** object in a Visual Basic 6.0 project, it was not necessary to set the object to **Nothing**; it would automatically be disposed when the form was closed.

In Visual Basic .NET, the BindingCollection Class must be explicitly disposed in the Form.Closing Event event of the form.

What to do next

- Add the following code to the **Closing** event of the form where the **BindingCollection** object was declared. This example assumes a form named MyDataForm and a **BindingCollection** named ADOBind.

```
' Visual Basic .NET
Private Sub MyDataForm_Closing(ByVal sender as Object, ByVal e As System.ComponentModel.C
ancelEventArgs) Handles MyBase.Closing
   ADOBind.Clear()
   ADOBind.Dispose()
   ADOBind = Nothing
End Sub
```

Data-bound properties cannot be bound to Null values

In Visual Basic 6.0, properties of a control could be bound to a database field using the **BindingCollection** object; if the database value was **Null**, the type was automatically coerced to the type of the property.

In Visual Basic .NET, only properties that are of the **String** data type can be bound to a database value that is **Null**; due to strict typing, binding any other data type will cause a InvalidCastException error.

What to do next

- Determine the data type for each property bound to a database field, and either remove the binding for any property whose data type is not **String**, or modify the database so that it does not allow **Null** values.

See Also

Data Changes in Visual Basic .NET

Timer Interval property behavior has changed

In Visual Basic 6.0 you could disable a **Timer** control by setting the **Interval** property to 0. In Visual Basic .NET, the lower range for the **Interval** property is 1. If you set the interval to 0, it will throw a run-time exception. The Visual Basic .NET Timer component uses the **Enabled** property to allow you to disable or enable it.

The following code illustrates the changes to the **Timer** control.

```
' Visual Basic 6.0
Public Function TimerOn(Interval As Integer)
   If Interval > 0 Then
      Timer1.Interval = Interval   ' Enables the timer.
   Else
      Timer1.Interval = 0         ' Disables the timer.
   End If
End Function
```

```
' After upgrade to Visual Basic .NET
Public Function TimerOn(ByRef Interval As Short) As Object
   If Interval > 0 Then
      ' UPGRADE_WARNING: Timer Property Form1.Timer1.Interval has a new
      ' behavior.
      Timer1.Interval = Interval   ' Enables the timer.
   Else
      ' UPGRADE_WARNING: Timer property Timer1.Interval cannot have
      ' a value of 0.
      Timer1.Interval = 0         ' Disables the timer.
   End If
End Function
```

What to do next

- Find any code that sets the **Interval** property to 0.
- Replace it with code that sets the **Enabled** property to **false**.
- Find any code that sets the **Interval** property to a value greater than 0.
- Add a line of code to set the **Enabled** property to **true**.

> **Note** The **Enabled** property only needs to be set the first time the interval is set. The **Timer** will remain enabled until it is explicitly disabled by setting the **Enabled** property to **false**.

```
' Modified Visual Basic .NET code
Public Function TimerOn(ByRef Interval As Short) As Object
   If Interval > 0 Then
      Timer1.Enabled = True      ' Enables the timer.
   Else
      Timer1.Enabled = False      ' Disables the timer.
   End If
End Function
```

See Also

Timer Control Changes in Visual Basic .NET

Unable to determine which equivalent constant is appropriate for this context

In some cases, constants or enumerations for Visual Basic 6.0 are not upgraded because there are two or more Visual Basic .NET equivalents. For example, the Visual Basic 6.0 constant **vbRightJustify** could be mapped to **System.Windows.Forms.HorizontalAlignment.Right**, **System.Drawing.ContentAlignment.TopRight**, or **System.Drawing.ContentAlignment.MiddleRight** in Visual Basic .NET, depending on the type of control. In cases where the type of control is not known, the constant cannot be mapped.

```
' Visual Basic 6.0
Dim x As Control
Set x = Text1
x.Alignment = vbRightJustify
```

```
' After upgrade to Visual Basic .NET
Dim x As Object
x = Text1
' UPGRADE_ISSUE: Unable to determine which constant to upgrade
' vbRightJustify to.
x.Alignment = vbRightJustify
```

What to do next

- Determine which Visual Basic .NET constant or enumeration is appropriate for the given context and modify the code. You can use the Intellisense feature of the code editor to get a list of available enumerations.

  ```
  ' Modified Visual Basic .NET code
  Dim x As Object
  x = Text1
  x.TextAlign = System.Windows.Forms.HorizontalAlignment.Right
  ```

See Also

Constant Changes in Visual Basic .NET

Uncomment and change the following line to return the collection enumerator

In Visual Basic 6.0, collection classes created using the Class Builder add-in included a **NewEnum** property that allowed you to enumerate the collection using **For...Each** syntax. It was also possible to create your own collection classes and add your own enumerator property.

Collections in Visual Basic .NET support enumeration through the **System.Collections.IEnumerator** class; the **GetEnumerator** function was added to your code to replace the **NewEnum** property.

What to do next

- For collections created using the Class Builder, mCol is the default name for the collection class. If you changed the default name, or if this is a collection that you created on your own, you will need to replace mCol with the name of your collection class:

```
GetEnumerator = MyCollection.GetEnumerator
```

- If you used the default name (mCol), uncomment the line containing the GetEnumerator assignment:

```
GetEnumerator = mCol.GetEnumerator
```

See Also

NewEnum property was commented out | System.Collections Namespace

Unload method cannot be upgraded

In cases where an object is late bound, the **Unload** method cannot be upgraded. For example, the following Visual Basic 6.0 code will cause a compilation error after upgrading to Visual Basic .NET.

```
' Visual Basic 6.0
Dim o As Object
Private Sub Command1_Click()
    Set o = New Form1
    o.Show
End Sub

Private Sub Command2_Click()
    Unload o
End Sub
```

```
' After upgrade to Visual Basic .NET
Dim o As Object
Private Sub Command1_Click(ByVal EventSender As System.Object, ByVal EventArgs As System.Even
tArgs) Handles Command1.Click
    o = New Form1
    o.Show()
End Sub

Private Sub Command2_Click(ByVal EventSender As System.Object, ByVal EventArgs As System.Even
tArgs) Handles Command2.Click
    ' UPGRADE_ISSUE: Unload o was not upgraded.
    Unload o
End Sub
```

What to do next

- Modify the code to be early bound to Form1 instead of Object, and call the **Close** method instead of **Unload**.

```
' Modified Visual Basic .NET code
Dim o As Form1
Private Sub Command1_Click(ByVal EventSender As System.Object, ByVal EventArgs As System.
EventArgs) Handles Command1.Click
    o = New Form1
    o.Show()
End Sub

Private Sub Command2_Click(ByVal EventSender As System.Object, ByVal EventArgs As System.
EventArgs) Handles Command2.Click
    o.Close()
End Sub
```

Form Object Changes in Visual Basic .NET | Control Changes in Visual Basic .NET

Value for a property could not be resolved

During upgrade, some Visual Basic 6.0 properties are mapped to Visual Basic .NET properties with different values. In these cases, properties that are resolved at run time by evaluating a variable or function return cannot be resolved by the upgrade tool.

For example, the **AutoSize** property of a **PictureBox** control is upgraded to the **SizeMode** property of the Windows Forms **PictureBox** control. If the property was set to **true** or **false** (or their numeric equivalents) in the original code, it will be mapped to **System.Windows.Forms.PictureBoxSizeMode.AutoSize** (for **true**) or **System.Windows.Forms.PictureBoxSizeMode.Normal** (for **false**). If the property was set to the value of a variable or function return, the value is not known and cannot be properly upgraded.

```
' Visual Basic 6.0
Dim x As Boolean
x = False
Picture1.AutoSize = True
Picture2.AutoSize = False
Picture3.AutoSize = x
' MyAutoSize is a function that returns either True or False.
Picture4.AutoSize = MyAutoSize ()

' After upgrade to Visual Basic .NET
Dim x As Boolean
x = False
Picture1.SizeMode = System.Windows.Forms.PictureBoxSizeMode.AutoSize
Picture2.SizeMode = System.Windows.Forms.PictureBoxSizeMode.Normal
' x cannot be resolved.
Picture3.SizeMode = x
' MyAutoSize () cannot be resolved.
Picture4.SizeMode = MyAutoSize ()
```

What to do next

- If the property value was stored in a variable, change the value (and type if necessary) of the variable where it is set.

```
' Modified VisualBasic .NET code
Dim x As String
x = " System.Windows.Forms.PictureBoxSizeMode.Normal"
Picture3.SizeMode = x
```

  Note Before modifying the variable, search your code to make sure it is not referenced elsewhere. If the variable is shared, you may need to create a new variable rather than modifying the existing variable.

- If the property value was the return value of a function, modify the function to return the correct value.

```
' Visual Basic 6.0
Public Function MyAutoSize () As Boolean
    MyAutoSize = True
End Function

' Modified Visual Basic .NET code
Public Function MyAutoSize () As System.Windows.Forms.PictureBoxSizeMode
   MyAutoSize = System.Windows.Forms.PictureBoxSizeMode.AutoSize
End Function
```

Control Changes in Visual Basic .NET

Variables must be explicitly declared

In Visual Basic 6.0, it was possible to declare a group of variables in a single **Dim** statement. A common usage was to declare a series of letters as integer values: `DefInt A-Z`.

In Visual Basic .NET, each variable must be individually declared; the **DefBool**, **DefByte**, **DefInt**, **DefLng**, **DefCur**, **DefSng**, **DefDbl**, **DefDec**, **DefDate**, **DefStr**, **DefObj**, and **DefVar** statements are no longer supported.

During upgrade, any variables declared using these statements are explicitly declared as the correct type as shown in the following example:

```
' Visual Basic 6.0
DefInt A-C

' After upgrade to Visual Basic .NET
' UPGRADE_NOTE: DefInt A-C statement was removed. Variables were explicitly declared as type
Short.
Dim A As Short
Dim B As Short
Dim C As Short
```

What to do next

- No further action is necessary. This note was added to make you aware of the syntax change and the changes made to your code.

See Also

Data Type Changes in Visual Basic

Visual Basic 6.0 function was upgraded to a different Visual Basic .NET function

When a Visual Basic 6.0 application is upgraded to Visual Basic .NET, some functions are upgraded to functions that, although they behave the same, have a different name.

For example, the **Erase** function for fixed-length arrays upgrades to **System.Array.Clear**:

```
' Visual Basic 6.0
Dim a(10) As Integer
Erase a

' After upgrade to Visual Basic .NET
Dim a(10) As Short
' UPGRADE_NOTE: Erase was upgraded to System.Array.Clear.
System.Array.Clear(a, 0, a.Length)
```

> **Note** In some cases, a variable has to be renamed because the original name conflicts with a reserved word. For example, a variable named Day will be renamed Day_Renamed; Day was not a reserved name in Visual Basic 6.0, but it is in Visual Basic .NET.

What to do next

- No further action is necessary. This note was added to make you aware of the changes to your code, because the code looks significantly different.

VisualBasic.Compatibility Namespace Reference

Functions and objects in the **VisualBasic.Compatibility** namespace are provided for use by the Visual Basic 6.0 to Visual Basic .NET upgrade tools. In most cases they duplicate functionality that can be achieved using other parts of the .NET Framework; they are only necessary where the Visual Basic 6.0 code model differs significantly from the .NET implementation.

The following tables list functions and objects in the **VisualBasic.Compatibility** namespace. Additional functions and objects related to the **Microsoft.Compatibility.Data** namespace are not listed; they are the equivalents of the ADO data binding in Visual Basic 6.0.

VisualBasic.Compatibility Functions

Function	Description
CopyArray	Duplicates Visual Basic 6.0 functionality of assigning an array to a Variant.
CursorToIPicture	Used in format conversion.
Eqv	Duplicates the Visual Basic 6.0 **Eqv** (equivalence) operator.
FontChangeBold	Used in converting Visual Basic 6.0 fonts to Visual Basic .NET **Font** objects.
FontChangeGdiCharSet	Used in converting Visual Basic 6.0 fonts to Visual Basic .NET **Font** objects.
FontChangeItalic	Used in converting Visual Basic 6.0 fonts to Visual Basic .NET **Font** objects.
FontChangeName	Used in converting Visual Basic 6.0 fonts to Visual Basic .NET **Font** objects.
FontChangeSize	Used in converting Visual Basic 6.0 fonts to Visual Basic .NET **Font** objects.
FontChangeStrikeout	Used in converting Visual Basic 6.0 fonts to Visual Basic .NET **Font** objects.
FontChangeUnderline	Used in converting Visual Basic 6.0 fonts to Visual Basic .NET **Font** objects.
FontToIFont	Used in format conversion.
Format	Duplicates the Visual Basic 6.0 **Format** function.
FromPixelsX	Used for coordinate conversion.
FromPixelsY	Used for coordinate conversion.
FromPixelsUserHeight	Used for coordinate conversion.
FromPixelsUserWidth	Used for coordinate conversion.
FromPixelsUserX	Used for coordinate conversion.
FromPixelsUserY	Used for coordinate conversion.
GetActiveControl	Duplicates the Visual Basic 6.0 **Screen.ActiveControl** property.
GetCancel	Duplicates the functionality of the **Cancel** property of a Visual Basic 6.0 **CommandButton**.
GetDefault	Duplicates the functionality of the **Default** property of a Visual Basic 6.0 **CommandButton**.
GetEXEName	Duplicates the Visual Basic 6.0 **App.EXEName** property.
GetHInstance	Duplicates the Visual Basic 6.0 **App.HInstance** property.
GetItemData	Duplicates the functionality of the **ItemData** property of a Visual Basic 6.0 **ListBox** or **ComboBox**.
GetItemString	Duplicates the functionality of retrieving a value from a list in a Visual Basic 6.0 **ListBox** or **ComboBox**.
GetPath	Duplicates the Visual Basic 6.0 **App.Path** property.
IconToIpicture	Used in format conversion.
IFontToFont	Used in format conversion.
ImageToIPicture	Used in format conversion.
ImageToIPictureDisp	Used in format conversion.
Imp	Duplicates the Visual Basic 6.0 **Imp** (implication) operator.
IPictureDispToImage	Used in format conversion.
IPictureToImage	Used in format conversion.
LoadResData	Duplicates the Visual Basic 6.0 **LoadResData** function.
LoadResPicture	Duplicates the Visual Basic 6.0 **LoadResPicture** function.
LoadResString	Duplicates the Visual Basic 6.0 **LoadResString** function.
PixelsToTwipsX	Used for coordinate conversion.
PixelsToTwipsY	Used for coordinate conversion.
SendKeys	Duplicates the Visual Basic 6.0 **SendKeys** function.
SetCancel	Duplicates the functionality of the **Cancel** property of a Visual Basic 6.0 **CommandButton**.
SetDefault	Duplicates the functionality of the **Default** property of a Visual Basic 6.0 **CommandButton**.
SetItemData	Duplicates the functionality of the **ItemData** property of a Visual Basic 6.0 **ListBox** or **ComboBox**.
SetItemString	Duplicates the functionality of setting a value in a list in a Visual Basic 6.0 **ListBox** or **ComboBox**.

SetResourceBaseName	Used with **LoadRes** functions when a resource file uses a non-standard naming convention.
ShowForm	Duplicates the functionality of the **Show** method of a Visual Basic 6.0 form.
TabLayout	Used when converting **Debug.Print** statements that contain the **Tab** or **Spc** keywords.
ToPixelsX	Used for coordinate conversion.
ToPixelsY	Used for coordinate conversion.
ToPixelsUserHeight	Used for coordinate conversion.
ToPixelsUserWidth	Used for coordinate conversion.
ToPixelsUserX	Used for coordinate conversion.
ToPixelsUserY	Used for coordinate conversion.
TwipsPerPixelX	Duplicates the Visual Basic **Screen.TwipsPerPixelX** property.
TwipsPerPixelY	Duplicates the Visual Basic **Screen.TwipsPerPixelY** property.
TwipsToPixelsX	Used for coordinate conversion.
TwipsToPixelsY	Used for coordinate conversion.
ValidateControls	Duplicates the functionality of the **ValidateControls** method of a Visual Basic 6.0 form.
WhatsThisMode	Duplicates the functionality of the **WhatsThisMode** method of a Visual Basic 6.0 form.
Zorder	Used for converting the z-order of controls.

VisualBasic.Compatibility Objects

Object	Description
BaseControlArray	Parent class for Visual Basic 6.0 control array emulation.
BaseOcxArray	Parent class for emulated arrays of ActiveX controls.
ButtonArray	Emulates a Visual Basic 6.0 control array of **CommandButton** controls.
CheckBoxArray	Emulates a Visual Basic 6.0 control array of **CheckBox** controls.
CheckedListBoxArray	Emulates a Visual Basic 6.0 control array of **ListBox** controls with the **Style** property set to Checked.
ComboBoxArray	Emulates a Visual Basic 6.0 control array of **ComboBox** controls.
DirListBox	Emulates a Visual Basic 6.0 **DirListBox** control.
DirListBoxArray	Emulates a Visual Basic 6.0 control array of **DirListBox** controls.
DriveListBox	Emulates a Visual Basic 6.0 **DriveListBox** control.
DriveListBoxArray	Emulates a Visual Basic 6.0 control array of **DriveListBox** controls.
FileListBox	Emulates a Visual Basic 6.0 **FileListBox** control.
FileListBoxArray	Emulates a Visual Basic 6.0 control array of **FileListBox** controls.
FixedLengthString	Emulates Visual Basic 6.0 fixed-length strings.
GroupBoxArray	Emulates a Visual Basic 6.0 control array of **Frame** controls.
HScrollBarArray	Emulates a Visual Basic 6.0 control array of **HScrollBar** controls.
LabelArray	Emulates a Visual Basic 6.0 control array of **Label** controls.
ListBoxArray	Emulates a Visual Basic 6.0 control array of **ListBox** controls.
ListBoxItem	Emulates the **ItemData** property of a **ListBox** control.
MenuItemArray	Emulates a Visual Basic 6.0 control array of **Menu** controls.
PanelArray	Emulates a Visual Basic 6.0 control array of **PictureBox** controls that contain child controls.
PictureBoxArray	Emulates a Visual Basic 6.0 control array of **PictureBox** controls.
RadioButtonArray	Emulates a Visual Basic 6.0 control array of **OptionButton** controls.
TabControlArray	Emulates a Visual Basic 6.0 control array of **TabStrip** controls.
TextBoxArray	Emulates a Visual Basic 6.0 control array of **TextBox** controls.
TimerArray	Emulates a Visual Basic 6.0 control array of **Timer** controls.
VscrollBarArray	Emulates a Visual Basic 6.0 control array of **VScrollBar** controls.

Converting Visual J++ Applications to Visual C#

Microsoft® Visual Studio® .NET provides the ability to convert projects created in Visual J++® version 6.0 or written in the Java language to Visual C#™ so that you can take advantage of the .NET Framework. Java Language Conversion Assistant generates a new Visual C# project from an existing Visual J++ 6.0 project or Java-language files. The Java Language Conversion Assistant wizard makes it easy to convert your existing files.

In This Section

Converting Visual J++ or Java-Language Projects to Visual C#
Describes how to use Java Language Conversion Assistant.
Java Language Conversion Assistant
Provides an overview of upgrading a Visual J++ 6.0 project or Java-language files to Visual C#.
Java Language Conversion Assistant Wizard
Describes how to use the wizard.
Manually Upgrading Unconverted Code
Explains how to upgrade code that could not be converted automatically.

Converting Visual J++ or Java-Language Projects to Visual C#

Use Java Language Conversion Assistant to convert Visual J++ 6.0 projects and Java-language files for further development in Visual C#. Java Language Conversion Assistant does not modify your existing project, but rather creates a new Visual C# project based upon the original project. Any errors, warnings, or issues generated in the course of conversion are displayed in a conversion report after the new project has been generated. These errors, warnings, and issues are also noted in comments in the converted code to help you manually convert the parts of the project that cannot be converted automatically.

> **Note** If you are new to Visual C#, take some time to familiarize yourself with the language before attempting this process. For more information, see C# Language Tour.

Visual J++ Projects

To convert a Visual J++ project

1. Start Visual Studio .NET.
2. On the **File** menu, point to **Open**, and click **Convert**.
3. Select **Java Language Conversion Assistant**, and click **OK**.
4. On the **Source Files** page, select **Visual J++ 6.0 project** .
5. On the **Select a project file** page, click **Browse**.
6. Browse to the correct .vjp file, and select it.

   > **Note** If the CLASSPATH directive of your .vjp file specifies .jar or .class files, they are ignored.

7. On the **Specify a directory for your new project** page, specify the name and directory of the new project to be created.
8. On the **Begin conversion** page, click **Next**.
9. Fix code that could not be converted automatically. For more information, see Manually Upgrading Unconverted Code.

Java-Language Projects

To convert a Java-language project

1. Start Visual Studio .NET
2. On the **File** menu, point to **Open**, and click **Convert**.
3. Select **Java Language Conversion Assistant**, and click **OK**.
4. On the **Source Files** page, click **A directory containing the project's files**.
5. On the **Select source directory** page, click **Browse**.
6. Browse to the correct project, and select it.

   > **Note** You will not see the files in the directory you select, but all .jav and .java files in it will be converted. All other files in the directory are ignored.

7. On the **Configure your new project** page, specify the following:

   - Name of the project to be created.
   - Directory in which the any additional files for your project are located.

     > **Note** You will not see the files in the directory you select, but all .jav and .java files in it will be converted. All other files in the directory are ignored.

   - Output type of the project.

8. On the **Specify a directory for your new project** page, specify the name and directory of the new project to be created.
9. On the **Begin your conversion** page, click **Next**.
10. Fix code that could not be converted automatically. For more information, see Manually Upgrading Unconverted Code.

Java Language Conversion Assistant

Java Language Conversion Assistant is a tool that converts Visual J++ 6.0 projects and Java-language files to Visual C#. By converting these files to Visual C#, you can leverage your existing code base and take advantage of the benefits of the .NET Framework.

The new Visual C# project contains all the new Visual C# code that can be generated automatically from the existing Visual J++ or Java-language code. For more information, see Converting Visual J++ or Java-language Projects to Visual C#.

You can use Java Language Conversion Assistant to convert Visual J++ or Java-language applications and applet projects. They are converted in the following way:

Before Conversion	After Conversion
Applications	Windows Forms applications
Applets	Web user controls

You can host converted Web user controls in a browser just as you would an applet. Hosted controls are declared in HTML pages with the **OBJECT** tag, instead of the **APPLET** tag. Use the **classid** attribute to identify the control by specifying the path to the control and the fully qualified name of the control, separated by the pound sign (#), as shown in the following example:

```
<OBJECT id="myControl" classid="http:ControlLibrary1.dll#ControlLibrary1.myControl" VIEWASTEX
T></OBJECT>
```

For the control to be displayed properly, the .dll file containing the control must either be in the same virtual directory as the Web page that is displaying it or be installed in the global assembly cache.

Support Classes

To convert functionality in the original project that is not available in Visual C#, Java Language Conversion Assistant creates *support classes* (also called *managers*) that duplicate the original functionality. Support classes are sometimes substantially different architecturally from the classes they emulate. Although every effort is made to preserve the original architecture of your application in the converted project, the primary goal of these support classes is to duplicate the original functionality.

Conversion Report

There might be some code in your project that could not be converted automatically. After you run the Java Language Conversion Assistant wizard, you can view the conversion report that details all errors, warnings, and issues encountered during the conversion process. Unconverted code is noted in the code of the new project by comments labeled UPGRADE_TODO. You can view conversion comments on the task list. Each conversion comment contains a link to a Help topic about how to convert that code manually. For more information, see Manually Upgrading Unconverted Code.

Converting Visual J++ Applications to Visual C#

Java Language Conversion Assistant Wizard

Use the Java Language Conversion Assistant wizard to convert Visual J++ and Java-language projects to Visual C#. With the wizard, you can create a new project and copy files from your original project for conversion from Visual J++ or the Java language to Visual C#. A report detailing any errors, warnings, or issues encountered in the conversion process is generated. Errors, warnings, and issues are also noted as comments in the code of the new project and can be viewed on the task list.

To access the Java Language Conversion Assistant wizard

1. On the **File** menu, point to **Open**, and click **Convert**.
2. Click **Java Language Conversion Assistant**, and click **OK**.

See Also

Java Language Conversion Assistant | Converting Visual J++ or Java-Language Projects to Visual C# | Manually Upgrading Unconverted Code

Manually Upgrading Unconverted Code

After Java Language Conversion Assistant converts your Visual J++ project or Java-language files, the new Visual C# project might contain code that could not be converted automatically. Comments are inserted in the code of the new project to help you convert that code to Visual C# manually.

Comment Type	Description
UPGRADE_TODO	Code that could not be converted automatically
UPGRADE_WARNING	Code that might be problematic
UPGRADE_NOTE	Code that might exhibit a different behavior from the original code

There might also be some compiler errors that must be corrected before the application compiles. Each comment contains a brief description of the issue and a link to a Help topic about how to convert the code.

To upgrade unconverted code manually

1. After running the Java Language Conversion Assistant wizard, open your project in Visual Studio .NET.
2. On the **View** menu, select **Show Tasks**, and then either **Comment** or **All**.

   The conversion notes are displayed on the **Task List**.

3. On the **Task List**, double-click the first conversion note.

   The focus moves to the location of that comment in the code.

4. Examine the note and the code to which it pertains. For more information on correcting that error manually, click the link in the conversion note to display a Help topic for that error.

   Some of the conversion notes in the converted code for JSP pages are not clickable. You can cut and paste the note in the Help **Search** box. For a list of errors, warnings, and issues, see Java Language Errors, Warnings, and Issues. For a list of Help topics for JSP classes and methods that cannot be converted automatically, see Javax.servlet.jsp Error Messages.

5. Upgrade the code manually.
6. Repeat Steps 3 to 5 until all conversion notes have been addressed.

Java Language Conversion Assistant | Converting Visual J++ or Java-Language Projects to Visual C#

What's New in Java Language Conversion Assistant

The following features are included with this version of Java Language Conversion Assistant:

- Support for JavaServer Pages (JSP)
- Servlet support
- Improved applet support
- Support for different character-encoding systems
- Support for collections
- Performance enhancements

JavaServer Pages

JavaServer Pages can now be converted to ASP.NET applications to develop information-rich Web applications that are easy to maintain. Development time is reduced, and existing business systems can be tapped for database and other support. You can change the page layout without affecting the dynamically generated content. Tag handlers are converted to Web user controls.

Servlet Support

Java Language Conversion Assistant now converts servlet classes that allow you to extend the functionality of your Web server and interact with your existing business systems. These are platform-independent, light-weight applications that are very much like applets, but run on the server side. They can access enterprise databases through ODBC and are ideal for building interactive Web applications.

Improved Applet Support

Java Language Conversion Assistant includes additional support for converting applets to Windows Forms user controls. Applets can now take advantage of additional .NET functionality while maintaining their behavior.

Support for Different Character-Encoding Systems

Encoding support has been expanded to include all the major character-encoding systems. Files that are encoded in the current system ANSI code page keep this encoding after conversion. Any other encoding is converted to UTF-8 encoding.

The following encoding systems are currently supported:

- Windows system ANSI code pages
- UTF-8 Unicode
- UTF-16 Unicode
- ISO Latin alphabet No. 2 (Central European)
- ISO Latin alphabet No. 3
- ISO Latin alphabet No. 4 (Baltic States)
- ISO Latin/Arabic alphabet
- ISO Latin/Cyrillic alphabet
- ISO Latin/Greek alphabet
- ISO Latin/Hebrew alphabet
- ISO Latin alphabet No. 9
- EUC Japanese
- EUC Korean
- EUC Chinese Simplified
- Chinese National Standard

For issues with matching character encodings, see Matching Code Pages.

Support for Collections

Java Language Conversion Assistant now offers support for a unified approach to handling and manipulating collections. The Java 1.2 Collections API can be converted to the classes in the **System.Collections** namespace, which present methods to represent and use collections to reduce development effort and increase productivity.

Performance Enhancements

Overall performance for large projects has been improved dramatically in this version of Java Language Conversion Assistant. Conversion time has been reduced 70 percent for sample projects of about 25 MB (580+ lines of code). Conversion time for medium-sized projects (about 250 KB) has been reduced by 50 percent.

Converting Web Applications

When converting Web applications from JSP to ASP.NET, several additional steps are necessary. Java Language Conversion Assistant establishes the application root directory, moves servlet classes to a different directory, replaces links, and resolves tag library descriptors defined in the Web.xml file. You must set the context path and domain parameters for your Web application.

In This Section

Establishing the Directory Structure for a Web Application
Explains how to establish the directory structure for your Web application.
Link Replacement
Describes how Java Language Conversion Assistant replaces links in your converted Web application.
Resolution of Tag Library Descriptors
Describes the conversion of tag library descriptors included in the Web.xml file.

Establishing the Directory Structure for a Web Application

When converting a Web application, Java Language Conversion Assistant establishes a different directory structure for the new application. You must add two parameters containing the context path and domain on which your application will run.

To establish the directory structure

1. Add a parameter called *ContextPath* at the command line.

   This is the starting point for all URL references in the Web application.

   `jconvert.\projecttype ASP.NET\ContextPath AppName`

2. Add a parameter called *Domain* at the command line to provide the host name in applications with an empty context path.

   This parameter is necessary to avoid replacement of links to servlets or JSP pages outside the current application. If no host name is provided, all absolute links are processed. It is not necessary to include **http://**.

   ```
   jconvert.\projecttype ASP.NET\Domain www.mydomain.com
   ```

Any servlet classes are moved to the output directory (the virtual root). The directory structure created in the process of conversion does not necessarily correspond to the directory in which the servlet is located.

Example

In the following example, the Web application root directory is \website\AppName. The servlet classes are moved to a different directory in the converted directory structure.

Original Directory Structure

```
mt\src
mt\src\com\ais\servlets
mt\src\com\ais\servlets\Servlet1.java
mt\src\com\ais\servlets\Servlet2.java
mt\src\com\ais\beans
mt\src\com\ais\beans\CatalogBean.java
mt\src\com\ais\customtags
mt\src\com\ais\customtags\TableTag.java
mt\misc\pack1\myclasses
mt\misc\pack1\myclasses\DbHelper.java
mt\website
mt\website\AppName
mt\website\AppName\jsp\
mt\website\AppName\jsp\Search.jsp
mt\website\AppName\jsp\content\Catalog.jsp
mt\website\AppName\html\Index.html
mt\website\AppName\images\Logo.gif
mt\website\AppName\WEB-INF
mt\website\AppName\WEB-INF\Web.xml
mt\website\AppName\WEB-INF\MyTags.tld
```

Equivalent Converted Directory

```
outdir\src
outdir\src\com\ais\beans
outdir\src\com\ais\beans\CatalogBean.cs
outdir\src\com\ais\customtags
outdir\src\com\ais\customtags\TableTag.cs
outdir\misc\pack1\myclasses
outdir\misc\pakc1\myclasses\Dbhelper.cs
outdir\website
outdir\website\AppName
outdir\website\AppName\com\ais\servlets\Servlet1.aspx
outdir\website\AppName\com\ais\servlets\Servlet2.aspx
```

```
outdir\website\AppName\jsp\
outdir\website\AppName\jsp\Search.aspx
outdir\website\AppName\jsp\content\Catalog.aspx
outdir\website\AppName\html\Index.html
outdir\website\AppName\images\Logo.gif
outdir\website\AppName\WEB-INF
outdir\website\AppName\WEB-INF\Web.xml
outdir\website\AppName\WEB-INF\MyTags.tld
```

Link Replacement

Java Language Conversion Assistant replaces all links to work with the converted directory structure. This section assumes the directory structure defined in Establishing the Directory Structure for a Web Application.

There are basically three types of URLs:

- Absolute URLs with domain information.

```
http://www.somehost.com/servlet/pack1/Servlet1
```

- Absolute URLs without domain information.

```
/servlet/pack1/Servlet1
```

- Relative URLs.

```
pack1.Servlet1
```

The URL that a client uses to access a Web application has the following form:

```
http://hoststring/ContextPath/ServletPath/pathInfo.
```

In this example, the elements are defined as follows:

hoststring
Host name that is mapped either to a virtual host or to *hostname*:*portNumber*.
ContextPath
Name of the Web application. This can be empty.
ServletPath
Servlet that is mapped to the servlet path.
pathInfo
Remaining portion of the URL, typically the file name.

Java Language Conversion Assistant makes the following changes:

- Changes the context path (if present) to the name of the corresponding virtual root defined in the conversion, plus the Web application root.
- If the context path is not present, the VROOT is inserted in the link.
- If the file extension is .jsp, it is changed to .aspx.

Example

Original URL

```
http://hoststring/ContextPath//dir/JSP1.jsp?param1=1
http://HostNameProvided/dir/JSP1.jsp?param1=1
```

Equivalent Converted URL

```
http://hoststring/VRoot/website/AppName/dir/JSP1.aspx?param1=1
http://HostNameProvided/VRoot/website/AppName/dir/JSP1.aspx?param1=1
```

If the link contains the servlet token and the complete name of a servlet, the servlet token is eliminated, and dots (.) in the complete name are changed to slashes (/). If the link to the servlet is relative, the reference is changed to include the VROOT and the converted servlet directory structure.

Example

Original URL

```
http://hoststring/ContextPath/servlet/com.ais.servlets.Servlet1
com.ais.servlets.Servlet1
```

Equivalent Converted URL

```
http://hoststring/VRoot/com/ais/servlets/Servlet1.aspx
/VRoot/com/ais/servlets/Servlet1.aspx
```

If the servlet token is followed by a servlet name found in the Web.xml file, the complete name of the servlet is inserted in the link.

Example

Original XML

```
<servlet>
    <servlet-name>test</servlet-name>
    <servlet-class>com.ais.servlets.Servlet1</servlet-class>
</servlet>
```

Original URL

```
http://hoststring/ContextPath/servlets/test
```

Equivalent Converted URL

```
http://hoststring/VRoot/com/ais/servlets/Servlet1.aspx
```

If the Web application name is followed by a pattern defined in the servlet mapping in Web.xml, the name of the servlet is determined and inserted in the link. The pattern can contain wildcards (*).

Example

Original XML

```
<servlet>
    <servlet-name>test</servlet-name>
    <servlet-class>com.ais.servlets.Servlet1</servlet-class>
</servlet>
<servlet-mapping>
    <servlet-name>test</servlet-name>
    <url-pattern>/*.asp</url-pattern>
</servlet-mapping>
```

Original URL

```
http://hoststring/ContextPath/abc.asp
```

Equivalent Converted URL

```
http://hoststring/VRoot/com/ais/servlets/Servlet1.aspx
```

Links calculated at run time are not converted by Java Language Conversion Assistant. Instead, you must manually add the necessary parameters. This applies to the following cases:

- Links with the expressions <%=%>, jsp:forward, jsp:include, or jsp:execute and the XML tags <a href> and <form action>.
- Any **javax.servlet** method whose parameters represent a path to a Web resource, for example, the **Response.redirect** method.

Example

Original Java-Language Code

```
<jsp:include page="<%=value%>">
```

Equivalent Visual C# Code

```
<%-- //UPGRADE_TODO: Expected format of parameters of action jsp:include are different in the
equivalent in .NET --%>
<% Server.Execute(value)%>
```

Resolution of Tag Library Descriptors

When the **uri** attribute of the **taglib** directive refers to a **taglib-uri** defined in the Web.xml file, the location of the tag library descriptor (TLD) is taken from that file.

Example

Original XML

```
<taglib>
    <taglib-uri>/MYTEST</taglib-uri>
    <taglib-location>WEB-INF/myTagLib.tld</taglib-location>
</taglib>
```

Original JSP

```
<%taglib uri="/MYTEST" prefix="myTag"%>
```

Equivalent TLD to be parsed

```
/WEB-INF/myTagLib.tld
```

Conversion of JSP Custom Tag Libraries

Due to the differences between JSP custom tags and .NET Web user controls, a set of support classes that emulate JSP custom tag processing are created during conversion. Those classes are the base of converted JSP custom tag class handlers. Support classes are created for the following classes in the **javax.servlet.jsp.tagext** package:

Original Java-Language Class	Generated Support Class
BodyContent	**WCBodyContent**
Tag	**WCBase**
IterationTag	**WCIterationBase**
BodyTag	**WCBodyBase**
BodyTagSupport	**WCBodyImpl**
TagSupport	**WCIterationImpl**

Compile Converted Servlet Classes Before Opening Them

When converting servlet classes, you must resolve all conversion issues and compile your code before you can open a Web Forms page for the application. The Web Forms page cannot be opened in the designer view until the code is compiled. If you try to open it before compiling, you receive an error.

Matching Code Pages

If you find that your code after conversion has strange characters, the most likely cause is a missing or mismatched code page for character encoding. Java Language Conversion Assistant matches encoding in the following manner:

- Files that are encoded in the current system ANSI code page keep this encoding after conversion.
- Any other encoding is converted to UTF-8 encoding.

Unicode files that start with a Unicode byte-order mark are identified automatically as Unicode. If a file does not start with a byte-order mark and the encoding switch is not specified, the file is assumed to be in the current ANSI code page of the system.

To change the system ANSI code page you are currently using

1. Go to **Control Panel**, and double-click **Regional Options** (in Windows 2000) or **Regional and Language Options** (in Windows XP).
2. Click **Advanced**, and select the desired code page.

If your source files are in a non-ANSI character encoding or you have Unicode source files that do not start with a byte-order mark, you must use the encoding switch.

The following character encodings can be specified in the encoding switch:

Encoding	Switch
Latin alphabet No. 2 (Central European)	ISO-8859-2
Latin alphabet No. 3	ISO-8859-3
Latin alphabet No. 4 (Baltic States)	ISO-8859-4
Latin/Cyrillic alphabet	ISO-8859-5
Latin/Arabic alphabet	ISO-8859-6
Latin/Greek alphabet	ISO-8859-7
Latin/Hebrew alphabet	ISO-8859-8
Latin alphabet No. 9	ISO-8859-15
Japanese	EUC-JP
Korean	EUC-KR
Chinese Simplified	EUC-CN
Chinese National Standard	GB18030
UTF-8 without byte-order mark	UTF-8

To use a specific encoding, you must have support for it installed on your system. See your system documentation for details. When using the encoding switch, all files in the project must be in the same encoding.

If you are using an encoding system that is not supported in JLCA, you might lose characters that cannot be converted. In some cases, a file might be lost.

JLCA Diagnostic Messages Listed by Package

This section contains links to all the diagnostic messages for the Java Language Conversion Assistant. The pages containing the links are organized by package.

Java Language Errors, Warnings, and Issues

(1002) Compile Error: Invalid Statements

(1003) Note: Declaration changed from Final to Variable

(1005) Note: Initialize expression was moved to method or constructor

(1011) Note: New code element generated

(1012) Note: Break statement with label is not supported

(1014) Note: Labeled statement moved by Java Language Conversion Assistant

(1015) Note: Continue statement with label is not supported

(1019) Note: Inner classes not provided with enclosing instance

(1021) Note: Inner class member field this$0 is not supported

(1022) Note: Local class declaration is not supported

(1023) Note: Final variable copied to inner class as member field

(1024) Global Note: Anonymous class declaration is not supported

(1025) Note: Interfaces nested within interfaces are not allowed in C#

(1027) Note: Synchronized methods are not supported in .NET

(1042) Global Warning: Narrowing conversions for primitive types may generate runtime errors

(1043) To Do: Method or property returns a different value in the .NET Framework

(1045) Note: Interfaces cannot contain fields in the .NET Framework

(1062) To Do: NULL value of database columns can be checked by using OleDbDataReader.isDBNull

(1063) To Do: Modify connection string(s) to match the .NET Framework format

(1064) To Do: Modify the string connection to match the .NET Framework format and add the java.util.Properties information to it

(1066) To Do: setLoginTimeout must be a parameter to connection string for OleDbConnection constructor

(1075) Note: Font constructor may generate non-equivalent instances

(1077) To Do: Inheritance for class not supported

(1078) To Do: Make sure that resources used in this class are valid resources files

(1079) Compile Error: All the methods inherited from an abstract class must be implemented

(1083) Note: Bit arrays must be of the same size to allow the operation

(1086) Compile Error: Field equivalent cannot be assigned to an integer variable

(1088) To Do: There is no NULL value defined for a .NET structure

(1089) To Do: Access and file format of configuration settings are different

(1091) Runtime Warning: The equivalent constructor has a different number of parameters

(1092) To Do: Expected value or type of a parameter is different

(1093) To Do: Change code to access value of a .NET class member

(1095) To Do: Class element not mapped in the current release

(1096) Note: Fields mapped to enumerations initialized with integer values

(1099) Note: Exceptions thrown by method may be different

(1100) Note: Catch clauses in a try statement with the same exception

(1101) Runtime Warning: Mapped parameters may throw an exception

(1102) Compile Error: Class must be modified to call superclass

(1103) Compile Error: Field has a different type

(1104) To Do: Use ConnectionString property to set logon and password

(1105) To Do: Method invocation is not necessary

(1107) Global Note: Migration of setAllowAddNew, setAllowDelete, and setAllowUpdate of the DataGrid class

(1108) To Do: Property or method must be set or called before an invocation

(1109) Compile Error: Migrated parameter not compatible with parameter type of method

(1113) Compile Error: Member is reserved for internal use of its package

(1114) To Do: Parameter of setFilter in the OpenFileDialog and SaveFileDialog classes must be changed

(1115) Global Warning: Unsafe code requires a compiler switch to compile

(1116) To Do: COM Custom marshaller may become invalid

(1118) To Do: Check boxes do not provide mutual exclusion when grouped

(1119) Note: User control event attribute not valid

(1123) Note: Class maps to interface

(1124) Note: Code was removed from method body

(1128) Compile Error: Break statement at finally clause level is invalid

(1130) To Do: Equivalent of java.sql.DatabaseMetaData handles query results in System.Data.DataTable

(1132) To Do: Equivalent class does not throw exception for malformed URL

(1135) Global Error: The System.Windows.Forms.Application.Run method must be called for the main window

(1137) To Do: User get or set method converted to property has name collisions

(1139) Global Warning: Directory was not converted

(1140) Global Warning: Thread name can be set just once

(1141) Note: Java Language Conversion Assistant commented code from Java Callable Wrapper class for a COM coclass

(1142) To Do: The event method needs be overloaded

(1143) To Do: Method is not an override method

(1144) Runtime Warning: Add extra logic into componentHidden

(1145) Runtime Warning: Add extra logic into componentShown

(1146) To Do: Declaration and construction for class instance in different lines cannot be converted

(1147) To Do: The <classname> class is marked as sealed

(1148) Note: Synchronized keyword has been removed

(1151) To Do: Inaccesible constructor

(1152) To Do: You must manually migrate access to the registry

(1153) To Do: Untranslated statement

(1154) Note: Parameter to constructor of equivalent of class com.ms.wfc.data.ui.DataNavigator

(1155) To Do: Class that derives from Delegate or MulticastDelegate

(1156) Compile Error: Wrong statements

(1157) Compile Error: Method with the same parameter types

(1158) To Do: The way of accessing the file was modified

(1159) Global Warning: Path of archives that depend on the working directory

(1160) To Do: One interface includes the functionality of another one

(1167) Note: getParameter calls without a string literal

(1168) To Do: getParameter that requires rename of parameters

(1169) Note: The default value of property has been changed

(1170) Global Warning: Class mapped to a struct; cannot contain or return a null value

(1171) Note: getSource method must be in an event handling routine

(1172) Global Error: Input project file is corrupt

(1173) To Do: Hexadecimal literal returns a different value

(1174) Note: The form to load a binary file in .NET is different

(1175) Global Warning: Unsigned long detected

(1177) Runtime Warning: Implemenentation of interface was converted to a single class

(1178) To Do: Method needs to be modified

(1179) Global Warning: Request the OleDbManager connection string

(1180) Note: Only one transactional attribute is supported

(1181) Runtime Warning: Expressions used more than once in C# code

(1182) To Do: Session parameters are stored in a different order

(1183) Runtime Warning: Init functionality has been converted

(1184) To Do: <ClassName> requires changing the type of the receiving instance

(1185) To Do: Queue access is obtained differently

(1186) Compile Error: Class hierarchy differences may cause compile errors

(1187) Runtime Warning: <Member type> may be executed every time the ASP.NET page loads

(1191) Note: Instance field was converted to static

(1195) To Do: Change in override modifier for nonvirtual method

(1197) To Do: Delegate instantiated with String value for function name

(1198) Note: Inheritance of servlet classes can cause wrong manipulation of variables

(1200) Note: Base class shared fields have been redeclared with the new modifier

(1202) To Do: Reference conversion needs user modification

(1203) Note: Using the class interface to expose public members

(1204) Note: Access modifiers were changed

(1205) To Do: Methods with parameters of primitive type overloaded with parameters of wrapper class type

(1206) Global Note: Converted project must be compiled before opening in Visual Studio designer view

(1207) To Do: Types extending from COM objects should override all methods

(1209) Note: Method was not converted to property

(1220) To Do: Reset method must be implemented

(1221) To Do: Parent invocations in methods from applets

(1223) Global Warning: Output of bidirectional languages

(1224) To Do: Method returns different type

(2001) Runtime Warning: Some server-side tags that must be unique could be repeated when including files

(2002) Runtime Warning: Dynamic file inclusion is not allowed in Aspx

(2003) Note: Attribute "buffer" can have only two valid values in ASP.NET

(2004) Note: Request scope was changed to Session scope

(2005) Global Error: Web.Config customErrors Mode property must be set to "On"

(2006) To Do: File will not be converted

(2007) Note: Script variables can be out of scope when moving blocks inside custom tags to methods

(4013) Note: Specified TLD file could not be found or parsed

(4015) Note: User control ID has been changed

(5000) To Do: Method is not marked as virtual

Legacy ActiveX Control Reference

The following links apply to ActiveX controls that are available to use with Visual Basic .NET.

> **Note** There are performance limitations for Windows Forms when ActiveX controls are added to them.

Masked Edit Control
: Provides reference information about this control, which provides restricted data input as well as formatted data output. This control supplies visual cues about the type of data being entered or displayed.

MSChart Control
: Provides reference information about this control, which graphically displays data.

AmbientProperties Object (ActiveX Controls)

An **AmbientProperties** object holds ambient information from a container to suggest behavior to controls contained within the container.

Remarks

Containers provide ambient properties in order to suggest behavior to controls. As an example, **BackColor** is one of the standard ambient properties; the container is suggesting what the well-behaved control should set its **BackColor** property to.

The **AmbientProperties** object's properties are the ambient properties of the container. These properties are read-only.

Some ambient properties are standard, while others are specific to certain containers. A control may access non-standard ambient properties, but this will make the control container-specific. The control should handle the case where an ambient property is not present in the current container.

When the control is compiled, Visual Basic has no way of knowing what container-specific ambient properties may be available when the control is run; therefore references to container-specific ambient properties will always be late bound.

The **AmbientProperties** object is not available when the Initialize event is raised; but is available when the InitProperties event or ReadProperties event is raised.

The **AmbientProperties** object has several standard properties:

- The **BackColor** property, a Color that contains the suggested interior color of the contained control. The Visual Basic supplied default if the container does not support this property is 0x80000005: the system color for a window background.
- The **DisplayAsDefault** property, a Boolean that specifies if the control is the default control. The Visual Basic supplied default if the container does not support this property is **False**.
- The **DisplayName** property, a String containing the name that the control should display for itself. The Visual Basic supplied default if the container does not support this property is an empty string: "".
- The **Font** property, a **Font** object that contains the suggested font information of the contained control. The Visual Basic supplied default if the container does not support this property is MS Sans Serif 8.
- The **ForeColor** property, a Color that contains the suggested foreground color of the contained control. The Visual Basic supplied default if the container does not support this property is 0x80000008: the system color for window text.
- The **LocaleID** property, a Long that specifies the language and country/region of the user. The Visual Basic supplied default if the container does not support this property is the current system locale ID.
- The **MessageReflect** property, a Boolean that specifies if the container supports message reflection. The Visual Basic supplied default if the container does not support this property is **False**.
- The **Palette** property, a **Picture** object whose palette specifies the suggested palette for the contained control.
- The **ScaleUnits** property, a String containing the name of the coordinate units being used by the container. The Visual Basic supplied default if the container does not support this property is an empty string: "".
- The **ShowGrabHandles** property, a Boolean that specifies if the container handles the showing of grab handles. The Visual Basic supplied default if the container does not support this property is **True**.
- The **ShowHatching** property, a Boolean that specifies if the container handles the showing of hatching. The Visual Basic supplied default if the container does not support this property is **True**.
- The **SupportsMnemonics** property, a Boolean that specifies if the container handles access keys for the control. The Visual Basic supplied default if the container does not support this property is **False**.
- The **TextAlign** property, an enumeration that specifies how text is to be aligned. The Visual Basic supplied default if the container does not support this property is **0 - General Align**.
- The **UserMode** property, a Boolean that specifies if the environment is in design mode or end user mode. The Visual Basic supplied default if the container does not support this property is **True**.
- The **UIDead** property, a Boolean that specifies if the User Interface is unresponsive. The Visual Basic supplied default if the container does not support this property is **False**.

> **Note** When you access the Font property of the AmbientProperties object, you do not get a reference to the container's font. Rather, you get a copy (clone) of the font. The reason for this is that AmbientProperties.Font is commonly used to initialize a control's font whenever an instance of the control is added to a container. If a reference to the font itself were supplied, then changing the control's font would change the container's font as well. If for some reason your control requires a reference to the container's font, you can obtain it by accessing the container through the Parent property of the UserControl object.

DataBinding Object (ActiveX Controls)

The **DataBinding** object represents a bindable property of a component.

Syntax

DataBinding

Remarks

There is one **DataBinding** object for each property of a component marked as Bindable in the **Procedure Attributes** dialog box.

Visual Basic version 4.0 supported binding only one property of a control to a database at a time. Later versions of Visual Basic give you the ability to bind multiple properties of a control to a database. This is used most commonly with **User** controls.

Alignment Property (ActiveX Controls)

Returns or sets a value that determines the alignment of text in a control.

Syntax

object.**Alignment** [= *number*]

The **Alignment** property syntax has these parts:

Part	Description
Object	An object expression that evaluates to an object in the Applies To list .
Number	An integer that specifies the type of alignment.

Remarks

By default, text is left-aligned.

Ambient Property (ActiveX Controls)

Returns an **AmbientProperties** object holding the ambient properties of the container. The **Ambient** property is not available at the control's authoring time, and read-only at the control's run time.

Syntax

object.**Ambient**

The **Ambient** property syntax has this part:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.

See Also

Applies To: AmbientProperties Object (ActiveX Controls)

Appearance Property (ActiveX Controls)

Returns or sets a value that determines the appearance of the object.

Syntax

object.**Appearance**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Settings

The **Appearance** property settings are:

Setting	Description
0	Flat. Paints controls and forms without visual effects.
1	(Default) 3D. Paints control or object with three-dimensional effects.

See Also

Applies To: Masked Edit Control

BackColor, ForeColor Properties (ActiveX Controls)

BackColor — returns or sets the background color of an object.

ForeColor — returns or sets the foreground color used to display text and graphics in an object.

Syntax

object.**BackColor** [= *color*]

object.**ForeColor** [= *color*]

The **BackColor** and **ForeColor** property syntax's have these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
color	A value or constant that determines the background or foreground colors of an object, as described in Settings.

Settings

Visual Basic uses the Microsoft Windows operating environment red-green-blue (RGB) color scheme. The settings for *color* are:

Setting	Description
Normal RGB colors	Colors specified by using the Color palette or by using the **RGB** or **QBColor** functions in code.
System default colors	Colors specified by system color constants listed in the Visual Basic (VB) object library in the Object Browser. The Windows operating environment substitutes the user's choices as specified in the Control Panel settings.

For all forms and controls, the default settings at design time are:

- **BackColor** — set to the system default color specified by the constant **vbWindowBackground**.
- **ForeColor** — set to the system default color specified by the constant **vbWindowText**.

Remarks

The valid range for a normal RGB color is 0 to 16,777,215 (&HFFFFFF). The high byte of a number in this range equals 0; the lower 3 bytes, from least to most significant byte, determine the amount of red, green, and blue, respectively. The red, green, and blue components are each represented by a number between 0 and 255 (&HFF). If the high byte isn't 0, Visual Basic uses the system colors, as defined in the user's Control Panel settings and by constants listed in the Visual Basic (VB) object library in the Object Browser.

To display text in the Windows operating environment, both the text and background colors must be solid. If the text or background colors you've selected aren't displayed, one of the selected colors may be dithered — that is, comprised of up to three different-colored pixels. If you choose a dithered color for either the text or background, the nearest solid color will be substituted.

> **Note** The **Animation** control displays only two types of AVI files, either uncompressed or compressed in RLE8 format. AVI files compressed with RLE8 display only 8-bit colors. The BackColor property for the **Animation** control is "rounded" to the closest 8-bit color in the standard palette.

See Also

Applies To: Masked Edit Control

BorderStyle Property (ActiveX Controls)

Returns or sets the border style for an object.

Syntax

object.**BorderStyle** = [*value*]

The **BorderStyle** property syntax has these parts:

Part	Description
Object	An object expression that evaluates to an object in the Applies To list.
Value	A value or constant that determines the border style, as described in Settings .

Settings

The **BorderStyle** property settings are:

Constant	Setting	Description
*xxx***None**	0	None (no border or border-related elements).
*xxx***FixedSingle**	1	Fixed Single.

> **Note** Constants for ActiveX controls are prefaced by three letters which are specific to the control. For example, the Masked Edit control uses **mskNone**. However, the description remains the same unless indicated.

See Also

Applies To: Masked Edit Control | MSChart Control

BorderStyle Constants (ActiveX Controls)

Following are the constants associated with the **BorderStyle** property:

Constant	Value	Description
*xxx***None**	0	(Default) No border or border-related elements.
*xxx***FixedSingle**	1	(Default for **ListView** control) Fixed single. There is a single line border around the control.

Note Constants for ActiveX controls are prefaced by three letters which are specific to the control. For example, the Masked Edit control uses **mskNone**. However, the description remains the same unless indicated.

See Also

Masked Edit Control | MSChart Control

CausesValidation Property (ActiveX Controls)

Returns or sets a value that determines whether the Validate event will occur on a second control from which the second control's focus is being shifted.

Syntax

object.**CausesValidation** [= *boolean*]

The **CausesValidation** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether the control from which the focus is being shifted fires the Validate event.

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The control from which the focus has shifted fires its Validate event.
False	The control from which the focus has shifted does not fire its Validate event.

Remarks

The **CausesValidation** property works in tandem with the Validate event to limit when a control can lose focus.

Example

See Validate Event (ActiveX Controls).

See Also

Validate Event (ActiveX Controls)

Applies To: MSChart Control

Container Property (ActiveX Controls)

Returns or sets the container of a control on a **Form**. Not available at design time.

Syntax

Set *object*.**Container** [= *container*]

The **Container** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
container	An object expression that evaluates to an object that can serve as a container for other controls, as described in Remarks.

Remarks

The following controls can contain other controls:

- **Frame** control
- **PictureBox** control
- **SSTab** control

Example

This example demonstrates moving a **CommandButton** control from container to container on a **Form** object. To try this example, paste the code into the Declarations section of a form that contains a **Frame** control, a **PictureBox** control and a **CommandButton**, and then press F5.

```
Private Sub Form_Click()
   Static intX As Integer
   Select Case intX
      Case 0
         Set Command1.Container = Picture1
         Command1.Top= 0
         Command1.Left= 0
      Case 1
         Set Command1.Container = Frame1
         Command1.Top= 0
         Command1.Left= 0
      Case 2
         Set Command1.Container = Form1
         Command1.Top= 0
         Command1.Left= 0
   End Select
   intX = intX + 1
End Sub
```

See Also

Applies To: Masked Edit Control | MSChart Control

Count Property (ActiveX Controls)

Returns the number of objects in a collection.

Syntax

object.**Count**

The *object* placeholder is an object expression that evaluates to an object in the Applies To list.

Remarks

You can use this property with a **For...Next** statement to carry out an operation on the forms or controls in a collection. For example, the following code moves all controls on a form 0.5 inches to the right (**ScaleMode** property setting is 1 or **vbTwips**):

```
For I = 0 To Form1.Controls.Count - 1
   Form1.Controls(I).Left = Form1.Controls(I).Left + 720
Next I
```

You can also use this kind of structure to quickly enable or disable all controls on a form.

When used with the **If TypeOf** statement, you can cycle through all controls and change, for example, the **Enabled** property setting of only the text boxes or the **BackColor** property setting of only the option buttons.

See Also

Applies To: MSChart Control | DataPoints Collection | Labels Collection | LightSources Collection | SeriesCollection Collection

DataBindings Property (ActiveX Controls)

Returns the **DataBindings** collection object containing the bindable properties available to the developer.

Syntax

object.**DataBindings**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: MSChart Control

DataChanged Property (ActiveX Controls)

Returns or sets a value indicating that the data in the bound control has been changed by some process other than that of retrieving data from the current record. Not available at design time.

Syntax

object.**DataChanged** [= *boolean*]

The **DataChanged** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
value	A Boolean expression that indicates whether data has changed, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The data currently in the control isn't the same as in the current record.
False	(Default) The data currently in the control, if any, is the same as the data in the current record .

Remarks

When a data control moves from record to record, it passes data from fields in the current record to controls bound to the specific field or the entire record. As data is displayed in the bound controls, the **DataChanged** property is set to **False**. If the user or any other operation changes the value in the bound control, the **DataChanged** property is set to **True**. Simply moving to another record doesn't affect the **DataChanged** property.

When the data control starts to move to a different record, the Validate event occurs. If **DataChanged** is **True** for any bound control, the data control automatically invokes the **Edit** and **Update** methods to post the changes to the database.

If you don't wish to save changes from a bound control to the database, you can set the **DataChanged** property to **False** in the Validate event.

Inspect the value of the **DataChanged** property in your code for a control's Change event to avoid a cascading event. This applies to both bound and unbound controls.

Data Type

Boolean

See Also

Applies To: Masked Edit Control

DataField Property (ActiveX Controls)

Returns or sets the name of a field that a data consumer will be bound to.

Syntax

object.**DataField** [= *string*]

The **DataField** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
string	A string expression that evaluates to the name of one of the fields in the **Recordset** object specified by a da ta source.

Remarks

Bound controls provide access to specific data in your database. Bound controls that manage a single field typically display the value of a specific field in the current record. The **DataSource** property of a bound control specifies a valid data source, and the **DataField** property specifies a valid field name in the **Recordset** object created by the data source. Together, these properties specify what data appears in the bound control.

When you use a **QueryDef** object or SQL statement that returns the results of an expression, the field name is automatically generated by the Microsoft Jet database engine. For example, when you code an SQL aggregate function or an expression in your SQL query, unless you alias the aggregate fields using an AS clause, the field names are automatically generated. Generally, the expression field name is Expr1 followed by a three-character number starting with 000. The first expression returned would be named Expr1000.

It's recommended that you code your SQL queries to alias expression columns as shown below:

```
Adodc1.RecordSource = "Select AVG(Sales)  " _
   & " AS AverageSales From SalesTable"
Text1.DataField = "AverageSales"
Adodc1.Refresh
```

> **Note** Make sure the **DataField** property setting is valid for each bound control. If you change the setting of a data control's **RecordSource** property and then use **Refresh**, the **Recordset** identifies the new object. This may invalidate the **DataField** settings of bound controls and produce a trappable error.

See Also

DataSource Property (ActiveX Controls)

Applies To: Masked Edit Control

DataFormat Property (ActiveX Controls)

Sets or returns the **StdDataFormat** object to which a bound object is attached. Read/write both at design time and run time.

Syntax

object.**DataFormat** = *formatobject*

The **DataFormat** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
formatobject	Required. A **StdDataFormat** object.

Remarks

The **DataFormat** property can also be set through a property page from the Properties window. If the setting in code differs from the property page, the property page setting is used for the first record fetched, and from then on the values in code will be used.

The **DataFormat** property of the **DataCombo** control is an **Extender** property. Therefore it is always visible on the property sheet and can be set in code. However the **DataCombo** control only formats the top item in its list. This can be disconcerting to the end user who sees a formatted top item, but is only given a list of unformatted items to select from. The formatted item may also mislead end users who assume the item will be entered in the database as formatted. For these reasons, it is advisable to not set the **DataFormat** property when using the **DataCombo** control.

See Also

Applies To: Masked Edit Control

DataMember Property (ActiveX Controls)

Returns or sets a specified data member from among several offered by the data provider.

Syntax

object.**DataMember** [= *string*]

Part	Description
object	Required. An object expression that evaluates to an object in the Applies To list .
string	The name of a data member.

Remarks

A data provider can have multiple sets of data that a data consumer can choose to bind to. Each set of data is called a "data member," and is identified by a unique string.

For example, when using a **Data Environment** that contains several **Command** objects as a **DataSource**, the **DataMember** specifies which **Command** object to use.

When using a class module or a user control as a data source, program the **GetDataMember** to return an appropriate data member. The event's *DataMember* argument contains the value of the **DataMember** property. By querying the argument, you can determine what data member is requested, and pass back the appropriate data through the *Data* argument.

See Also

Applies To: MSChart Control

DataSource Property (ActiveX Controls)

Returns or sets a data source through which a data consumer is bound to a database.

Syntax

object.**DataSource** [=*datasource*]

The **DataSource** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
datasource	An object reference that qualifies as a data source, including **ADO Recordset** objects, and classes or use r controls defined as data sources (**DataSourceBehavior** property = **vbDataSource**).

Remarks

Use the **Set** statement to set the **DataSource** property, as shown below:

```
Set DataGrid1.DataSource = ADODC1
```

See Also

Applies To: MSChart Control

DragIcon Property (ActiveX Controls)

Returns or sets the icon to be displayed as the pointer in a drag-and-drop operation.

Syntax

object.**DragIcon** [= *icon*]

The **DragIcon** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
icon	Any code reference that returns a valid icon, such as a reference to a form's icon (`Form1.Icon`), a reference to another control's **DragIcon** property (`Text1.DragIcon`), or the **LoadPicture** function.

Settings

The settings for *icon* are:

Setting	Description
(none)	(Default) An arrow pointer inside a rectangle.
Icon	A custom mouse pointer. You specify the icon by setting it using the Properties window at design time. You can also use the **LoadPicture** function at run time. The file you load must have the .ico filename extension and format.

Remarks

You can use the **DragIcon** property to provide visual feedback during a drag-and-drop operation — for example, to indicate that the source control is over an appropriate target. **DragIcon** takes effect when the user initiates a drag-and-drop operation. Typically, you set **DragIcon** as part of a MouseDown or DragOver event procedure.

> **Note** At run time, the **DragIcon** property can be set to any object's **DragIcon** or **Icon** property, or you can assign it an icon returned by the **LoadPicture** function.

When you set the **DragIcon** property at run time by assigning the **Picture** property of one control to the **DragIcon** property of another control, the **Picture** property must contain an .ico file, not a .bmp file.

Example

This example changes the **DragIcon** property setting each time you drag a **PictureBox** control. To try this example, paste the code into the Declarations section of a form that contains a **PictureBox** control. Set the **DragMode** property = 1, and then press F5 and click and drag the **PictureBox** control.

```
Private Sub Form_DragDrop (Source As Control, X As Single, Y As Single)
   Dim Pic   ' Declare variable.
   Source.Move X, Y   ' Set position of control.
   Pic = "ICONS\OFFICE\CRDFLE01.ICO"   ' Get name of icon file.
   If Source.DragIcon = False Then   ' If no picture loaded,
      Source.DragIcon = LoadPicture(Pic)   ' load picture.
   Else
      Source.DragIcon = LoadPicture()   ' Unload picture.
   End If
End Sub
```

See Also

Drag Method (ActiveX Controls) | DragDrop Event (ActiveX Controls) | DragMode Property (ActiveX Controls) | MousePointer Property (ActiveX Controls)

Applies To: MSChart Control | Masked Edit Control

DragMode Property (ActiveX Controls)

Returns or sets a value that determines whether manual or automatic drag mode is used for a drag-and-drop operation.

Syntax

object.**DragMode** [= *number*]

The **DragMode** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
number	An integer that specifies the drag mode, as described in Settings.

Settings

The settings for *number* are:

Constant	Setting	Description
VbManual	0	(Default) Manual — requires using the **Drag** method to initiate a drag-and-drop operation on the source control.
VbAutomatic	1	Automatic — clicking the source control automatically initiates a drag-and-drop operation. **OLE** container controls are automatically dragged only when they don't have the focus.

Remarks

When **DragMode** is set to 1 (Automatic), the control doesn't respond as usual to mouse events. Use the 0 (Manual) setting to determine when a drag-and-drop operation begins or ends; you can use this setting to initiate a drag-and-drop operation in response to a keyboard or menu command or to enable a source control to recognize a MouseDown event prior to a drag-and-drop operation.

Clicking while the mouse pointer is over a target object or form during a drag-and-drop operation generates a **DragDrop** event for the target object. This ends the drag-and-drop operation. A drag-and-drop operation may also generate a DragOver event.

> **Note** While a control is being dragged, it can't recognize other user-initiated mouse or keyboard events (**KeyDown**, **KeyPress** or **KeyUp**, **MouseDown**, **MouseMove**, or **MouseUp**). However, the control can receive events initiated by code.

Example

This example enables and disables the ability to drag a **CommandButton** control each time a form is clicked. To try this example, paste the code into the Declarations section of a form that contains a **CommandButton**, and then press F5 and click the form.

```
Private Sub Form_Click ()
 ' Check DragMode.
   If Command1.DragMode = vbManual Then
      ' Turn it on.
  Command1.DragMode = vbAutomatic
   Else
      ' Or turn it off.
     Command1.DragMode = vbManual
   End If
End Sub
```

See Also

DragDrop Event (ActiveX Controls) | DragIcon Property (ActiveX Controls) | DragOver Event (ActiveX Controls)

Applies To: MSChart Control | Masked Edit Control

Drag-and-Drop Constants (ActiveX Controls)

DragOver Event

Constant	Value	Description
vbEnter	0	Source control dragged into target
vbLeave	1	Source control dragged out of target
vbOver	2	Source control dragged from one position in target to another

Drag Method (Controls)

Constant	Value	Description
vbCancel	0	Cancel drag operation
vbBeginDrag	1	Begin dragging control
vbEndDrag	2	Drop control

DragMode Property

Constant	Value	Description
vbManual	0	Manual
vbAutomatic	1	Automatic

Enabled Property (ActiveX Controls)

Returns or sets a value that determines whether a form or control can respond to user-generated events.

Syntax

object.**Enabled** [= *boolean*]

The **Enabled** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list. If *object* is omitted, t he form associated with the active form module is assumed to be *object*.
boolean	A Boolean expression that specifies whether *object* can respond to user-generated events.

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) Allows *object* to respond to events.
False	Prevents *object* from responding to events.

Remarks

The **Enabled** property allows objects to be enabled or disabled at run time. For example, you can disable objects that don't apply to the current state of the application. You can also disable a control used purely for display purposes, such as a text box that provides read-only information.

See Also

Applies To: Masked Edit Control | MSChart Control

Font Property (ActiveX Controls)

Returns a **Font** object.

Syntax

object.**Font**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

Use the **Font** property of an object to identify a specific **Font** object whose properties you want to use. For example, the following code changes the **Bold** property setting of a **Font** object identified by the **Font** property of a **TextBox** object:

```
txtFirstName.Font.Bold = True
```

See Also

Applies To: AxisTitle Object | Masked Edit Control

Height, Width Properties (ActiveX Controls)

Return or set the dimensions of an object or the width of the **Columns** object of a **DataGrid** control. For the **Printer** and **Screen** objects, not available at design time.

Syntax

object.**Height** [= *number*]

object.**Width** [= *number*]

The **Height** and **Width** property syntaxes have these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
number	A numeric expression specifying the dimensions of an object, as described in Settings.

Settings

Measurements are calculated as follows:

- **Control** — measured from the center of the control's border so that controls with different border widths align correctly. These properties use the scale units of a control's container.

Remarks

Use the **Height**, **Width**, **Left**, and **Top** properties for operations or calculations based on an object's total area, such as sizing or moving the object. Use the **ScaleLeft**, **ScaleTop**, **ScaleHeight**, and **ScaleWidth** properties for operations or calculations based on an object's internal area, such as drawing or moving objects within another object.

Example

This example sets the size of a form to 75 percent of screen size and centers the form when it is loaded. To try this example, paste the code into the Declarations section of a form. Then press F5 and click the form.

```
Private Sub Form_Click ()
   Width = Screen.Width * .75   ' Set width of form.
   Height = Screen.Height * .75   ' Set height of form.
   Left = (Screen.Width - Width) / 2   ' Center form horizontally.
   Top = (Screen.Height - Height) / 2   ' Center form vertically.
End Sub
```

See Also

Left, Top Properties (ActiveX Controls) | Move Method (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control | Pen Object | StatLine Object | Wall Object

HelpContextID Property (ActiveX Controls)

Returns or sets an associated context number for an object. Used to provide context-sensitive Help for your application.

Syntax

object.**HelpContextID** [= *number*]

The **HelpContextID** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list. If *object* is omitted, the form associated with the active form module is assumed to be *object*.
number	A numeric expression that specifies the context number of the Help topic associated with *object*.

Settings

The settings for *number* are:

Setting	Description
0	(Default) No context number specified.
> 0	An integer specifying a valid context number.

Remarks

For context-sensitive Help on an object in your application, you must assign the same context number to both *object* and to the associated Help topic when you compile your Help file.

If you've created a Microsoft Windows operating environment Help file for your application and set the application's **HelpFile** property, when a user presses the F1 key, Visual Basic automatically calls Help and searches for the topic identified by the current context number.

The current context number is the value of **HelpContextID** for the object that has the focus. If **HelpContextID** is set to 0, then Visual Basic looks in the **HelpContextID** of the object's container, and then that object's container, and so on. If a nonzero current context number can't be found, the F1 key is ignored.

For a **Menu** control, **HelpContextID** is normally read/write at run time. But **HelpContextID** is read-only for menu items that are exposed or supplied by Visual Basic to add-ins, such as the Add-In Manager command on the Add-Ins menu.

See Also

Applies To: Masked Edit Control | MSChart Control

HideSelection Property (ActiveX Controls)

Returns a value that determines whether selected text appears highlighted when a control loses the focus.

Syntax

object.**HideSelection**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Return Values

The **HideSelection** property return values are:

Value	Description
True	(Default) Selected text doesn't appear highlighted when the control loses the focus .
False	Selected text appears highlighted when the control loses the focus.

Remarks

You can use this property to indicate which text is highlighted while another form or a dialog box has the focus — for example, in a spell-checking routine.

See Also

Applies To: Masked Edit Control

hWnd Property (ActiveX Controls)

Returns a handle to a form or control.

> **Note** This property is not supported for the **OLE** container control.

Syntax

object.**hWnd**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

The Microsoft Windows operating environment identifies each form and control in an application by assigning it a handle, or **hWnd**. The **hWnd** property is used with Windows API calls. Many Windows operating environment functions require the **hWnd** of the active window as an argument.

> **Note** Because the value of this property can change while a program is running, never store the **hWnd** value in a variable.

See Also

Applies To: Masked Edit Control | MSChart Control

Index Property (ActiveX Controls)

Returns or sets the number that uniquely identifies an object in a collection.

Syntax

object.**Index**

The object placeholder is an object expression that evaluates to an object in the Applies To list.

Remarks

The **Index** property is set by default to the order of the creation of objects in a collection. The index for the first object in a collection will always be one (1).

The value of the **Index** property of an object can change when objects in the collection are reordered, such as when you set the **Sorted** property to **True**. If you expect the **Index** property to change dynamically, it may be more useful to refer to objects in a collection by using the **Key** property.

See Also

Index Property (Brush) | Index Property (Intersection) | Name Property (ActiveX Controls) | Tag Property (ActiveX Controls)

Applies To: Brush Object | Intersection Object | Masked Edit Control | MSChart Control

Key Property (ActiveX Controls)

Returns or sets a string that uniquely identifies a member in a collection.

Syntax

object.**Key** [= *string*]

The **Key** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
string	A unique string identifying a member in a collection.

Remarks

If the string is not unique, an error will occur.

You can set the **Key** property when you use the **Add** method to add an object to a collection.

The value of the **Index** property of an object can change when objects in the collection are reordered, such as when you set the **Sorted** property to **True**. If you expect the **Index** property to change dynamically, refer to objects in a collection using the **Key** property.

In addition, you can use the **Key** property to make your Visual Basic project "self-documenting" by assigning meaningful names to the objects in a collection.

See Also

Applies To: LightSources Collection

Left, Top Properties (ActiveX Controls)

Left — returns or sets the distance between the internal left edge of an object and the left edge of its container.

Top — returns or sets the distance between the internal top edge of an object and the top edge of its container.

Syntax

object.**Left** [= *value*]

object.**Top** [= *value*]

The **Left** and **Top** property syntaxes have these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
value	A numeric expression specifying distance.

Remarks

For a form, the **Left** and **Top** properties are always expressed in twips; for a control, they are measured in units depending on the coordinate system of its container. The values for these properties change as the object is moved by the user or by code.

For either property, you can specify a single-precision number.

Use the **Left**, **Top**, **Height**, and **Width** properties for operations based on an object's external dimensions, such as moving or resizing. Use the **ScaleLeft**, **ScaleTop**, **ScaleHeight**, and **ScaleWidth** properties for operations based on an object's internal dimensions, such as drawing or moving objects that are contained within the object.

Example

This example sets the size of a form to 75 percent of screen size and centers the form when it is loaded. To try this example, paste the code into the Declarations section of a form, and then press F5 and click the form.

```
Private Sub Form_Click ()
   Width = Screen.Width * .75   ' Set width of form.
   Height = Screen.Height * .75   ' Set height of form.
   Left = (Screen.Width - Width) / 2   ' Center form horizontally.
   Top = (Screen.Height - Height) / 2   ' Center form vertically.
End Sub
```

See Also

Height, Width Properties (ActiveX Controls) | Move Method (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

MouseIcon Property (ActiveX Controls)

Returns or sets a custom mouse icon.

Syntax

object.**MouseIcon = LoadPicture(***pathname***)**

object.**MouseIcon [=** *picture***]**

The **MouseIcon** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
pathname	A string expression specifying the path and filename of the file containing the custom icon .
picture	The **Picture** property of a **Form** object, **PictureBox** control, or **Image** control.

Remarks

The **MouseIcon** property provides a custom icon that is used when the **MousePointer** property is set to 99.

You can use the **MouseIcon** property to load either cursor or icon files. The **MouseIcon** property provides your program with easy access to custom cursors of any size, with any desired hot spot location. Visual Basic does not load animated cursor (.ani) files, even though 32-bit versions of Windows support these cursors.

Applies To: Masked Edit Control

MousePointer Property (ActiveX Controls)

Returns or sets a value indicating the type of mouse pointer displayed when the mouse is over a particular part of an object at run time.

Syntax

object.**MousePointer** [= *value*]

The **MousePointer** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
value	An integer specifying the type of mouse pointer displayed, as described in Settings .

Settings

The settings for *value* are:

Constant	Value	Description
*xxx***Default**	0	(Default) Shape determined by the object.
*xxx***Arrow**	1	Arrow.
*xxx***Crosshair**	2	Cross (crosshair pointer).
*xxx***IBeam**	3	I beam.
*xxx***IconPointer**	4	Icon (small square within a square).
*xxx***SizePointer**	5	Size (four-pointed arrow pointing north, south, east, and west) .
*xxx***SizeNESW**	6	Size NE SW (double arrow pointing northeast and southwest).
*xxx***SizeNS**	7	Size N S (double arrow pointing north and south).
*xxx***SizeNWSE**	8	Size NW SE (double arrow pointing northwest and southeast).
*xxx***SizeWE**	9	Size W E (double arrow pointing west and east).
*xxx***UpArrow**	10	Up Arrow.
*xxx***Hourglass**	11	Hourglass (wait).
*xxx***NoDrop**	12	No Drop.
*xxx***ArrowHourglass**	13	Arrow and hourglass.
*xxx***ArrowQuestion**	14	Arrow and question mark.
*xxx***SizeAll**	15	Size all.
*xxx***Custom**	99	Custom icon specified by the **MouseIcon** property.

> **Note** The *xxx* prefix refers to the ActiveX control in use. For example, the Masked Edit control uses **msk** for the prefix. Prefixes for the constants change with the specific control or group of controls. However, the description remains the same unless indicated.

Remarks

You can use this property when you want to indicate changes in functionality as the mouse pointer passes over controls on a form or dialog box. The Hourglass setting (11) is useful for indicating that the user should wait for a process or operation to finish.

> **Note** If your application calls DoEvents, the **MousePointer** property may temporarily change when over an ActiveX control.

MousePointer Constants (ActiveX Controls)

Following are the constants for mouse pointers:

Constant	Value	Description
*xxx***Default**	0	(Default) Shape determined by the object.
*xxx***Arrow**	1	Arrow.
*xxx***Cross**	2	Cross (cross-hair pointer).
*xxx***IBeam**	3	I Beam.
*xxx***Icon**	4	Icon (small square within a square).
*xxx***Size**	5	Size (four-pointed arrow pointing north, south, east, and west).
*xxx***SizeNESW**	6	Size NE SW (double arrow pointing northeast and southwest).
*xxx***SizeNS**	7	Size N S (double arrow pointing north and south).
*xxx***SizeNWSE**	8	Size NW, SE.
*xxx***SizeEW**	9	Size E W (double arrow pointing east and west).
*xxx***UpArrow**	10	Up Arrow.
*xxx***Hourglass**	11	Hourglass (wait).
*xxx***NoDrop**	12	No Drop.
*xxx***ArrowHourglass**	13	Arrow and hourglass.
*xxx***ArrowQuestion**	14	Arrow and question mark.
*xxx***SizeAll**	15	Size all.
*xxx***Custom**	99	Custom icon specified by the **MouseIcon** property.

Note The *xxx* prefix refers to the ActiveX control in use. For example, the Masked Edit control uses **msk** for the prefix. Prefixes for the constants change with the specific control or group of controls. However, the description remains the same unless indicated.

See Also

MousePointer Property (ActiveX Controls)

Name Property (ActiveX Controls)

Returns the name used in code to identify a form, control, or data access object. Read-only at run time.

Returns or sets the name of a font object.

Syntax

object.**Name**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list. If *object* is omitted, the form associated with the active form module is assumed to be *object*.

Remarks

The default name for new objects is the kind of object plus a unique integer. For example, the first new **Form** object is Form1, a new **MDIForm** object is MDIForm1, and the third **TextBox** control you create on a form is Text3.

An object's **Name** property must start with a letter and can be a maximum of 40 characters. It can include numbers and underline (_) characters but can't include punctuation or spaces. Forms can't have the same name as another public object such as **Clipboard**, **Screen**, or **App**. Although the **Name** property setting can be a keyword, property name, or the name of another object, this can create conflicts in your code.

You can use a form's **Name** property with the **Dim** statement at run time to create other instances of the form. You can't have two forms with the same name at design time.

You can create an array of controls of the same type by setting the **Name** property to the same value. For example, when you set the name of all option buttons in a group to MyOpt, Visual Basic assigns unique values to the **Index** property of each control to distinguish it from others in the array. Two controls of different types can't share the same name.

> **Note** Although Visual Basic often uses the **Name** property setting as the default value for the **Caption**, **LinkTopic**, and **Text** properties, changing one of these properties doesn't affect the others.

Changing the case of the **Name** property value for a Form or other module without otherwise changing the name itself, however, can cause a "Conflicting names" error message the next time the project containing the form or module is loaded. For example, changing "Form1" to "form1" will cause the error; changing "Form1" to "formX" will not.

The error is caused by the way module names are stored within the project file — the procedure for changing names within the project file isn't case sensitive, while the procedure for reading names on project load is.

See Also

Index Property (ActiveX Controls) | Text Property (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

Object Property (ActiveX Controls)

Returns the object and/or a setting of an object's method or property.

Syntax

object.**Object**[.*property* | .*method*]

The **Object** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
property	Property that the object supports.
method	Method that the object supports.

Remarks

Use this property to specify an object you want to use in an Automation task.

You use the object returned by the **Object** property in an Automation task by using the properties and methods of that object. For information on which properties and methods an object supports, see the documentation for the application that created the object.

See Also

Applies To: Masked Edit Control | MSChart Control

OLEDragMode Property (ActiveX Controls)

Returns or sets whether the component or the programmer handles an OLE drag/drop operation.

Syntax

object.**OLEDragMode** = *mode*

The **OLEDragMode** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mode	An integer which specifies the method with which an component handles OLE drag/drop operations, as de scribed in Settings.

Settings

The settings for *mode* are:

Constant	Value	Description
*xxx***OLEDragManual**	0	Manual. The programmer handles all OLE drag/drop operations.
*xxx***OLEDragAutomatic**	1	Automatic. The component handles all OLE drag/drop operations .

Remarks

When **OLEDragMode** is set to **Manual**, you must call the **OLEDrag** method to start dragging, which then triggers the **OLEStartDrag** event.

When **OLEDragMode** is set to **Automatic**, the source component fills the **DataObject** object with the data it contains and sets the *effects* parameter before initiating the OLEStartDrag event (as well as the OLESetData and other source-level OLE drag/drop events) when the user attempts to drag out of the control. This gives you control over the drag/drop operation and allows you to intercede by adding other formats, or by overriding or disabling the automatic data and formats using the **Clear** or **SetData** methods.

If the source's **OLEDragMode** property is set to **Automatic**, and no data is loaded in the **OLEStartDrag** event, or *aftereffects* is set to **0**, then the OLE drag/drop operation does not occur.

> **Note** If the **DragMode** property of a control is set to **Automatic**, the setting of **OLEDragMode** is ignored, because regular Visual Basic drag and drop events take precedence.

See Also

Applies To: Masked Edit Control | MSChart Control

OLEDropMode Property (ActiveX Controls)

Returns or sets how a target component handles drop operations.

Syntax

object.**OLEDropMode** [= *mode*]

The **OLEDropMode** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mode	An enumerated integer which specifies the method which a component handles OLE drag/drop operations, as described in Settings.

Settings

The settings for *mode* are:

Constant	Value	Description
*xxx***OLEDropNone**	0	None. The target component does not accept OLE drops and displays the No Drop cursor.
*xxx***OLEDropManual**	1	Manual. The target component triggers the OLE drop events, allowing the programmer to handle the OLE drop operation in code.
*xxx***OLEDropAutomatic**	2	Automatic. The target component automatically accepts OLE drops if the **DataObject** object contains data in a format it recognizes. No mouse or OLE drag/drop events on the target will occur when **OLEDropMode** is set to *xxx***OLEDropAutomatic**.

Remarks

> **Note** The target component inspects what is being dragged over it in order to determine which events to trigger: the OLE drag/drop events, or the Visual Basic drag/drop events. There is no collision of components or confusion about which events are fired, because only one type of object can be dragged at a time.

Applies To: Masked Edit Control | MSChart Control

Parent Property (ActiveX Controls)

Returns the form, object, or collection that contains a control or another object or collection.

Syntax

object.**Parent**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

Use the **Parent** property to access the properties, methods, or controls of an object's parent. For example:

```
MyButton.Parent.MousePointer = 4
```

The **Parent** property is useful in an application in which you pass objects as arguments. For example, you could pass a control variable to a general procedure in a module, and use the **Parent** property to access its parent form.

There is no relationship between the **Parent** property and the **MDIChild** property. There is, however, a parent-child relationship between an **MDIForm** object and any **Form** object that has its **MDIChild** property set to **True**.

Example

This example passes a control from a form that doesn't have the focus to a procedure in a module, and then displays the state of the control on the parent form. To try this example, create three forms: Form1, containing a **CommandButton** control, and Form2 and Form3, each containing a **CheckBox** control. You must also create a new module (click Add Module in the Project menu). Paste the code into the Declarations sections of the respective forms or module, and then press F5 to run the program.

```
' Enter this code into Form1.
Private Sub Form_Load ()
   Form2.Show   ' Display all forms.
   Form3.Show
   Form2.AutoRedraw = True
   Form3.AutoRedraw = True
End Sub

Private Sub Command1_Click ()
   ReadCheckBox Form2.Check1   ' Call procedure in other module
   ReadCheckBox Form3.Check1   ' and send control as argument.
End Sub

' Enter this code into Module1.
Sub ReadCheckBox (Source As Control)
   If Source.Value Then
      Source.Parent.Cls   ' Clear parent form.
      Source.Parent.Print "CheckBox is ON."  ' Display on parent form.
   Else
      Source.Parent.Cls   ' Clear parent form.
      Source.Parent.Print "CheckBox is OFF."  ' Display on parent form.
   End If
End Sub
```

Applies To: Masked Edit Control | MSChart Control

RecordSource Property (ActiveX Controls)

Returns or sets the underlying table, SQL statement, or stored procedure.

Syntax

object.**RecordSource** [= *value*]

The **RecordSource** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
value	A string expression specifying a name, as described in Settings.

Settings

The settings for *value* are:

Setting	Description
A table name	The name of one of the tables defined in the **Database** object's **TableDefs** collection.
An SQL query	A valid SQL string using syntax appropriate for the data source.
stored procedure	The name of a stored procedure in the database. When using DAO, the name of one of the **QueryDef** objects in the **Database** object's **QueryDefs** collection.

Remarks

The **RecordSource** property specifies the source of the records accessible through bound controls on your form.

If you set the **RecordSource** property to the name of an existing table in the database, all of the fields in that table are visible to the bound controls attached to the **Data** control. For table-type recordsets (**RecordsetType** = **vbRSTypeTable**), the order of the records retrieved is set by the **Index** object that you select using the **Index** property of the **Recordset**. For dynaset-type and snapshot-type **Recordset** objects, you can order the records by using a SQL statement with an Order By clause in the **RecordSource** property of the **Data** control. Otherwise, the data is returned in no particular order.

If you set the **RecordSource** property to the name of an existing **QueryDef** in the database, all fields returned by the **QueryDef** are visible to the bound controls attached to the **Data** control. The order of the records retrieved is set by the **QueryDef** object's query. For example, the **QueryDef** may include an ORDER BY clause to change the order of the records returned by the **Recordset** created by the **Data** control or a WHERE clause to filter the records. If the **QueryDef** doesn't specify an order, the data is returned in no particular order.

> **Note** At design-time, the **QueryDef** objects displayed in the Properties window for the **RecordSource** property are filtered out to display only **QueryDef** objects that are usable with the **Data** control. **QueryDef** objects which have parameters, and **QueryDef** objects which have the following types are not displayed: **dbQAction**, **dbQCrosstab**, **dbQSQLPassThrough** and **dbQSetOperation**.

If you set the **RecordSource** property to an SQL statement that returns records, all fields returned by the SQL query are visible to the bound controls attached to the **Data** control. This statement may include an ORDER BY clause to change the order of the records returned by the **Recordset** created by the **Data** control or a WHERE clause to filter the records. If the database you specify in the **Database** and **Connect** property isn't a Microsoft Jet engine database, and if the **dbSQLPassThrough** option is set in the **Options** property, your SQL query must use the syntax required by that database engine.

> **Note** Whenever your **QueryDef** or SQL statement returns a value from an expression, the field name of the expression is created automatically by the Microsoft Jet database engine. Generally, the name is Expr1 followed by a three-character number beginning with 000. For example, the first expression would be named: Expr1000.

In most cases you'll want to alias expressions so you know the name of the column to bind to the bound control. See the SQL SELECT statement AS clause for more information.

After changing the value of the **RecordSource** property at run time, you must use the **Refresh** method to enable the change and rebuild the **Recordset**.

At run time, if the **Recordset** specifies an invalid **Table** name, **QueryDef** name, or contains invalid SQL syntax, a trappable error will result. If this error occurs during the initial Form_Load procedure, the error is not trappable.

> **Note** Make sure each bound control has a valid setting for its **DataField** property. If you change the setting of a **Data** control's **RecordSource** property and then use **Refresh**, the **Recordset** identifies the new object. This may invalidate the **DataField** settings of bound controls and cause a trappable error.

Data Type

String

See Also

DataField Property (ActiveX Controls) | DataSource Property (ActiveX Controls) | Index Property (ActiveX Controls)

Applies To: MSChart Control

SelLength, SelStart, SelText Properties (ActiveX Controls)

SelLength — returns or sets the number of characters selected.

SelStart — returns or sets the starting point of text selected; indicates the position of the insertion point if no text is selected.

SelText — returns or sets the string containing the currently selected text; consists of a zero-length string ("") if no characters are selected.

These properties aren't available at design time.

Syntax

object.**SelLength** [= *number*]

object.**SelStart** [= *index*]

object.**SelText** [= *value*]

The **SelLength**, **SelStart**, and **SelText** property syntaxes have these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
number	A numeric expression specifying the number of characters selected. For **SelLength** and **SelStart**, the valid range of settings is 0 to text length — the total number of characters in the edit area of a **ComboBox** or **TextBox** control.
index	A numeric expression specifying the starting point of the selected text, as described in Settings.
value	A string expression containing the selected text.

Remarks

Use these properties for tasks such as setting the insertion point, establishing an insertion range, selecting substrings in a control, or clearing text. Used in conjunction with the **Clipboard** object, these properties are useful for copy, cut, and paste operations.

When working with these properties:

- Setting **SelLength** less than 0 causes a run-time error.
- Setting **SelStart** greater than the text length sets the property to the existing text length; changing **SelStart** changes the selection to an insertion point and sets **SelLength** to 0.
- Setting **SelText** to a new value sets **SelLength** to 0 and replaces the selected text with the new string.

Example

This example enables the user to specify some text to search for and then searches for the text and selects it, if found. To try this example, paste the code into the Declarations section of a form that contains a wide **TextBox** control, and then press F5 and click the form.

```
Private Sub Form_Load ()
   Text1.Text = "Two of the peak human experiences"
   Text1.Text = Text1.Text & " are good food and classical music."
End Sub
Private Sub Form_Click ()
   Dim Search, Where   ' Declare variables.
   ' Get search string from user.
   Search = InputBox("Enter text to be found:")
   Where = InStr(Text1.Text, Search)   ' Find string in text.
   If Where Then   ' If found,
      Text1.SetFocus
      Text1.SelStart = Where - 1   ' set selection start and
      Text1.SelLength = Len(Search)   ' set selection length.
   Else
      MsgBox "String not found."   ' Notify user.
   End If
End Sub
```

See Also

SelText Property (Masked Edit Control) | Text Property (ActiveX Controls)

Applies To: Masked Edit Control

TabIndex Property (ActiveX Controls)

Returns or sets the tab order of most objects within their parent form.

Syntax

object.**TabIndex** [= *index*]

The **TabIndex** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	An integer from 0 to (*n*–1), where *n* is the number of controls on the form that have a **TabIndex** property. A ssigning a **TabIndex** value of less than 0 generates an error.

Remarks

By default, Visual Basic assigns a tab order to controls as you draw them on a form, with the exception of the **Menu**, **Timer**, **Data**, **Image**, **Line** and **Shape** controls, which are not included in the tab order. At run time, invisible or disabled controls and controls that can't receive the focus (**Frame** and **Label** controls) remain in the tab order but are skipped during tabbing.

Each new control is placed last in the tab order. If you change the value of a control's **TabIndex** property to adjust the default tab order, Visual Basic automatically renumbers the **TabIndex** of other controls to reflect insertions and deletions. You can make changes at design time using the Properties window or at run time in code.

The **TabIndex** property isn't affected by the **ZOrder** method.

> **Note** A control's tab order doesn't affect its associated access key. If you press the access key for a **Frame** or **Label** control, the focus moves to the next control in the tab order that can receive the focus.

When loading forms saved as ASCII text, controls with a **TabIndex** property that aren't listed in the form description are automatically assigned a **TabIndex** value. In subsequently loaded controls, if existing **TabIndex** values conflict with earlier assigned values, the controls are automatically assigned new values.

When you delete one or more controls, you can use the **Undo** command to restore the controls and all their properties except for the **TabIndex** property, which can't be restored. **TabIndex** is reset to the end of the tab order when you use Undo.

Example

This example reverses the tab order of a group of buttons by changing the **TabIndex** property of a command button array. To try this example, paste the code into the Declarations section of a form that contains four **CommandButton** controls. Set the **Name** property to CommandX for each button to create the control array, and then press F5 and click the form to reverse the tab order of the buttons.

```
Private Sub Form_Click ()
   Dim I, X   ' Declare variables.
   ' Reverse tab order by setting start value of X.
   If Command1(0).TabIndex = 0 Then X = 4 Else X = 1
      For I = 0 To 3
         Command1(I).Caption = X   ' Set caption.
         Command1(I).TabIndex = X - 1   ' Set tab order.
         If Command1(0).TabIndex = 3 Then
            X = X - 1   ' Decrement X.
         Else
            X = X + 1   ' Increment X.
         End If
      Next I
End Sub
```

See Also

TabStop Property (ActiveX Controls) | ZOrder Method (ActiveX Controls)

Applies To: MSChart Control

TabStop Property (ActiveX Controls)

Returns or sets a value indicating whether a user can use the TAB key to give the focus to an object.

Syntax

object.**TabStop** [= *boolean*]

The **TabStop** property syntax has these parts:

Part	Description
Object	An object expression that evaluates to an object in the Applies To list.
Boolean	A Boolean expression specifying whether the object is a tab stop, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) Designates the object as a tab stop.
False	Bypasses the object when the user is tabbing, although the object still holds its place in the actual tab order, as determined by the **TabIndex** property.

Remarks

This property enables you to add or remove a control from the tab order on a form.

See Also

TabIndex Property (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

Tag Property (ActiveX Controls)

Returns or sets an expression that stores any extra data needed for your program. Unlike other properties, the value of the **Tag** property isn't used by Visual Basic; you can use this property to identify objects.

Syntax

object.**Tag** [= *expression*]

The **Tag** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
expression	A string expression identifying the object. The default is a zero-length string ("") .

Remarks

You can use this property to assign an identification string to an object without affecting any of its other property settings or causing side effects. The **Tag** property is useful when you need to check the identity of a control or **MDIForm** object that is passed as a variable to a procedure.

> **Tip** When you create a new instance of a form, assign a unique value to the **Tag** property.
>
> **Note** The **Tag** property is of type Variant for ActiveX control collections such as **Toolbar Button** objects, **TreeView Node** objects, **ListView ListItem** and **ColumnHeader** objects, **ImageList ListImage** objects, **TabStrip Tab** objects, and **StatusBar Panel** objects. You can use the **Tag** property to pass values, but it does not allow you to pass objects.

Example

This example displays a unique icon for each control being dragged. To try this example, paste the code into the Declarations section of a form that contains three **PictureBox** controls. Set the **DragMode** property to 1 for Picture1 and Picture2, and then press F5. Use the mouse to drag Picture1 or Picture2 over Picture3 controls.

```
Private Sub Form_Load ()
  Picture1.Tag = "ICONS\ARROWS\POINT03.ICO"
  Picture2.Tag = "ICONS\ARROWS\POINT04.ICO"
End Sub

Private Sub Picture3_DragOver (Source As Control, X As Single, Y As Single, State As Integer)
   If State = vbEnter Then
      ' Select based on each PictureBox's Name property.
      Select Case Source.Name
      Case "Picture1"
         ' Load icon for Picture1.
         Source.DragIcon = LoadPicture(Picture1.Tag)
        Case "Picture2"
         ' Load icon for Picture2.
         Source.DragIcon = LoadPicture(Picture2.Tag)
      End Select
   ElseIf State = vbLeave Then
      ' When source isn't over Picture3, unload icon.
      Source.DragIcon = LoadPicture ()
   End If
End Sub
```

See Also

Name Property (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

Text Property (ActiveX Controls)

Returns or sets the text contained in an object.

Syntax

object.**Text** [= *string*]

The **Text** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
string	A string expression specifying the text appearing in the object.

Example

This example populates a **TreeView** control with the titles of files in a **ListBox** control. When an item in the **TreeView** control is clicked, the **Text** property is displayed in a **Label** on the form. To try the example, place **TreeView**, **Label**, and **ListBox** controls on a form and paste the code into the form's Declarations section. Run the example and click on any item to see its **Text** property.

```
Private Sub Form_Load()
   Dim nodX As Node  ' Declare an object variable for the Node.
   Dim i As Integer  ' Declare a variable for use as a counter.

   ' Add one Node to the TreeView control, and call it the first node
   Set nodX = TreeView1.Nodes.Add()
   nodX.Text = "First Node"

   'Populate the ListBox
      List1.AddItem "Node1"   ' Add each item to list.
      List1.AddItem "Node2"
      List1.AddItem "Node3"
      List1.AddItem "Node4"
      List1.AddItem "Node5"
      List1.AddItem "Node6"
      List1.AddItem "Node7"

   ' Add child nodes to the first Node object. Use the
   ' ListBox to populate the control.
   For i = 0 To List1.ListCount - 1
      Set nodX = TreeView1.Nodes.Add(1, tvwChild)
      nodX.Text = List1.List(i)
   Next i
   Treeview1.Nodes(1).Selected = True
   nodX.EnsureVisible   ' Make sure the node is visible.
End Sub

Private Sub TreeView1_NodeClick(ByVal Node As Node)
   ' Display the clicked Node object's Text property.
   Label1.Caption = Node.Text
End Sub
```

See Also

SelLength, SelStart, SelText Properties (ActiveX Controls)

Applies To: AxisTitle Object | DataPointLabel Object

ToolTipText Property (ActiveX Controls)

Returns or sets a ToolTip.

Syntax

object.**ToolTipText** [= *ToolTipText*]

The **ToolTipText** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
ToolTipText	The string that is displayed when the mouse pointer hovers over the object.

See Also

Applies To: MSChart Control

Visible Property (ActiveX Controls)

Returns or sets a value indicating whether an object is visible or hidden.

Syntax

object.**Visible** [= *boolean*]

The **Visible** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression specifying whether the object is visible or hidden .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) Object is visible.
False	Object is hidden.

Remarks

To hide an object at startup, set the **Visible** property to **False** at design time. Setting this property in code enables you to hide and later redisplay a control at run time in response to a particular event.

> **Note** Using the **Show** or **Hide** method on a form is the same as setting the form's **Visible** property in code to **True** or **False**, respectively.

Example

This example creates animation using two **PictureBox** controls. To try this example, paste the code into the Declarations section of a form that contains two icon-sized **PictureBox** controls. Set the **Name** property to Picture1 for both **PictureBox** controls to create an array, and then press F5 and click the picture to view the animation.

```
Private Sub Form_Load ()
   Dim I   ' Declare variable.
   Picture1(0).BorderStyle = 0   ' Set BorderStyle.
   Picture1(1).BorderStyle = 0
   ' Load icons into picture boxes.
   Picture1(1).Picture = LoadPicture("ICONS\OFFICE\FILES03B.ICO")
   Picture1(0).Picture = LoadPicture("ICONS\OFFICE\FILES03A.ICO")
   For I = 0 To 1
      Picture1(I).Move 400, 400   ' Place graphics at same spot.
   Next I
   Picture1(1).Visible = False   ' Set to invisible.
   Picture1(0).Visible = True   ' Set to visible.
End Sub

Private Sub Picture1_Click (Index As Integer)
   Dim I   ' Declare variable.
   For I = 0 To 1
      ' Switch the visibility for both graphics.
      Picture1(I).Visible = Not Picture1(I).Visible
   Next I
End Sub
```

WhatsThisHelpID Property (ActiveX Controls)

Returns or sets an associated context number for an object. Use to provide context-sensitive Help for your application using the What's This pop-up in Help for 32-bit Windows operating systems.

Syntax

object.**WhatsThisHelpID** [= *number*]

The **WhatsThisHelpID** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
number	A numeric expression specifying a Help context number, as described in Settings.

Settings

The settings for *number* are:

Setting	Description
0	(Default) No context number specified.
>0	An integer specifying the valid context number for the What's This topic associated with the object.

Remarks

Thirty-two–bit Windows operating systems use the What's This button in the upper-right corner of the window to start Windows Help and load a topic identified by the **WhatsThisHelpID** property.

ZOrder Method (ActiveX Controls)

AboutBox Method

Displays the About box for the control.

Syntax

object.**AboutBox**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

This is the same as clicking About in the Properties window.

See Also

Applies To: MSChart Control

Clear Method (ActiveX Controls)

Removes all objects in a collection.

Syntax

*object.***Clear**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

To remove only one object from a collection, use the **Remove** method.

Example

This example adds six **Panel** objects to a **StatusBar** control, creating a total of seven **Panel** objects. A click on the form clears all **Panel** objects when their number reaches seven. If the number of **Panel** objects is less than seven, each click on the form will add a new **Panel** object to the control until the number seven is once again reached. To try the example, place a **StatusBar** control on a form and paste the code into the Declarations section. Run the example and click on the form to clear all **Panel** objects and subsequently add **Panel** objects.

```
Private Sub Form_Load()
   Dim pnlX As Panel   ' Declare object variable for Panel objects.
   Dim I As Integer

   ' Add 6 Panel objects to the single default Panel object,
   ' making 7 Panel objects.
   For I = 1 to 6
      Set pnlX = StatusBar1.Panels.Add
   Next I
End Sub

Private Sub Form_Click()
   ' If the Count of the collection is 7, then clear the collection.
   ' Otherwise, add one Panel and use the collection's Count property
   ' to set its Style.
   If StatusBar1.Panels.Count = 7 Then
      StatusBar1.Panels.Clear
   Else
      Dim pnlX As Panel
      Set pnlX = StatusBar1.Panels.Add( , , "simple", 0)
      ' The Style property is enumerated from 0 to 6. Use the Panels
      ' Count property -1 to set the Style property for the new Panel.
      ' Display all panels regardless of form width.
      pnlX.minwidth = TextWidth("simple")
      pnlX.AutoSize = sbrSpring
      pnlX.Style = Statusbar1.Panels.Count - 1
   End If
End Sub
```

See Also

Remove Method (ActiveX Controls)

Applies To: LightSources Collection

Drag Method (ActiveX Controls)

Begins, ends, or cancels a drag operation of any control except the **Line**, **Menu**, **Shape**, **Timer**, or **CommonDialog** controls. Doesn't support named arguments.

Syntax

object.**Drag** *action*

The **Drag** method syntax has these parts:

Part	Description
object	Required. An object expression that evaluates to an object in the Applies To list. If *object* is omitted, the object whose event procedure contains the **Drag** method is assumed.
action	Optional. A constant or value that specifies the action to perform, as described in Settings. If *action* is omitted, the default is to begin dragging the object.

Settings

The settings for *action* are:

Constant	Value	Description
*xxx***Cancel**	0	Cancels drag operation
*xxx***BeginDrag**	1	Begins dragging *object*
*xxx***EndDrag**	2	Ends dragging and drop *object*

Remarks

These constants are listed in the Visual Basic (VB) object library in the Object Browser.

Using the **Drag** method to control a drag-and-drop operation is required only when the **DragMode** property of the object is set to Manual (0). However, you can use **Drag** on an object whose **DragMode** property is set to Automatic (1 or **vbAutomatic**).

If you want the mouse pointer to change shape while the object is being dragged, use either the **DragIcon** or **MousePointer** property. The **MousePointer** property is only used if no **DragIcon** is specified.

The **Drag** method generally acts synchronously, meaning that subsequent statements aren't executed until the drag action is complete. It can, however, act asynchronously if the **DragMode** property for the control is set to Manual (0 or **vbManual**).

Example

This example uses the **Drag** method to drag the filename of a bitmap (.bmp) file to a picture box where the bitmap is displayed. To try this example, paste all of the code into the Declarations section of a form that contains **DriveListBox**, **DirListBox**, **FileListBox**, **PictureBox**, and **Label** controls. Use the default names for all of the controls. Size and position all controls so they can be easily seen and used. The size and position of the label is unimportant because it's changed at run time. When the program begins, you can browse your file system and load any bitmaps. Once you've located a bitmap that you want to display, click the filename of that bitmap, and drag it to the picture box.

```
Private Sub Form_Load ()
   Picture1.AutoSize = -1   ' Turn on AutoSize.
   Label1.Visible = 0   ' Make the label invisible.
   File1.Pattern = "*.BMP; *.ICO; *.WMF"   ' Set file patterns.
End Sub

Private Sub Dir1_Change ()   ' Any change in Dir1
   File1.Path = Dir1.Path   ' is reflected in File1.
End Sub

Private Sub Drive1_Change ()   ' Any change in Drive1
   Dir1.Path = Drive1.Drive   ' is reflected in Dir1.
End Sub

Private Sub File1_MouseDown (Button As Integer, Shift As Integer, X As Single, Y As Single)
```

```
   Dim DY   ' Declare variable.
   DY = TextHeight("A")   ' Get height of one line.
   Label1.Move File1.Left, File1.Top + Y - DY /2, File1.Width, DY
   Label1.Drag   ' Drag label outline.
End Sub

Private Sub Dir1_DragOver (Source As Control, X As Single, Y As Single, State As Integer)
   ' Change pointer to no drop.
   If State = 0 Then Source.MousePointer = 12
   ' Use default mouse pointer.
   If State = 1 Then Source.MousePointer = 0
End Sub

Private Sub Drive1_DragOver (Source As Control, X As Single, Y As Single, State As Integer)
   ' Change pointer to no drop.
   If State = 0 Then Source.MousePointer = 12
   ' Use default mouse pointer.
   If State = 1 Then Source.MousePointer = 0
End Sub

Private Sub Form_DragOver (Source As Control, X As Single, Y As Single, State As Integer)
   ' Change pointer to no drop.
   If State = 0 Then Source.MousePointer = 12
   ' Use default mouse pointer.
   If State = 1 Then Source.MousePointer = 0
End Sub

Private Sub File1_DragOver (Source As Control, X As Single, Y As Single, State As Integer)
   On Error Resume Next
   If State = 0 And Right$(File1.Filename,4) = ".ICO" Then
      Label1.DragIcon = LoadPicture(File1.Path + "\" + File1.Filename)
   If Err Then MsgBox "The icon file can't be loaded."
   ElseIf State = 1 Then
      Label1.DragIcon = LoadPicture ()   ' Use no drag icon.
   End If
End Sub

Private Sub Picture1_DragDrop (Source As Control, X As Single, Y As Single)
   On Error Resume Next
   Picture1.Picture = LoadPicture(File1.Path + "\" + File1.Filename)
   If Err Then MsgBox "The picture file can't be loaded."
End Sub
```

Applies To: Masked Edit Control | MSChart Control

Move Method (ActiveX Controls)

Moves a control. Doesn't support named arguments.

Syntax

object.**Move** *left*, *top*, *width*, *height*

The **Move** method syntax has these parts:

Part	Description
object	Optional. An object expression that evaluates to an object in the Applies To list. If *object* is omitted, the form with the focus is assumed to be *object*.
left	Required. Single-precision value indicating the horizontal coordinate (x-axis) for the left edge of *object*.
top	Optional. Single-precision value indicating the vertical coordinate (y-axis) for the top edge of *object*.
width	Optional. Single-precision value indicating the new width of *object*.
height	Optional. Single-precision value indicating the new height of *object*.

Remarks

Only the *left* argument is required. However, to specify any other arguments, you must specify all arguments that appear in the syntax before the argument you want to specify. For example, you can't specify *width* without specifying *left* and *top*. Any trailing arguments that are unspecified remain unchanged.

For forms and controls in a **Frame** control, the coordinate system is always in twips. Moving a form on the screen or moving a control in a **Frame** is always relative to the origin (0,0), which is the upper-left corner. When moving a control on a **Form** object or in a **PictureBox** (or an MDI child form on an **MDIForm** object), the coordinate system of the container object is used. The coordinate system or unit of measure is set with the **ScaleMode** property at design time. You can change the coordinate system at run time with the **Scale** method.

Example

This example uses the **Move** method to move a form around on the screen. To try this example, paste the code into the Declarations section of a form, and then press F5 and click the form.

```
Private Sub Form_Click ()
   Dim Inch, Msg   ' Declare variables.
   Msg = "Choose OK to resize and move this form by "
   Msg = Msg & "changing the value of properties."
   MsgBox Msg   ' Display message.
   Inch = 1440   ' Set inch in twips.
   Width = 4 * Inch   ' Set width.
   Height = 2 * Inch   ' Set height.
   Left = 0   ' Set left to origin.
   Top = 0   ' Set top to origin.
   Msg = "Now choose OK to resize and move this form "
   Msg = Msg & "using the Move method."
   MsgBox Msg   ' Display message.
   Move Screen.Width - 2 * Inch, Screen.Height - Inch, 2 * Inch, Inch
End Sub
```

Height, Width Properties (ActiveX Controls) | Left, Top Properties (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

OLEDrag Method (ActiveX Controls)

Causes a component to initiate an OLE drag/drop operation.

Syntax

object.**OLEDrag**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

When the **OLEDrag** method is called, the component's OLEStartDrag event occurs, allowing it to supply data to a target component.

See Also

Applies To: Masked Edit Control | MSChart Control

Refresh Method (ActiveX Controls)

Forces a complete repaint of a form or control.

Syntax

object.**Refresh**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

Use the **Refresh** method when you want to:

- Completely display one form while another form loads.
- Update the contents of a file-system list box, such as a **FileListBox** control.
- Update the data structures of a **Data** control.

Refresh can't be used on MDI forms but can be used on MDI child forms. You can't use **Refresh** on **Menu** or **Timer** controls.

Generally, painting a form or control is handled automatically while no events are occurring. However, there may be situations where you want the form or control updated immediately. For example, if you use a file list box, a directory list box, or a drive list box to show the current status of the directory structure, you can use **Refresh** to update the list whenever a change is made to the directory structure.

You can use the **Refresh** method on a **Data** control to open or reopen the database (if the **DatabaseName**, **ReadOnly**, **Exclusive**, or **Connect** property settings have changed) and rebuild the dynaset in the control's **Recordset** property.

See Also

Applies To: Masked Edit Control | MSChart Control

Remove Method (ActiveX Controls)

Removes a specific member from a collection.

Syntax

object.**Remove** *index*

The **Remove** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	An integer or string that uniquely identifies the object within the collection. Use an integer to specify the value of the **Index** property; use a string to specify the value of the **Key** property.

Remarks

To remove all the members of a collection, use the **Clear** method.

Example

This example adds six **Panel** objects to a **StatusBar** control, creating a total of seven **Panel** objects. When you click on the form, the code checks to see how many **Panel** objects there are. If there is only one **Panel** object, the code adds six **Panel** objects. Otherwise, it removes the first panel. To try the example, place a **StatusBar** control on a form and paste the code into the Declarations section. Run the example and click on the form to remove one **Panel** object at a time, and subsequently add **Panel** objects.

```
Private Sub Form_Load()
   Dim pnlX As Panel  ' Declare object variable for Panel objects.
   Dim i As Integer

   ' Add 6 Panel objects to the single default Panel object,
   ' making 7 Panel objects.
   For i = 1 To 6
      Set pnlX = StatusBar1.Panels.Add(, , , i)
      pnlX.AutoSize = sbrSpring
   Next i
End Sub

Private Sub Form_Click()
   ' If the Count of the collection is 1, add 6 Panel objects.
   ' Otherwise, remove the first panel from the collection.
   If StatusBar1.Panels.Count = 1 Then
      Dim sbrX As Panel
      Dim i As Integer
      For i = 1 To 6 ' Each panel has its style set by i.
         Set sbrX = StatusBar1.Panels.Add(, , , i)
         sbrX.AutoSize = sbrSpring
      Next i
   Else ' Remove the first panel.
      StatusBar1.Panels.Remove 1
   End If
End Sub
```

See Also

Clear Method (ActiveX Controls) | Index Property (ActiveX Controls) | Key Property (ActiveX Controls)

Applies To: LightSources Collection

SetFocus Method (ActiveX Controls)

Moves the focus to the specified control or form.

Syntax

object.**SetFocus**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

The object must be a **Form** object, **MDIForm** object, or control that can receive the focus. After invoking the **SetFocus** method, any user input is directed to the specified form or control.

You can only move the focus to a visible form or control. Because a form and controls on a form aren't visible until the form's Load event has finished, you can't use the **SetFocus** method to move the focus to the form being loaded in its own Load event unless you first use the **Show** method to show the form before the Form_Load event procedure is finished.

You also can't move the focus to a form or control if the **Enabled** property is set to **False**. If the **Enabled** property has been set to **False** at design time, you must first set it to **True** before it can receive the focus using the **SetFocus** method.

See Also

Enabled Property (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

ShowWhatsThis Method (ActiveX Controls)

Displays a selected topic in a Help file using the What's This popup provided by Help in 32-bit Windows operating systems.

Syntax

object.**ShowWhatsThis**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

The **ShowWhatsThis** method is very useful for providing context-sensitive Help from a context menu in your application. The method displays the topic identified by the **WhatsThisHelpID** property of the object specified in the syntax.

Example

This example displays the What's This Help topic for a **CommandButton** control by selecting a menu command from a context menu created for the button. Set the **WhatsThisHelp** property of the form to **True**. Place a **CommandButton** control on a form, create a menu using the Menu Editor with a top-level invisible item named mnuBtnContextMenu, and a sub-menu named `mnuBtnWhatsThis` with a caption of "What's This?".

```
Private ThisControl As Control

Private Sub Command1_MouseUp(Button As Integer, Shift As Integer, X As Single, Y As Single)
      If Button = vbRightButton Then
         Set ThisControl = Command1
         PopupMenu mnuBtnContextMenu
      End If
   Set ThisControl = Nothing
End Sub

Private Sub mnuBtnWhatsThis_Click()
   ThisControl.ShowWhatsThis
End Sub
```

See Also

WhatsThisHelpID Property (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

ValidateControls Method (ActiveX Controls)

Ensures that the contents of the last control on the form are valid before exiting the form.

Syntax

object.**ValidateControls**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list. If *object* is omitted, the **Form** with the focus is assumed to be *object*.

See Also

Validate Event (ActiveX Controls) | ValidationError Event

Applies To: Masked Edit Control

ZOrder Method (ActiveX Controls)

Places a specified **MDIForm**, **Form**, or control at the front or back of the z-order within its graphical level. Doesn't support named arguments.

Syntax

object.**ZOrder** *position*

The **ZOrder** method syntax has these parts:

Part	Description
object	Optional. An object expression that evaluates to an object in the Applies To list. If *object* is omitted, the form with the focus is assumed to be *object*.
Position	Optional. Integer indicating the position of *object* relative to other instances of the same *object*. If position is 0 or omitted, *object* is positioned at the front of the z-order. If position is 1, *object* is positioned at the back of the z-order.

Remarks

The z-order of objects can be set at design time by choosing the Bring To Front or Send To Back menu command from the Edit menu.

Within an **MDIForm** object, **ZOrder** sends MDI child forms to either the front or the back of the MDI client area, depending on the value of *position*. For an **MDIForm** or **Form** object, **ZOrder** sends the form to either the front or the back of the screen, depending on the value of *position*. As a result, forms can be displayed in front of or behind other running applications.

Three graphical layers are associated with forms and containers. The back layer is the drawing space where the results of the graphics methods are displayed. Next is the middle layer where graphical objects and **Label** controls are displayed. The front layer is where all nongraphical controls like **CommandButton**, **CheckBox**, or **ListBox** are displayed. Anything contained in a layer closer to the front covers anything contained in the layer(s) behind it. **ZOrder** arranges objects only within the layer where the object is displayed.

Unformat Event (ActiveX Controls)

Validate Event (ActiveX Controls)

Change Event (ActiveX Controls)

Indicates the contents of a control or a property value have changed. How and when this event occurs varies with the control.

Syntax

Private Sub *object*_**Change(**[*index* **As Integer**]**)**

The Change event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
index	An integer that uniquely identifies a control if it's in a control array.

Remarks

The Change event procedure can synchronize or coordinate data display among controls. For example, you can use a scroll bar's Change event procedure to update the scroll bar's **Value** property setting in a **TextBox** control. Or you can use a Change event procedure to display data and formulas in a work area and results in another area.

> **Note** A **Change** event procedure can sometimes cause a cascading event. This occurs when the control's Change event alters the control's contents, for example, by setting a property in code that determines the control's value, such as the **Text** property setting for a **TextBox** control.

To prevent a cascading event:

- If possible, avoid writing a Change event procedure for a control that alters that control's contents. If you do write such a procedure, be sure to set a flag that prevents further changes while the current change is in progress.
- Avoid creating two or more controls whose Change event procedures affect each other, for example, two **TextBox** controls that update each other during their Change events.
- Avoid using a **MsgBox** function or statement in this event for **HScrollBar** and **VScrollBar** controls.

See Also

Applies To: Masked Edit Control

Click Event (ActiveX Controls)

Occurs when the user presses and then releases a mouse button over an object. It can also occur when the value of a control is changed.

Syntax

Private Sub *object*_**Click(**[*index* **As Integer**]**)**

The Click event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
index	An integer that uniquely identifies a control if it's in a control array.

Remarks

Typically, you attach a Click event procedure to a **CommandButton** control, **Menu** object, or **PictureBox** control to carry out commands and command-like actions. For the other applicable controls, use this event to trigger actions in response to a change in the control.

You can use a control's **Value** property to test the state of the control from code. Clicking a control generates MouseDown and MouseUp events in addition to the Click event. The order in which these three events occur varies from control to control. If the order of events is important in your application, test the control to determine the event order.

> **Note** To distinguish between the left, right, and middle mouse buttons, use the MouseDown and MouseUp events.

If there is code in the Click event, the DlbClick event will never trigger, because the Click event is the first event to trigger between the two. As a result, the mouse click is intercepted by the Click event, so the DblClick event doesn't occur.

See Also

Applies To: MSChart Control

DblClick Event (ActiveX Controls)

Occurs when the user presses and releases a mouse button and then presses and releases it again over an object.

Syntax

Private Sub *object*_**DblClick (***index* **As Integer)**

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
index	Identifies the control if it's in a control array.

Remarks

The argument *Index* uniquely identifies a control if it's in a control array. You can use a DblClick event procedure for an implied action, such as double-clicking an icon to open a window or document. You can also use this type of procedure to carry out multiple steps with a single action, such as double-clicking to select an item in a list box and to close the dialog box.

To produce such shortcut effects in Visual Basic, you can use a DblClick event procedure for a list box or file list box in tandem with a default button — a **CommandButton** control with its **Default** property set to **True**. As part of the DblClick event procedure for the list box, you simply call the default button's Click event.

For those objects that receive Mouse events, the events occur in this order: MouseDown, MouseUp, Click, DblClick, and MouseUp.

If DblClick doesn't occur within the system's double-click time limit, the object recognizes another Click event. The double-click time limit may vary because the user can set the double-click speed in the Control Panel. When you're attaching procedures for these related events, be sure that their actions don't conflict. Controls that don't receive DblClick events may receive two clicks instead of a DblClick.

> **Note** To distinguish between the left, right, and middle mouse buttons, use the MouseDown and MouseUp events.

If there is code in the **Click** event, the **DlbClick** event will never be raised.

Example

This example displays a selected list item in a **TextBox** control when either a **CommandButton** control is clicked or a list item is double-clicked. To try this example, paste the code into the Declarations section of a **Form** object that contains a **ListBox** control, a **TextBox** control, and a **CommandButton** control. Then run the example and click the **CommandButton** control or double-click an item in the **ListBox** control.

```
Private Sub Form_Load ()
   List1.AddItem "John"   ' Add list box entries.
   List1.AddItem "Paul"
   List1.AddItem "George"
   List1.AddItem "Ringo"
End Sub

Private Sub List1_DblClick ()
   Command1.Value = True   ' Trigger Click event.
End Sub

Private Sub Command1_Click ()
   Text1.Text = List1.Text   ' Display selection.
End Sub
```

See Also

Click Event (ActiveX Controls) | MouseDown, MouseUp Events (ActiveX Controls)

Applies To: MSChart Control

DragDrop Event (ActiveX Controls)

Occurs when a drag-and-drop operation is completed as a result of dragging a control over an object and releasing the mouse button or using the **Drag** method with its *action* argument set to 2 (Drop).

Syntax

Private Sub Form_DragDrop(*source* **As Control**, *x* **As Single**, *y* **As Single)**

Private Sub MDIForm_DragDrop(*source* **As Control**, *x* **As Single**, *y* **As Single)**

Private Sub *object*_**DragDrop(**[*index* **As Integer**,]*source* **As Control**, *x* **As Single**, *y* **As Single)**

The DragDrop event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	An integer that uniquely identifies a control if it's in a control array.
source	The control being dragged. You can include properties and methods in the event procedure with this argument — for example, `Source.Visible = 0`.
x, *y*	A number that specifies the current horizontal (*x*) and vertical (*y*) position of the mouse pointer within the target form or control. These coordinates are always expressed in terms of the target's coordinate system as set by the **ScaleHeight**, **ScaleWidth**, **ScaleLeft**, and **ScaleTop** properties.

Remarks

Use a DragDrop event procedure to control what happens after a drag operation is completed. For example, you can move the source control to a new location or copy a file from one location to another.

When multiple controls can potentially be used in a *source* argument:

- Use the **TypeOf** keyword with the **If** statement to determine the type of control used with *source*.
- Use the control's **Tag** property to identify a control, and then use a DragDrop event procedure.

> **Note** Use the **DragMode** property and **Drag** method to specify the way dragging is initiated. Once dragging has been initiated, you can handle events that precede a DragDrop event with a DragOver event procedure.

Example

This example demonstrates the visual effect of dropping a **PictureBox** control onto another **PictureBox** control. To try this example, paste the code into the Declarations section of a form that contains three **PictureBox** controls. Set the **DragMode** property for Picture1 and Picture2 to 1 (Automatic). Use the **Picture** property to assign bitmaps to Picture1 and Picture2, and then press F5 and drag Picture1 or Picture2 over Picture3.

```
Private Sub Picture3_DragDrop (Source As Control, X as Single, Y As Single)
   If TypeOf Source Is PictureBox Then
      ' Set Picture3 bitmap to same as source control.
      Picture3.Picture = Source.Picture
   End If
End Sub
```

See Also

Drag Method (ActiveX Controls) | DragIcon Property (ActiveX Controls) | DragMode Property (ActiveX Controls) | DragOver Event (ActiveX Controls) | MouseDown, MouseUp Events (ActiveX Controls) | MouseMove Event (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

DragOver Event (ActiveX Controls)

Occurs when a drag-and-drop operation is in progress. You can use this event to monitor the mouse pointer as it enters, leaves, or rests directly over a valid target. The mouse pointer position determines the target object that receives this event.

Syntax

Private Sub Form_DragOver(*source* **As Control**, *x* **As Single**, *y* **As Single**, *state* **As Integer)**

Private Sub MDIForm_DragOver(*source* **As Control**, *x* **As Single**, *y* **As Single**, *state* **As Integer)**

Private Sub *object*_**DragOver(**[*index* **As Integer**,]*source* **As Control**, *x* **As Single**, *y* **As Single**, *state* **As Integer)**

The DragOver event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	An integer that uniquely identifies a control if it's in a control array.
source	The control being dragged. You can refer to properties and methods in the event procedure with this argument — for example, `Source.Visible = False`.
x, *y*	A number that specifies the current horizontal (*x*) and vertical (*y*) position of the mouse pointer within the target form or control. These coordinates are always expressed in terms of the target's coordinate system as set by the **ScaleHeight**, **ScaleWidth**, **ScaleLeft**, and **ScaleTop** properties.
state	An integer that corresponds to the transition state of the control being dragged in relation to a target form or control:
	0 = Enter (source control is being dragged within the range of a target).
	1 = Leave (source control is being dragged out of the range of a target).
	2 = Over (source control has moved from one position in the target to another).

Remarks

Use a DragOver event procedure to determine what happens after dragging is initiated and before a control drops onto a target. For example, you can verify a valid target range by highlighting the target (set the **BackColor** or **ForeColor** property from code) or by displaying a special drag pointer (set the **DragIcon** or **MousePointer** property from code).

Use the *state* argument to determine actions at key transition points. For example, you might highlight a possible target when *state* is set to 0 (Enter) and restore the object's previous appearance when *state* is set to 1 (Leave).

When an object receives a DragOver event while *state* is set to 0 (Enter):

- If the source control is dropped on the object, that object receives a DragDrop event.
- If the source control isn't dropped on the object, that object receives another DragOver event when *state* is set to 1 (Leave).

> **Note** Use the **DragMode** property and **Drag** method to specify the way dragging is initiated. For suggested techniques with the *source* argument, see Remarks for the DragDrop event topic.

Example

This example demonstrates one way to indicate a valid drop target. The pointer changes from the default arrow to a special icon when a **TextBox** control is dragged over a **PictureBox** control. The pointer returns to the default when the source is dragged elsewhere. To try this example, paste the code into the Declarations section of a form that contains a small **TextBox** and a **PictureBox**. Set the **TextBox** control's **DragMode** property to 1, and then press F5 and drag the **TextBox** over the **PictureBox**.

```
Private Sub Picture1_DragOver (Source As Control, X As Single, Y As Single, State As Integer)
   Select Case State
      Case vbEnter
   ' Load icon.
         Source.DragIcon = LoadPicture("ICONS\ARROWS\POINT03.ICO")
      Case vbLeave
         Source.DragIcon = LoadPicture()   ' Unload icon.
   End Select
End Sub
```

```
Private Sub Picture1_DragDrop (Source As Control, X As Single, Y As Single)
   Source.DragIcon = LoadPicture()   ' Unload icon.
End Sub
```

Format Event (ActiveX Controls)

Occurs after the **StdDataFormat** object formats the value.

Syntax

Sub *object*_**Format**(**ByRef** *datavalue* **As StdDataValue**)

The Format event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
datavalue	**StdDataValue** object.

Remarks

The Format event allows you to do formatting that the standard settings of the **StdDataFormat** object cannot accomplish.

See Also

Unformat Event (ActiveX Controls)

Applies To: Masked Edit Control

GotFocus Event (ActiveX Controls)

Occurs when an object receives the focus, either by user action, such as tabbing to or clicking the object, or by changing the focus in code using the **SetFocus** method. A form receives the focus only when all visible controls are disabled.

Syntax

Private Sub Form_GotFocus( )

Private Sub *object*_**GotFocus(**[*index* **As Integer**]**)**

The GotFocus event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
index	An integer that uniquely identifies a control if it's in a control array.

Remarks

Typically, you use a GotFocus event procedure to specify the actions that occur when a control or form first receives the focus. For example, by attaching a GotFocus event procedure to each control on a form, you can guide the user by displaying brief instructions or status bar messages. You can also provide visual cues by enabling, disabling, or showing other controls that depend on the control that has the focus.

> **Note** An object can receive the focus only if its **Enabled** and **Visible** properties are set to **True**. To customize the keyboard interface in Visual Basic for moving the focus, set the tab order or specify access keys for controls on a form.

Example

This example displays a status bar message when a button in an **OptionButton** group gets the focus. To try this example, paste the code into the Declarations section of a form that contains two **OptionButton** controls and a **Label** control. Set the **Name** property for both **OptionButton** controls to OptionGroup, and then press F5 and click the **OptionButton** controls.

```
Private Sub Form_Load ()
   Label1.AutoSize = True
End Sub

Private Sub OptionGroup_GotFocus (Index As Integer)
   Select Case Index
      Case 0
         Label1.Caption = "Option 1 has the focus."
      Case 1
         Label1.Caption = "Option 2 has the focus."
   End Select
End Sub

Private Sub OptionGroup_LostFocus (Index As Integer)
   Label1.Caption = ""
End Sub
```

KeyDown, KeyUp Events (ActiveX Controls)

Occur when the user presses (KeyDown) or releases (KeyUp) a key while an object has the focus. (To interpret ANSI characters, use the **KeyPress** event.)

Syntax

Private Sub Form_KeyDown(*keycode* **As Integer**, *shift* **As Integer)**

Private Sub *object*_**KeyDown(**[*index* **As Integer**,]*keycode* **As Integer**, *shift* **As Integer)**

Private Sub Form_KeyUp(*keycode* **As Integer**, *shift* **As Integer)**

Private Sub *object*_**KeyUp(**[*index* **As Integer**,]*keycode* **As Integer**, *shift* **As Integer)**

The KeyDown and KeyUp event syntaxes have these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	An integer that uniquely identifies a control if it's in a control array.
keycode	A key code, such as **vbKeyF1** (the F1 key) or **vbKeyHome** (the HOME key). To specify key codes, use the constants in the Visual Basic (VB) object library in the Object Browser.
shift	An integer that corresponds to the state of the SHIFT, CTRL, and ALT keys at the time of the event. The *shift* argument is a bit field with the least-significant bits corresponding to the SHIFT key (bit 0), the CTRL key (bit 1), and the ALT key (bit 2). These bits correspond to the values 1, 2, and 4, respectively. Some, all, or none of the bits can be set, indicating that some, all, or none of the keys are pressed. For example, if both CTRL and ALT are pressed, the value of *shift* is 6.

Remarks

For both events, the object with the focus receives all keystrokes. A form can have the focus only if it has no visible and enabled controls. Although the KeyDown and KeyUp events can apply to most keys, they're most often used for:

- Extended character keys such as function keys.
- Navigation keys.
- Combinations of keys with standard keyboard modifiers.
- Distinguishing between the numeric keypad and regular number keys.

Use KeyDown and KeyUp event procedures if you need to respond to both the pressing and releasing of a key.

KeyDown and KeyUp aren't invoked for:

- The ENTER key if the form has a **CommandButton** control with the **Default** property set to **True**.
- The ESC key if the form has a **CommandButton** control with the **Cancel** property set to **True**.
- The TAB key.

KeyDown and KeyUp interpret the uppercase and lowercase of each character by means of two arguments: *keycode*, which indicates the physical key (thus returning A and a as the same key) and *shift*, which indicates the state of *shift*+*key* and therefore returns either A or a.

If you need to test for the *shift* argument, you can use the *shift* constants which define the bits within the argument. The constants have the following values:

Constant	Value	Description
vbShiftMask	1	SHIFT key bit mask.
VbCtrlMask	2	CTRL key bit mask.
VbAltMask	4	ALT key bit mask.

The constants act as bit masks that you can use to test for any combination of keys.

You test for a condition by first assigning each result to a temporary integer variable and then comparing *shift* to a bit mask. Use the **And** operator with the *shift* argument to test whether the condition is greater than 0, indicating that the modifier was pressed, as in this example:

```
ShiftDown = (Shift And vbShiftMask) > 0
```

In a procedure, you can test for any combination of conditions, as in this example:

```
If ShiftDown And CtrlDown Then
```

> **Note** If the **KeyPreview** property is set to **True**, a form receives these events before controls on the form receive the events. Use the **KeyPreview** property to create global keyboard-handling routines.

KeyPress Event (ActiveX Controls)

Occurs when the user presses and releases an ANSI key.

Syntax

Private Sub Form_KeyPress(*keyascii* **As Integer)**

Private Sub *object*_**KeyPress(**[*index* **As Integer**,]*keyascii* **As Integer)**

The KeyPress event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	An integer that uniquely identifies a control if it's in a control array.
keyascii	An integer that returns a standard numeric ANSI keycode. *Keyascii* is passed by reference; changing it send s a different character to the object. Changing *keyascii* to 0 cancels the keystroke so the object receives no c haracter.

Remarks

The object with the focus receives the event. A form can receive the event only if it has no visible and enabled controls or if the **KeyPreview** property is set to **True**. A KeyPress event can involve any printable keyboard character, the CTRL key combined with a character from the standard alphabet or one of a few special characters, and the ENTER or BACKSPACE key. A KeyPress event procedure is useful for intercepting keystrokes entered in a **TextBox** or **ComboBox** control. It enables you to immediately test keystrokes for validity or to format characters as they're typed. Changing the value of the *keyascii* argument changes the character displayed.

You can convert the *keyascii* argument into a character by using the expression:

```
Chr(KeyAscii)
```

You can then perform string operations and translate the character back to an ANSI number that the control can interpret by using the expression:

```
KeyAscii = Asc(char)
```

Use KeyDown and KeyUp event procedures to handle any keystroke not recognized by KeyPress, such as function keys, editing keys, navigation keys, and any combinations of these with keyboard modifiers. Unlike the KeyDown and KeyUp events, KeyPress doesn't indicate the physical state of the keyboard; instead, it passes a character.

KeyPress interprets the uppercase and lowercase of each character as separate key codes and, therefore, as two separate characters. KeyDown and KeyUp interpret the uppercase and lowercase of each character by means of two arguments: *keycode*, which indicates the physical key (thus returning A and a as the same key), and *shift*, which indicates the state of *shift+key* and therefore returns either A or a.

If the **KeyPreview** property is set to **True**, a form receives the event before controls on the form receive the event. Use the **KeyPreview** property to create global keyboard-handling routines.

> **Note** The ANSI number for the keyboard combination of CTRL+@ is 0. Because Visual Basic recognizes a *keyascii* value of 0 as a zero-length string (""), avoid using CTRL+@ in your applications.

vbKeyF14	&H7D	F14 key
vbKeyF15	&H7E	F15 key
vbKeyF16	&H7F	F16 key

LostFocus Event (ActiveX Controls)

Occurs when an object loses the focus, either by user action, such as tabbing to or clicking another object, or by changing the focus in code using the **SetFocus** method.

Syntax

Private Sub Form_LostFocus( )

Private Sub *object*_**LostFocus(**[*index* **As Integer**]**)**

The LostFocus event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
index	An integer that uniquely identifies a control if it's in a control array.

Remarks

A LostFocus event procedure is primarily useful for verification and validation updates. Using LostFocus can cause validation to take place as the user moves the focus from the control. Another use for this type of event procedure is enabling, disabling, hiding, and displaying other objects as in a GotFocus event procedure. You can also reverse or change conditions that you set up in the object's GotFocus event procedure.

If an .exe file built by Visual Basic displays a dialog box created by a .dll file also built in Visual Basic, the .exe file's form will get Deactivate and LostFocus events. This may be unexpected, because you should not get the Deactivate event:

- If the object is an out-of-process component.
- If the object isn't written in Visual Basic.
- In the development environment when calling a DLL built in Visual Basic.

Example

This example changes the color of a **TextBox** control when it receives or loses the focus (selected with the mouse or TAB key) and displays the appropriate text in the **Label** control. To try this example, paste the code into the Declarations section of a form that contains two **TextBox** controls and a **Label** control, and then press F5 and move the focus between Text1 and Text2.

```
Private Sub Text1_GotFocus ()
   ' Show focus with red.
   Text1.BackColor = RGB(255, 0, 0)
   Label1.Caption = "Text1 has the focus."
End Sub

Private Sub Text1_LostFocus ()
   ' Show loss of focus with blue.
   Text1.BackColor = RGB(0, 0, 255)
   Label1.Caption = "Text1 doesn't have the focus."
End Sub
```

LostFocus Event (ActiveX Controls)

Occurs when an object loses the focus, either by user action, such as tabbing to or clicking another object, or by changing the focus in code using the **SetFocus** method.

Syntax

Private Sub Form_LostFocus( )

Private Sub *object*_**LostFocus(**[*index* **As Integer**]**)**

The LostFocus event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
index	An integer that uniquely identifies a control if it's in a control array.

Remarks

A LostFocus event procedure is primarily useful for verification and validation updates. Using LostFocus can cause validation to take place as the user moves the focus from the control. Another use for this type of event procedure is enabling, disabling, hiding, and displaying other objects as in a GotFocus event procedure. You can also reverse or change conditions that you set up in the object's GotFocus event procedure.

If an .exe file built by Visual Basic displays a dialog box created by a .dll file also built in Visual Basic, the .exe file's form will get Deactivate and LostFocus events. This may be unexpected, because you should not get the Deactivate event:

- If the object is an out-of-process component.
- If the object isn't written in Visual Basic.
- In the development environment when calling a DLL built in Visual Basic.

Example

This example changes the color of a **TextBox** control when it receives or loses the focus (selected with the mouse or TAB key) and displays the appropriate text in the **Label** control. To try this example, paste the code into the Declarations section of a form that contains two **TextBox** controls and a **Label** control, and then press F5 and move the focus between Text1 and Text2.

```
Private Sub Text1_GotFocus ()
   ' Show focus with red.
   Text1.BackColor = RGB(255, 0, 0)
   Label1.Caption = "Text1 has the focus."
End Sub

Private Sub Text1_LostFocus ()
   ' Show loss of focus with blue.
   Text1.BackColor = RGB(0, 0, 255)
   Label1.Caption = "Text1 doesn't have the focus."
End Sub
```

GotFocus Event (ActiveX Controls) | SetFocus Method (ActiveX Controls) | TabIndex Property (ActiveX Controls) | TabStop Property (ActiveX Controls)

Applies To: Masked Edit Control | MSChart Control

MouseDown, MouseUp Events (ActiveX Controls)

Occur when the user presses (MouseDown) or releases (MouseUp) a mouse button.

Syntax

Private Sub Form_MouseDown(*button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

Private Sub MDIForm_MouseDown(*button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

Private Sub *object*_**MouseDown(**[*index* **As Integer**,]*button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

Private Sub Form_MouseUp(*button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

Private Sub MDIForm_MouseUp(*button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

Private Sub *object* _**MouseUp(**[*index* **As Integer**,]*button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

The MouseDown and MouseUp event syntaxes have these parts:

Part	Description
object	Returns an object expression that evaluates to an object in the Applies To list.
index	Returns an integer that uniquely identifies a control if it's in a control array.
button	Returns an integer that identifies the button that was pressed (MouseDown) or released (MouseUp) to c ause the event. The *button* argument is a bit field with bits corresponding to the left button (bit 0), right button (bit 1), and middle button (bit 2). These bits correspond to the values 1, 2, and 4, respectively. Onl y one of the bits is set, indicating the button that caused the event.
shift	Returns an integer that corresponds to the state of the SHIFT, CTRL, and ALT keys when the button specif ied in the *button* argument is pressed or released. A bit is set if the key is down. The *shift* argument is a b it field with the least-significant bits corresponding to the SHIFT key (bit 0), the CTRL key (bit 1), and the ALT key (bit 2). These bits correspond to the values 1, 2, and 4, respectively. The *shift* argument indicates the state of these keys. Some, all, or none of the bits can be set, indicating that some, all, or none of the k eys are pressed. For example, if both CTRL and ALT were pressed, the value of *shift* would be 6.
x, *y*	Returns a number that specifies the current location of the mouse pointer. The *x* and *y* values are always expressed in terms of the coordinate system set by the **ScaleHeight**, **ScaleWidth**, **ScaleLeft**, and **Scale Top** properties of the object.

Remarks

Use a MouseDown or MouseUp event procedure to specify actions that will occur when a given mouse button is pressed or released. Unlike the Click and DblClick events, MouseDown and MouseUp events enable you to distinguish between the left, right, and middle mouse buttons. You can also write code for mouse-keyboard combinations that use the SHIFT, CTRL, and ALT keyboard modifiers.

The following applies to both Click and DblClick events:

- If a mouse button is pressed while the pointer is over a form or control, that object "captures" the mouse and receives all mouse events up to and including the last MouseUp event. This implies that the *x*, *y* mouse-pointer coordinates returned by a mouse event may not always be in the internal area of the object that receives them.
- If mouse buttons are pressed in succession, the object that captures the mouse after the first press receives all mouse events until all buttons are released.

If you need to test for the *button* or *shift* arguments, you can use constants listed in the Visual Basic (VB) object library in the Object Browser to define the bits within the argument:

Constant (Button)	Value	Description
vbLeftButton	1	Left button is pressed
vbRightButton	2	Right button is pressed
vbMiddleButton	4	Middle button is pressed

Constant (Shift)	Value	Description
vbShiftMask	1	SHIFT key is pressed.
vbCtrlMask	2	CTRL key is pressed.
vbAltMask	4	ALT key is pressed.

The constants then act as bit masks you can use to test for any combination of buttons without having to figure out the unique bit field value for each combination.

> **Note** You can use a MouseMove event procedure to respond to an event caused by moving the mouse. The *button* argument for MouseDown and MouseUp differs from the *button* argument used for MouseMove. For MouseDown and MouseUp, the *button* argument indicates exactly one button per event, whereas for MouseMove, it indicates the current state of all buttons.

See Also

Applies To: MSChart Control

MouseMove Event (ActiveX Controls)

Occurs when the user moves the mouse.

Syntax

Private Sub Form_MouseMove(*button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

Private Sub MDIForm_MouseMove(*button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

Private Sub *object*_**MouseMove(**[*index* **As Integer**,] *button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single)**

The MouseMove event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	An integer that uniquely identifies a control if it's in a control array.
button	An integer that corresponds to the state of the mouse buttons in which a bit is set if the button is down. The *button* argument is a bit field with bits corresponding to the left button (bit 0), right button (bit 1), and middle button (bit 2). These bits correspond to the values 1, 2, and 4, respectively. It indicates the complete state of the mouse buttons; some, all, or none of these three bits can be set, indicating that some, all, or none of the buttons are pressed.
shift	An integer that corresponds to the state of the SHIFT, CTRL, and ALT keys. A bit is set if the key is down. The *shift* argument is a bit field with the least-significant bits corresponding to the SHIFT key (bit 0), the CTRL key (bit 1), and the ALT key (bit 2). These bits correspond to the values 1, 2, and 4, respectively. The *shift* argument indicates the state of these keys. Some, all, or none of the bits can be set, indicating that some, all, or none of the keys are pressed. For example, if both CTRL and ALT were pressed, the value of *shift* would be 6.
x, *y*	A number that specifies the current location of the mouse pointer. The *x* and *y* values are always expressed in terms of the coordinate system set by the **ScaleHeight**, **ScaleWidth**, **ScaleLeft**, and **ScaleTop** properties of the object.

Remarks

The MouseMove event is generated continually as the mouse pointer moves across objects. Unless another object has captured the mouse, an object recognizes a MouseMove event whenever the mouse position is within its borders.

If you need to test for the *button* or *shift* arguments, you can use constants listed in the Visual Basic (VB) object library in the Object Browser to define the bits within the argument:

Constant (Button)	Value	Description
vbLeftButton	1	Left button is pressed.
vbRightButton	2	Right button is pressed.
vbMiddleButton	4	Middle button is pressed.

Constant (Shift)	Value	Description
vbShiftMask	1	SHIFT key is pressed.
vbCtrlMask	2	CTRL key is pressed.
vbAltMask	4	ALT key is pressed.

The constants then act as bit masks you can use to test for any combination of buttons without having to figure out the unique bit field value for each combination.

You test for a condition by first assigning each result to a temporary integer variable and then comparing the *button* or *shift* arguments to a bit mask. Use the **And** operator with each argument to test if the condition is greater than zero, indicating the key or button is pressed, as in this example:

```
LeftDown = (Button And vbLeftButton) > 0
CtrlDown = (Shift And vbCtrlMask) > 0
```

Then, in a procedure, you can test for any combination of conditions, as in this example:

```
If LeftDown And CtrlDown Then
```

> **Note** You can use MouseDown and MouseUp event procedures to respond to events caused by pressing and releasing mouse buttons.

The *button* argument for MouseMove differs from the *button* argument for MouseDown and MouseUp. For MouseMove, the *button* argument indicates the current state of all buttons; a single MouseMove event can indicate that some, all, or no buttons are pressed. For MouseDown and MouseUp, the *button* argument indicates exactly one button per event.

Any time you move a window inside a MouseMove event, it can cause a cascading event. MouseMove events are generated when the window moves underneath the pointer. A MouseMove event can be generated even if the mouse is perfectly stationary.

Applies To: MSChart Control

OLECompleteDrag Event (ActiveX Controls)

Occurs when a source component is dropped onto a target component, informing the source component that a drag action was either performed or canceled.

Syntax

Private Sub *object*_**OLECompleteDrag**([*effect* **As Long**])

The OLECompleteDrag event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
effect	A long integer set by the source object identifying the action that has been performed, thus allowing the source to take appropriate action if the component was moved (such as the source deleting data if it is moved from one component to another). The possible values are listed in Settings.

Settings

The settings for *effect* are:

Constant	Value	Description
*xxx***DropEffectNone**	0	Drop target cannot accept the data, or the drop operation was canceled.
*xxx***DropEffectCopy**	1	Drop results in a copy of data from the source to the target. The original data is unaltered by the drag operation.
*xxx***DropEffectMove**	2	Drop results in data being moved from the drag source to the drop source. The drag source should remove the data from itself after the move.

Remarks

The **OLECompleteDrag** event is the final event to be called in an OLE drag/drop operation. This event informs the source component of the action that was performed when the object was dropped onto the target component. The target sets this value through the *effect* parameter of the **OLEDragDrop** event. Based on this, the source can then determine the appropriate action it needs to take. For example, if the object was moved into the target (*xxx***DropEffectMove**), the source needs to delete the object from itself after the move.

If **OLEDragMode** is set to **Automatic**, then Visual Basic handles the default behavior. The event still occurs, however, allowing the user to add to or change the behavior.

Most components support manual OLE drag and drop events, and some support automatic OLE drag and drop events.

Applies To: Masked Edit Control | MSChart Control

OLEDragDrop Event (ActiveX Controls)

Occurs when a source component is dropped onto a target component when the source component determines that a drop can occur.

Note This event occurs only if **OLEDropMode** is set to **1** (**Manual**).

Syntax

Private Sub *object*_**OLEDragDrop**(*data* **As DataObject**, *effect* **As Long**, *button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single**)

The OLEDragDrop event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
data	A **DataObject** object containing formats that the source will provide and, in addition, possibly the data for th ose formats. If no data is contained in the **DataObject**, it is provided when the control calls the **GetData** met hod. The **SetData** and **Clear** methods cannot be used here.
effect	A long integer set by the target component identifying the action that has been performed (if any), thus allowi ng the source to take appropriate action if the component was moved (such as the source deleting the data). T he possible values are listed in Settings.
button	An integer which acts as a bit field corresponding to the state of a mouse button when it is depressed. The left button is bit 0, the right button is bit 1, and the middle button is bit 2. These bits correspond to the values 1, 2, and 4, respectively. It indicates the state of the mouse buttons; some, all, or none of these three bits can be set, indicating that some, all, or none of the buttons are depressed.
shift	An integer which acts as a bit field corresponding to the state of the SHIFT, CTRL, and ALT keys when they are de pressed. The SHIFT key is bit 0, the CTRL key is bit 1, and the ALT key is bit 2. These bits correspond to the values 1, 2, and 4, respectively. The *shift* parameter indicates the state of these keys; some, all, or none of the bits can be set, indicating that some, all, or none of the keys are depressed. For example, if both the CTRL and ALT keys were depressed, the value of *shift* would be 6.
x,y	A number which specifies the current location of the mouse pointer. The *x* and *y* values are always expressed i n terms of the coordinate system set by the **ScaleHeight**, **ScaleWidth**, **ScaleLeft**, and **ScaleTop** properties of the object.

Settings

The settings for *effect* are:

Constant	Value	Description
*xxx***DropEffectNone**	0	Drop target cannot accept the data.
*xxx***DropEffectCopy**	1	Drop results in a copy of data from the source to the target. T he original data is unaltered by the drag operation.
*xxx***DropEffectMove**	2	Drop results in data being moved from drag source to drop s ource. The drag source should remove the data from itself aft er the move.
*xxx***DropEffectScroll**	-2147483648	A mask to indicate that the drop target window has scrolled/ would scroll.

Remarks

The source COM component should always mask values from the *effect* parameter to ensure compatibility with future implementations of COM components. Presently, only three of the 32 bits in the *effect* parameter are used. In future versions of Visual Basic, however, these other bits may be used. Therefore, as a precaution against future problems, drag sources and drop targets should mask these values appropriately before performing any comparisons.

For example, a source component should not compare an *effect* against, for example, **vbDropEffectCopy**, such as:

```
If Effect = mskDropEffectCopy...
```

Instead, the source component should mask the value or values being sought, as here:

```
If Effect And mskDropEffectCopy = mskDropEffectCopy...
```

-or-

```
If (Effect And mskDropEffectCopy)...
```

This allows for the definition of new drop effects in future versions of Visual Basic while preserving backwards compatibility with your existing code.

Most components support manual OLE drag and drop events, and some support automatic OLE drag and drop events.

OLEDragDrop Constants

OLE Drag Constants (OLEDragMode Property)

Constant	Value	Description
*xxx***OLEDragManual**	0	OLE drag/drop will be initialized only under programmatic control.
*xxx***OLEDragAutomatic**	1	OLE drag/drop will be initialized when the user drags "out" of the control, or under programmatic control.

OLE Drop Constants (OLEDropMode Property)

*xxx***OLEDropAutomatic**	2	Accepts an OLE drag/drop without programmatic control.
*xxx***OLEDropManual**	1	Accepts an OLE drag/drop under programmatic control only.
*xxx***OLEDropNone**	0	Accepts no OLE drag/drop operations.

OLE DropEffect Constants (OLE DragDrop Event)

*xxx***OLEDropEffectCopy**	1	A mask to indicate that a copy has taken place/would take place.
*xxx***OLEDropEffectMove**	2	A mask to indicate that a move has taken place/would take place.
*xxx***OLEDropEffectNone**	0	No OLE drag/drop operation has taken place/would take place.
*xxx***OLEDropEffectScroll**	-2147483648	A mask to indicate that the drop target window has scrolled/would scroll.

See Also

OLEDragDrop Event (ActiveX Controls) | OLEDragMode Property (ActiveX Controls) | OLEDropMode Property (ActiveX Controls)

OLEDragOver Event (ActiveX Controls)

Occurs when one component is dragged over another.

Syntax

Private Sub *object*_**OLEDragOver**(*data* **As DataObject**, *effect* **As Long**, *button* **As Integer**, *shift* **As Integer**, *x* **As Single**, *y* **As Single**, *state* **As Integer**)

The OLEDragOver event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
data	A **DataObject** object containing formats that the source will provide and, in addition, possibly the data for those formats. If no data is contained in the **DataObject**, it is provided when the control calls the **GetData** method. The **SetData** and **Clear** methods cannot be used here.
effect	A long integer initially set by the source object identifying all effects it supports. This parameter must be correctly set by the target component during this event. The value of *effect* is determined by logically **Or**'ing together all active effects (as listed in Settings). The target component should check these effects and other parameters to determine which actions are appropriate for it, and then set this parameter to one of the allowable effects (as specified by the source) to specify which actions will be performed if the user drops the selection on the component. The possible values are listed in Settings.
button	An integer which acts as a bit field corresponding to the state of a mouse button when it is depressed. The left button is bit 0, the right button is bit 1, and the middle button is bit 2. These bits correspond to the values 1, 2, and 4, respectively. It indicates the state of the mouse buttons; some, all, or none of these three bits can be set, indicating that some, all, or none of the buttons are depressed.
shift	An integer which acts as a bit field corresponding to the state of the SHIFT, CTRL, and ALT keys when they are depressed. The SHIFT key is bit 0, the CTRL key is bit 1, and the ALT key is bit 2. These bits correspond to the values 1, 2, and 4, respectively. The *shift* parameter indicates the state of these keys; some, all, or none of the bits can be set, indicating that some, all, or none of the keys are depressed. For example, if both the CTRL and ALT keys are depressed, the value of *shift* would be 6.
x,y	A number that specifies the current horizontal (*x*) and vertical (*y*) position of the mouse pointer within the target form or control. The *x* and *y* values are always expressed in terms of the coordinate system set by the **ScaleHeight**, **ScaleWidth**, **ScaleLeft**, and **ScaleTop** properties of the object.
state	An integer that corresponds to the transition state of the control being dragged in relation to a target form or control. The possible values are listed in Settings.

Settings

The settings for *effect* are:

Constant	Value	Description
*xxx***DropEffectNone**	0	Drop target cannot accept the data.
*xxx***DropEffectCopy**	1	Drop results in a copy of data from the source to the target. The original data is unaltered by the drag operation.
*xxx***DropEffectMove**	2	Drop results in data being moved from drag source to drop source. The drag source should remove the data from itself after the move.
*xxx***DropEffectScroll**	-2147483648 (&H80000000)	Scrolling is occurring or about to occur in the target component. This value is used in conjunction with the other values. **Note** Use only if you are performing your own scrolling in the target component.

The settings for *state* are:

Constant	Value	Description
*xxx***Enter**	0	Source component is being dragged within the range of a target.
*xxx***Leave**	1	Source component is being dragged out of the range of a target.

*xxx***Over**	2	Source component has moved from one position in the target to another .

Remarks

> **Note** If the *state* parameter is **vbLeave**, indicating that the mouse pointer has left the target, then the *x* and *y* parameters will contain zeros.

The source component should always mask values from the *effect* parameter to ensure compatibility with future implementations of COM components. Presently, only three of the 32 bits in the *effect* parameter are used. In future versions of Visual Basic, however, these other bits may be used. Therefore, as a precaution against future problems, drag sources and drop targets should mask these values appropriately before performing any comparisons.

For example, a source component should not compare an *effect* against, for example, **mskDropEffectCopy**, such as:

```
If Effect = mskDropEffectCopy...
```

Instead, the source component should mask for the value or values being sought, as here:

```
If Effect And mskDropEffectCopy = mskDropEffectCopy...
```

-or-

```
If (Effect And mskDropEffectCopy)...
```

This allows for the definition of new drop effects in future versions of Visual Basic while preserving backwards compatibility with your existing code.

Most components support manual OLE drag-and-drop events, and some support automatic OLE drag-and-drop events.

OLEGiveFeedback Event (ActiveX Controls)

Occurs after every OLEDragOver event. OLEGiveFeedback allows the source component to provide visual feedback to the user, such as changing the mouse cursor to indicate what will happen if the user drops the object, or provide visual feedback on the selection (in the source component) to indicate what will happen.

Syntax

Private Sub *object*_**OLEGiveFeedback**(*effect* **As Long**, *defaultcursors* **As Boolean**)

The OLEGiveFeedback event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
effect	A long integer set by the target component in the OLEDragOver event specifying the action to be perf ormed if the user drops the selection on it. This allows the source to take the appropriate action (such as giving visual feedback). The possible values are listed in Settings.
defaultcursors	A boolean value which determines whether Visual Basic uses the default mouse cursor provided by th e component, or uses a user-defined mouse cursor.
	True (default) = use default mouse cursor.
	False = do not use default cursor. Mouse cursor must be set with the **MousePointer** property of the **Screen** object.

Settings

The settings for *effect* are:

Constant	Value	Description
*xxx***DropEffectNone**	0	Drop target cannot accept the data.
*xxx***DropEffectCopy**	1	Drop results in a copy of data from the source to the target. T he original data is unaltered by the drag operation.
*xxx***DropEffectMove**	2	Drop results in data being moved from drag source to drop s ource. The drag source should remove the data from itself aft er the move.
*xxx***DropEffectScroll**	-2147483648 (&H80000000)	Scrolling is occurring or about to occur in the target compone nt. This value is used in conjunction with the other values. **Note** Use only if you are performing your own s crolling in the target component.

Remarks

If there is no code in the OLEGiveFeedback event, or if the *defaultcursors* parameter is set to **True**, then Visual Basic automatically sets the mouse cursor to the default cursor provided by the component.

The source component should always mask values from the *effect* parameter to ensure compatibility with future implementations of components. Presently, only three of the 32 bits in the *effect* parameter are used. In future versions of Visual Basic, however, these other bits may be used. Therefore, as a precaution against future problems, drag sources and drop targets should mask these values appropriately before performing any comparisons.

For example, a source component should not compare an *effect* against, for example, **mskDropEffectCopy**, such as:

```
If Effect = mskDropEffectCopy...
```

Instead, the source component should mask for the value or values being sought, as here:

```
If Effect And mskDropEffectCopy = mskDropEffectCopy...
```

-or-

```
If (Effect And mskDropEffectCopy)...
```

This allows for the definition of new drop effects in future versions of Visual Basic while preserving backwards compatibility with your existing code.

Most components support manual OLE drag and drop events, and some support automatic OLE drag and drop events.

OLESetData Event (ActiveX Controls)

Occurs on a source component when a target component performs the **GetData** method on the source's **DataObject** object, but before the data for the specified format has been loaded.

Syntax

Private Sub *object*_**OLESetData**(*data* **As DataObject**, *dataformat* **As Integer**)

The OLESetData event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
data	A **DataObject** object in which to place the requested data. The component calls the **SetData** method t o load the requested format.
dataformat	An integer specifying the format of the data that the target component is requesting. The source compo nent uses this value to determine what to load into the **DataObject** object.

Remarks

In certain cases, you may want to defer loading data into the **DataObject** object of a source component to save time, especially if the source component supports many formats. This event allows the source to respond to only one request for a given format of data. When this event is called, the source should check the *format* parameter to determine what needs to be loaded and then perform the **SetData** method on the **DataObject** object to load the data which is then passed back to the target component.

See Also

Applies To: Masked Edit Control | MSChart Control

OLEStartDrag Event (ActiveX Controls)

Occurs when a component's **OLEDrag** method is performed, or when a component initiates an OLE drag/drop operation when the **OLEDragMode** property is set to **Automatic**.

This event specifies the data formats and drop effects that the source component supports. It can also be used to insert data into the **DataObject** object.

Syntax

Private Sub *object*_**OLEStartDrag**(*data* **As DataObject**, *allowedeffects* **As Long**)

The OLEStartDrag event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
data	A **DataObject** object containing formats that the source will provide and, optionally, the data for thos e formats. If no data is contained in the **DataObject**, it is provided when the control calls the **GetData** method, and you should provide the values for the *data* parameter. The **SetData** and **Clear** methods cannot be used here.
allowedeffects	A long integer containing the effects that the source component supports. The possible values are liste d in Settings.

Settings

The settings for *allowedeffects* are:

Constant	Value	Description
*xxx***DropEffectNone**	0	Drop target cannot accept the data.
*xxx***DropEffectCopy**	1	Drop results in a copy of data from the source to the target. The origin al data is unaltered by the drag operation.
*xxx***DropEffectMove**	2	Drop results in data being moved from drag source to drop source. Th e drag source should remove the data from itself after the move.

Remarks

The source component should logically **Or** together the supported values and place the result in the *allowedeffects* parameter. The target component can use this value to determine the appropriate action, and what the appropriate user feedback should be.

The StartDrag event also occurs if the component's **OLEDragMode** property is set to **Automatic**. This allows you to add formats and data to the **DataObject** object after the component has done so. You can also override the default behavior of the component by clearing the **DataObject** object (using the **Clear** method) and then adding your data and formats.

You may want to defer placing data into the **DataObject** object until the target component requests it. This allows the source component to save time by not loading multiple data formats. When the target performs the **GetData** method on the **DataObject**, the source's OLESetData event will occur if the requested data is not contained in the **DataObject**. At this point, the data can be loaded into the **DataObject**, which will in turn provide the data to the target.

If the user does not load any formats into the **DataObject**, then the drag/drop operation is canceled.

Applies To: Masked Edit Control | MSChart Control

Unformat Event (ActiveX Controls)

Occurs after the **StdFormat** object unformats the value.

Syntax

Sub *object*_**Unformat**(**ByRef** *datavalue* **As StdDataValue**)

The Unformat event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
datavalue	**StdDataValue** object.

Remarks

This event allows the user to do unformatting that the standard settings of the **StdDataFormat** object cannot accomplish.

See Also

Format Event (ActiveX Controls)

Applies To: Masked Edit Control

Validate Event (ActiveX Controls)

Occurs before the focus shifts to a (second) control that has its **CausesValidation** property set to **True**.

Syntax

Private Sub *object*_**Validate(***KeepFocus* **As Boolean)**

The Validate event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
KeepFocus	Value that determines if the control loses focus. Setting *KeepFocus* to **True** specifies that the control ret ains the focus.

Remarks

The Validate event works in tandem with the **CausesValidation** property to prevent a control from losing the focus until certain criteria are met.

> **Caution** The Validate event only occurs when the control which is about to receive the focus has its **CausesValidation** property set to **True**.

Example

The example uses three controls to demonstrate the use of the Validate event and **CausesValidation** property. By default, the **CausesValidation** property of the two TextBox controls are set to **True**. Thus when you try to shift the focus from one TextBox to the other, the Validate event occurs. If Text1 doesn't contain a date, or if Text2 doesn't contain a number larger than 10, the shift of focus is prevented. Because the **CausesValidation** property of the Command1 control is set to **False**, however, you can always click the Help button.

To try the example, place one **CommandButton** and two **TextBox** controls on a form. Paste the code into the Declarations section of the form and run the project. Attempt to shift the focus by pressing the Tab key.

```
Private Sub Form_Load()
   ' Set the button's CausesValidation property to False. When the user
   ' clicks the button, the Validate event does not occur.
   ' Set the Caption property of the button to "Help".
   With Command1
      .CausesValidation = False
      .Caption = "Help"
   End With

   Show
   With Text1 ' Select text of Text1 and set focus to it.
      .SelLength = Len(Text1.Text)
      .SetFocus
   End With
End Sub

Private Sub Command1_Click()
   ' Give the user help when the button is clicked.
   MsgBox _
   "Text1 must be set to a date." & VbCrLF & _
   "Text2 must be a number less than 10."
End Sub

Private Sub Text1_Validate(KeepFocus As Boolean)
   ' If the value is not a date, keep the focus, unless the user
   ' clicks Help.
   If Not IsDate(Text1.Text) Then
      KeepFocus = True
      MsgBox "Please insert a date in this field.", ,   "Text1"
   End if
```

```
End Sub

Private Sub Text2_Validate(KeepFocus As Boolean)
   ' If the value is a number larger than 10, keep the focus.
   If Not IsNumeric(Text2.Text) Or Val(Text2.Text) > 10 Then
      KeepFocus = True
MsgBox _
"Please insert a number less than or equal to 10.", , "Text2"
   End If
End Sub
```

Validate Event (ActiveX Controls)

Occurs before the focus shifts to a (second) control that has its **CausesValidation** property set to **True**.

Syntax

Private Sub *object*_**Validate(***KeepFocus* **As Boolean)**

The Validate event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
KeepFocus	Value that determines if the control loses focus. Setting *KeepFocus* to **True** specifies that the control ret ains the focus.

Remarks

The Validate event works in tandem with the **CausesValidation** property to prevent a control from losing the focus until certain criteria are met.

> **Caution** The Validate event only occurs when the control which is about to receive the focus has its **CausesValidation** property set to **True**.

Example

The example uses three controls to demonstrate the use of the Validate event and **CausesValidation** property. By default, the **CausesValidation** property of the two TextBox controls are set to **True**. Thus when you try to shift the focus from one TextBox to the other, the Validate event occurs. If Text1 doesn't contain a date, or if Text2 doesn't contain a number larger than 10, the shift of focus is prevented. Because the **CausesValidation** property of the Command1 control is set to **False**, however, you can always click the Help button.

To try the example, place one **CommandButton** and two **TextBox** controls on a form. Paste the code into the Declarations section of the form and run the project. Attempt to shift the focus by pressing the Tab key.

```
Private Sub Form_Load()
   ' Set the button's CausesValidation property to False. When the user
   ' clicks the button, the Validate event does not occur.
   ' Set the Caption property of the button to "Help".
   With Command1
      .CausesValidation = False
      .Caption = "Help"
   End With

   Show
   With Text1 ' Select text of Text1 and set focus to it.
      .SelLength = Len(Text1.Text)
      .SetFocus
   End With
End Sub

Private Sub Command1_Click()
   ' Give the user help when the button is clicked.
   MsgBox _
   "Text1 must be set to a date." & VbCrLF & _
   "Text2 must be a number less than 10."
End Sub

Private Sub Text1_Validate(KeepFocus As Boolean)
   ' If the value is not a date, keep the focus, unless the user
   ' clicks Help.
   If Not IsDate(Text1.Text) Then
      KeepFocus = True
      MsgBox "Please insert a date in this field.", ,   "Text1"
   End if
```

```
End Sub

Private Sub Text2_Validate(KeepFocus As Boolean)
   ' If the value is a number larger than 10, keep the focus.
   If Not IsNumeric(Text2.Text) Or Val(Text2.Text) > 10 Then
      KeepFocus = True
MsgBox _
"Please insert a number less than or equal to 10.", , "Text2"
   End If
End Sub
```

Property Pages Dialog Box (ActiveX Controls)

Allows you to change a control's properties at design time.

Dialog Box Options

Tabs

Visual Basic creates a tabbed dialog box that acts like form by writing code to handle updating property values when a user changes values in the control.

You can add Property Pages to your project using the Add Property Pages command on the Project menu.

OK

Adds the Property Pages and closes the Property Pages dialog box.

Apply

Adds the Property Page without closing the dialog box.

Masked Edit Control

The **Masked Edit** control provides restricted data input as well as formatted data output. This control supplies visual cues about the type of data being entered or displayed. This is what the control looks like as an icon in the Toolbox:

File Name

MSMASK32.OCX

Class Name

MaskEdBox

Remarks

The **Masked Edit** control generally behaves as a standard text box control with enhancements for optional masked input and formatted output. If you do not use an input mask, the **Masked Edit** control behaves much like a standard text box.

If you define an input mask using the **Mask** property, each character position in the **Masked Edit** control maps to either a placeholder of a specified type or a literal character. Literal characters, or literals, can give visual cues about the type of data being used. For example, the parentheses surrounding the area code of a telephone number are literals: `(206)`.

If you attempt to enter a character that conflicts with the input mask, the control generates a ValidationError event. The input mask prevents you from entering invalid characters into the control.

The **Masked Edit** control has three bound properties: **DataChanged**, **DataField**, and **DataSource**. This means that it can be linked to a data control and display field values for the current record in the recordset. The **Masked Edit** control can also write out values to the recordset.

When the value of the field referenced by the **DataField** property is read, it is converted to a **Text** property string, if possible. If the recordset is updatable, the string is converted to the data type of the field.

To clear the **Text** property when you have a mask defined, you first need to set the **Mask** property to an empty string, and then the Ctl**Text** property to an empty string:

```
MaskedEdit1.Mask = ""
MaskedEdit1.Text = ""
```

When you define an input mask, the **Masked Edit** control behaves differently from the standard text box. The insertion point automatically skips over literals as you enter data or move the insertion point.

When you insert or delete a character, all nonliteral characters to the right of the insertion point are shifted, as necessary. If shifting these characters leads to a validation error, the insertion or deletion is prevented, and a ValidationError event is triggered.

Suppose the **Mask** property is defined as "?###", and the current value of the **Text** property is "A12." If you attempt to insert the letter "B" to the left of the letter "A," the "A" would shift to the right. Since the second value of the input mask requires a number, the letter "A" would cause the control to generate a ValidationError event.

The **Masked Edit** control also validates the values of the **Text** property at run time. If you set the **Text** property so that it conflicts with the input mask, the control generates a run-time error.

You may select text in the same way as for a standard text box control. When selected text is deleted, the control attempts to shift the remaining characters to the left of the selection.

Normally, when a selection in the **Masked Edit** control is copied onto the Clipboard, the entire selection, including literals, is transferred onto the Clipboard. You can use the **ClipMode** property to transfer only user-entered data onto the Clipboard — literal characters that are part of the input mask are not copied.

Example

In the example below, `medDate` is the masked edit control. `InitMedDate` is a function that could be called from the form Sub New.

> **Note** If you upgrade code from previous versions of Visual Basic, you will need to update the event declarations, which now include send and event args parameters.

```
Sub InitMedDate()
    With Me.medDate
        'This box will hold date information.
        .Mask = "##/##/##"
        .Text = "12/01/99"
        'The user likes bold Arial font at double the default.
        'Double the size of the control to fit.
        .FontName = "Arial"
        .FontBold = True
        .FontSize *= 2
        .Height *= 2
        .Width *= 2
    End With
End Sub

Public Sub medDate_Enter(ByVal sender As Object, ByVal e As System.EventArgs) Handles medDate
.Enter
    'The user prefers yellow on purple for entering text.
    Me.medDate.BackColor = Color.Purple
    Me.medDate.ForeColor = Color.Yellow
End Sub

Public Sub medDate_Leave(ByVal sender As Object, ByVal e As System.EventArgs) Handles medDate
.Leave
    'Set the colors back to the default after leaving the edit box.
    Me.medDate.BackColor = Me.medDate.DefaultBackColor
    Me.medDate.ForeColor = Me.medDate.DefaultForeColor
End Sub
```

See Also

Applies To: Masked Edit Control

AllowPrompt Property

Determines whether or not the prompt character is a valid input character.

Syntax

[*form*.]**MaskedEdit**.**AllowPrompt** [= {**True** | **False**}]

Remarks

The **AllowPrompt** property settings are as follows:

Setting	Description
False	(Default) The prompt character is not a valid input character. A ValidationError event is triggered if you enter the prompt character.
True	The prompt character is a valid input character.

For example, suppose you have defined a prompt character of 0, and you want the **Masked Edit** control to accept five digits between 0 and 9. You specify a mask of #####. If the **AllowPrompt** property is **False** and you enter 0, a ValidationError event occurs. If **AllowPrompt** is set to **True**, you can enter 0 as a valid input character.

Data Type

Integer (Boolean)

See Also

Masked Edit Control Constants | PromptChar Property | ValidationError Event

Applies To: Masked Edit Control

AutoTab Property

Determines whether or not the next control in the tab order receives the focus as soon as the **Text** property of the **Masked Edit** control is filled with valid data. The **Mask** property determines whether the values in the **Text** property are valid.

Syntax

[*form*.]**MaskedEdit**.**AutoTab**[= {**True** | **False**}]

Remarks

Automatic tabbing occurs only if all the characters defined by the **Mask** property are entered into the control, the characters are valid, and the **AutoTab** property is set to **True.**

Setting	Description
False	(Default) **AutoTab** is not on. A ValidationError event occurs when you enter more characters than are defined by the input mask.
True	**AutoTab** is on. When you enter all the characters defined by the input mask, focus goes to the next control in the tab sequence, and all subsequent characters entered are handled by the next control.

The **Masked Edit** control is considered filled when you enter the last valid character in the control, regardless of where the character is in the input mask. This property has no effect if the **Mask** property is set to the empty string ("").

Data Type

Integer (Boolean)

See Also

Text Property (MaskedEdit Control) | ValidationError Event

Applies To: Masked Edit Control

ClipMode Property

Determines whether to include or exclude the literal characters in the input mask when doing a cut or copy command.

Syntax

[*form*.]**MaskedEdit**.**ClipMode** [= *setting%*]

Remarks

The following table lists the **ClipMode** property settings for the **Masked Edit** control.

Setting	Description
mskIncludeLiterals (0)	(Default) Include literals on a cut or copy command.
mskExcludeLiterals (1)	Exclude literals on a cut or copy command.

This property has no effect if the **Mask** property is set to the empty string ("").

Data Type

Integer (Enumerated)

See Also

Masked Edit Control Constants

Applies To: Masked Edit Control

ClipText Property

Returns the text in the **Masked Edit** control, excluding literal characters of the input mask. This property is not available at design time and is read-only at run time.

Syntax

[*form*.]**MaskedEdit**.**ClipText**

Remarks

This property acts the same as the **SelText** property when the **Mask** property is set to the empty string ("").

Data Type

String

See Also

SelText Property (Masked Edit Control)

Applies To: Masked Edit Control

Format Property (Masked Edit Control)

Specifies the format for displaying and printing numbers, dates, times, and text.

Syntax

[*form*.]**MaskedEdit**.**Format** [= *posformat$; negformat$; zeroformat$; nullformat$*]

Parameter	Description
posformat$	Expression used to display positive values.
negformat$	Expression used to display negative values.
zeroformat$	Expression used to display zero values.
nullformat$	Expression used to display null or empty values.

Remarks

The **Format** property defines the format expressions used to display the contents of the control. You can use the same format expressions as defined by the Visual Basic **Format** function, with the exception that named formats ("On/Off") cannot be used.

This property can have from one to four parameters separated by semicolons. If one of the parameters is not specified, the format specified by the first parameter is used. If multiple parameters appear, the appropriate number of separators must be used. For example, to specify *posformat$* and *nullformat$*, use the syntax

[*form*.]*MaskedEdit*.**Format** = *posformat$;;; nullformat$*

The following table shows examples of standard formats that you may wish to use.

Data type	Value	Description
Number	(Default) Empty string	General Numeric format. Displays as entered.
Number	$#,##0.00;($#,##0.00)	Currency format. Uses thousands separator; displays negative numbers enclosed in parentheses.
Number	0	Fixed number format. Displays at least one digit.
Number	#,##0	Commas format. Uses commas as thousands separator.
Number	0%	Percent format. Multiplies value by 100 and appends a perce nt sign.
Number	0.00E+00	Scientific format. Uses standard scientific notation.
Date/Time	(Default) c	General Date and Time format. Displays date, time, or both.
Date/Time	dddddd	Long Date format. Same as the Long Date setting in the Inter national section of the Microsoft Windows Control Panel. Exa mple: Tuesday, May 26, 1992.
Date/Time	dd-mmm-yy	Medium Date format. Example: 26-May-92.
Date/Time	ddddd	Short Date format. Same as the Short Date setting in the Inter national section of the Microsoft Windows Control Panel. Exa mple: 5/26/92.
Date/Time	ttttt	Long Time format. Same as the Time setting in the Internatio nal section of the Microsoft Windows Control Panel. Example: 05:36:17 A.M.
Date/Time	hh:mm AM/PM	Medium Time format. Example: 05:36 A.M.
Date/Time	hh:mm	Short Time format. Example: 05:36.

Data Type

String

See Also

Format Event (ActiveX Controls) | Format Function | Unformat Event (ActiveX Controls)

Applies To: Masked Edit Control

FormattedText Property

The **FormattedText** property returns the string displayed in the **Masked Edit** control when the control does not have the focus. This property is not available at design time, and is read-only at run time.

Syntax

[*form*.]**MaskedEdit**.**FormattedText**

Remarks

If the **Format** property is equal to the empty string (""), this property is identical to the **Text** property, except that it is read-only. If the **HideSelection** property is set to **False**, the control does not display the formatted text when it does not have the focus. However, the formatted text is still available through this property.

Data Type

String

See Also

HideSelection Property (ActiveX Controls) | Text Property (MaskedEdit Control)

Applies To: Masked Edit Control

Mask Property

Determines the input mask for the control.

Syntax

[*form*.]**MaskedEdit**.**Mask** [= *string$*]

Remarks

You can define input masks at both design time and run time. However, the following are examples of standard input masks that you may want to use at design time. The control can distinguish between numeric and alphabetic characters for validation, but cannot check for valid content, such as the correct month or time of day.

Mask	Description
Null String	(Default) No mask. Acts like a standard text box.
##-???-##	Medium date (US). Example: 20-May-92
##-##-##	Short date (US). Example: 05-20-92
##:## ??	Medium time. Example: 05:36 AM
##:##	Short time. Example: 17:23

The input mask can consist of the following characters.

Mask character	Description
#	Digit placeholder.
.	Decimal placeholder. The actual character used is the one specified as the decimal placeholder in your international settings. This character is treated as a literal for masking purposes.
,	Thousands separator. The actual character used is the one specified as the thousands separator in your international settings. This character is treated as a literal for masking purposes.
:	Time separator. The actual character used is the one specified as the time separator in your international settings. This character is treated as a literal for masking purposes.
/	Date separator. The actual character used is the one specified as the date separator in your international settings. This character is treated as a literal for masking purposes.
\	Treat the next character in the mask string as a literal. This allows you to include the '#', '&', 'A', and '?' characters in the mask. This character is treated as a literal for masking purposes.
&	Character placeholder. Valid values for this placeholder are ANSI characters in the following ranges: 32-126 and 128-255.
>	Convert all the characters that follow to uppercase.
<	Convert all the characters that follow to lowercase.
A	Alphanumeric character placeholder (entry required). For example: a – z, A – Z, or 0 – 9.
a	Alphanumeric character placeholder (entry optional).
9	Digit placeholder (entry optional). For example: 0 – 9.
C	Character or space placeholder (entry optional). This operates exactly like the & placeholder, and ensures compatibility with Microsoft Access.
?	Letter placeholder. For example: a – z or A – Z.
Literal	All other symbols are displayed as literals; that is, as themselves.

When the value of the **Mask** property is an empty string ("""), the control behaves like a standard text box control. When an input mask is defined, underscores appear beneath every placeholder in the mask. You can only replace a placeholder with a character that is of the same type as the one specified in the input mask. If you enter an invalid character, the masked edit control rejects the character and generates a ValidationError event.

> **Note** When you define an input mask for the **Masked Edit** control and you tab to another control, the ValidationError event is generated if there are any invalid characters in the **Masked Edit** control.

Data Type

String

See Also

Text Property (MaskedEdit Control) | ValidationError Event

Applies To: Masked Edit Control

MaxLength Property

Sets or returns the maximum length of the **Masked Edit** control.

Syntax

[*form*.]**MaskedEdit**.**MaxLength** [= *setting%*]

Remarks

The **Masked Edit** control can have a maximum of 64 characters (the valid range for this property is 1 to 64). The default value is set to 64 characters, including literal characters in the input mask.

If the user enters characters beyond the specified maximum length, the control generates a beep.

Data Type

Integer

See Also

Applies To: Masked Edit Control

PromptChar Property

Sets or returns the character used to prompt a user for input.

Syntax

[*form*.]**MaskedEdit**.**PromptChar** [= *char$*]

Remarks

The underscore character "_" is the default character value for the property. The **PromptChar** property can only be set to exactly one character.

Use the **PromptInclude** property to specify whether prompt characters are contained in the **Text** property.

Use the **AllowPrompt** property to test whether a prompt character is entered by a user.

Data Type

String

See Also

AllowPrompt Property | PromptInclude Property

Applies To: Masked Edit Control

PromptInclude Property

Specifies whether prompt characters are contained in the **Text** property value. Use the **PromptChar** property to change the value of the prompt character.

Syntax

[*form*.]**MaskedEdit**.**PromptInclude** [= { **True** | **False** }]

Remarks

The following table lists the **PromptInclude** property settings for the **Masked Edit** control.

Setting	Description
False	The value of the **Text** property does not contain any prompt character.
True	(Default) The value of the **Text** property contains prompt characters, if any .

If the **Masked Edit** control is bound to a data control, the **PromptInclude** property affects how the data control reads the bound **Text** property. If **PromptInclude** is **False**, the data control ignores any literals or prompt characters in the **Text** property. In this mode, the value that the data control retrieves from the **Masked Edit** control is equivalent to the value of the **ClipText** property.

If **PromptInclude** is **True**, the data control uses the value of the **Text** property as the data value to store.

Data Type

Integer (Boolean)

See Also

DataBinding Object (ActiveX Controls) | DataField Property (ActiveX Controls) | Text Property (MaskedEdit Control)

Applies To: Masked Edit Control

SelText Property (Masked Edit Control)

Sets or returns the text contained in the control.

Syntax

[*form*.]**MaskedEdit**.**SelText**[= *string$*]

Remarks

If an input mask is not defined for the **Masked Edit** control, the **SelText** property behaves like the standard **SelText** property for the **Text Box** control.

If an input mask is defined and there is selected text in the **Masked Edit** control, the **SelText** property returns a text string. Depending on the value of the **ClipMode** property, not all the characters in the selected text are returned. If **ClipMode** is on, literal characters do not appear in the returned string.

When the **SelText** property is set, the **Masked Edit** control behaves as if text was pasted from the Clipboard. This means that each character in *string$* is entered into the control as if the user typed it in.

Data Type

String

See Also

ClipMode Property | SelLength, SelStart, SelText Properties (ActiveX Controls)

Applies To: Masked Edit Control

Text Property (MaskedEdit Control)

Sets or returns the text contained in the control. This property is not available at design time.

Syntax

[*form*.]**MaskedEdit**.**Text**[= *string$*]

Remarks

This property sets and retrieves the text in the **Masked Edit** control, including literal characters and underscores that are part of the input mask. When setting the **Text** property, the *string$* value must match the characters in the input mask exactly, including literal characters and underscores.

> **Note** The **ClipMode** property setting has no effect on the value of the **Text** property.

The **SelText** property provides an easier way of setting the text in the **Masked Edit** control.

Data Type

Variant

See Also

ClipMode Property | FormattedText Property | SelText Property (Masked Edit Control)

Applies To: Masked Edit Control

ValidationError Event

Occurs when the **Masked Edit** control receives invalid input, as determined by the input mask.

Syntax

Private Sub *ctlname*_**ValidationError**(*InvalidText* **As String**; *StartPosition* **As Integer**)

Remarks

InvalidText is the value of the **Text** property, including the invalid character. This means that any placeholders and literal characters used in the input mask are included in *InvalidText*.

StartPosition is the position in *InvalidText* where the error occurred (the first invalid character).

Masked Edit Control Constants

Appearance Constants

Constant	Value	Description
mskFlat	0	Flat. Paints controls and forms without visual effects.
mskThreeD	1	(Default) 3D. Paints controls with three-dimensional effec ts.

BorderStyle Constants

Constant	Value	Description
mskBSNone	0	No border
mskFixedSingle	1	Fixed single

ClipBoard Constants

Constant	Value	Description
mskCFRTF	&HFFFFBF01	Rich Text Format (.rtf file)
mskCFText	1	Text (.txt file)
mskCFBitmap	2	Bitmap (.bmp file)
mskCFMetafile	3	Metafile (.wmf file)
mskCFDIB	8	Device-independent bitma p
mskCFPalette	9	Color palette
mskCFEMetafile	14	Extended Metafile (.emf file)
mskCFFiles	15	Filename list

ClipMode Constants

Constant	Value	Description
mskIncludeLiterals	0	Include literals on cut or copy.
mskExcludeLiterals	1	Exclude literals on cut or copy .

DragOver Constants

Constant	Value	Description
mskEnter	0	Source control dragged into target.
mskLeave	1	Source control dragged out of target.
mskOver	2	Source control dragged from one position in target to an other.

Error Constants

Constant	Value	Description
mskDataObjectLocked	672	DataObject formats list may not be cleared or expande d outside of the OLEStartDrag event.
mskExpectedAnArgument	673	Expected at least one argument.
mskFormatNotByteArray	675	Non-intrinsic OLE drag and drop formats used with Set Data require Byte array data. GetData may return more bytes than were given to SetData.
mskGetNotSupported	394	Property is write-only.
mskInvalidObjectUse	425	Invalid object use.
mskInvalidProcedureCall	5	Invalid procedure call.

mskInvalidPropertyValue	380	Invalid property value.
mskRecursiveOleDrag	674	Illegal recursive invocation of OLE drag and drop.
mskSetNotSupported	383	Property is read-only.
mskWrongClipboardFormat	461	Specified format does not match format of data.

MousePointer Constants

Constant	Value	Description
mskDefault	0	Default
mskArrow	1	Arrow
mskCross	2	Crosshair
mskIbeam	3	I beam
mskIcon	4	Icon
mskSize	5	Size
mskSizeNESW	6	Size NE, SW mouse pointer
mskSizeNS	7	Size N, S mouse pointer
mskSizeNWSE	8	Size NW, SE mouse pointer
mskSizeEW	9	Size W, E mouse pointer
mskUpArrow	10	Up arrow
mskHourglass	11	Hourglass
mskNoDrop	12	No drop
mskArrowHourglass	13	Arrow and hourglass
mskArrowQuestion	14	Arrow and question mark
mskSizeAll	15	Size all
mskCustom	99	Custom icon specified by the **MouseIcon** propert y

OLEDrag Constants

Constant	Value	Description
mskOLEDragManual	0	OLE drag/drop is initialized only under programmatic con trol.
mskOLEDragAutomatic	1	OLE drag/drop is initialized when the user drags 'out' of t he control, or under programmatic control.

OLEDrop Constants

Constant	Value	Description
mskOLEDropNone	0	Accepts no OLE drag/drop operations.
mskOLEDropManual	1	Accepts an OLE drag/drop under programmatic control o nly.
mskOLEDropAutomatic	2	Accepts an OLE drag/drop without programmatic control.

OLEDropEffect Constants

Constant	Value	Description
mskOLEDropEffectNone	0	No OLE drag/drop operation has taken place/woul d take place.
mskOLEDropEffectCopy	1	A mask to indicate that a copy has taken place/wou ld take place.
mskOLEDropEffectMove	2	A mask to indicate that a move has take place/woul d take place.
mskOLEDropEffectScroll	&H80000000	A mask to indicate that the drop target window has scrolled/would scroll.

MSChart Control

A chart that graphically displays data.

Syntax

MSChart

Remarks

The **MSChart** control supports the following features:

- True three-dimensional representation.
- Support for all major chart types.
- Data grid population via random data and data arrays.

The **MSChart** control is associated with a data grid (**DataGrid** object). This data grid is a table that holds the data being charted. The data grid can also include labels used to identify series and categories on the chart. The person who designs your chart application fills the data grid with information by inserting data or by importing data from a spreadsheet or array.

Example

```
'In this example, the sales for two companies are shown for four months.
'Create the data array and bind it to the ChartData property.
   Dim Sales(,) As Object = New Object(, ) _
      {{"Company", "Company A", "Company B"}, _
      {"June", 20, 10}, _
      {"July", 10, 5}, _
      {"August", 30, 15}, _
      {"September", 14, 7}}
   chtSales.ChartData = Sales

   'Add a title and legend.
   With Me.chtSales
      .Title.Text = "Sales"
      .Legend.Location.LocationType = _
         MSChart20Lib.VtChLocationType.VtChLocationTypeBottom
      .Legend.Location.Visible = True
   End With

   'Add titles to the axes.
   With Me.chtSales.Plot
      .Axis(MSChart20Lib.VtChAxisId.VtChAxisIdX).AxisTitle.Text = "Year"
      .Axis(MSChart20Lib.VtChAxisId.VtChAxisIdY).AxisTitle.Text = "Millions of $"
   End With

   'Set custom colors for the bars.
   With Me.chtSales.Plot
      'Yellow for Company A
      ' -1 selects all the datapoints.
      .SeriesCollection(1).DataPoints(-1).Brush.FillColor.Set(250, 250, 0)
      'Purple for Company B
      .SeriesCollection(2).DataPoints(-1).Brush.FillColor.Set(200, 50, 200)
   End With
```

Error Messages (MSChart Control)

The **MSChart** control's errors that occur during program execution are handled like other errors. You must write your own error handling routine to trap and manage errors.

The following table lists the errors that can be trapped by exception handling.

Error Name	Explanation
GetNotSupported	Attempted to read a write-only property.
InvalidPropertyValue	Value is not appropriate for the property used.
SetNotSupported	Attempted to write to a read-only property.
VtChError	Function failed with a non-specific error.
VtChErrorInvalidAxis	One of the arguments in a method is a reference to an axis that does not exist on the chart.
VtChErrorInvalidHandle	Invalid chart handle passed.
VtChErrorInvalidSeriesNumber	One of the arguments in a method is a reference to a series that does not exis t on the chart.
VtChErrorNoData	Data necessary for the completion of the task is unavailable.
VtChErrorRestrictedVersion	The requested feature is not available in this version of the product.
VtErrorActionCanceled	User canceled operation. The user clicked outside the menu instead of selecti ng an item.
VtErrorArchivePointerMismatch	Tried to load a pointer into a reference.
VtErrorArchiveTypeMismatch	Encountered unexpected class type.
VtErrorArchiveVersion	Tried to load incompatible version.
VtErrorBufferTooSmall	String buffer is not large enough to hold the requested string. String has bee n truncated to fit the buffer.
VtErrorCannotOpenFile	Unable to open the requested file.
VtErrorCopyingObject	Failed to copy object.
VtErrorCorruptArchive	Persistent storage is corrupted.
VtErrorCorruptData	An internal error indicating that the **MSChart** control has encountered corru pt data and is unable to continue the requested action.
VtErrorCreateWindow	Could not create window.
VtErrorDefaultFontSubstituted	Default substituted for requested font.
VtErrorDeletingDeletedObject	An internal error indicating that the **MSChart** control attempted to delete an object that has already been deleted.
VtErrorDeletingUsedObject	An internal error indicating that the **MSChart** control attempted to delete an object that is still in use.
VtErrorDisplay	The **MSChart** control is unable to properly communicate with display drivers.
VtErrorDuplicateObject	Encountered duplicate object.
VtErrorDuplicateSymbol	Duplicate symbol.
VtErrorIconNotFound	Could not load icon.
VtErrorIdentifierTooBig	Identifier is too large.
VtErrorInvalidArgument	One of the function arguments was bad.
VtErrorInvalidFont	Requested font description is invalid.
VtErrorInvalidFontName	Requested font name is not available.
VtErrorInvalidIndex	Given index is out of bounds.
VtErrorInvalidObject	Object is uninitialized or invalid.
VtErrorInvalidRequest	The requested action is inappropriate or otherwise invalid.
VtErrorInvalidSyntax	Encountered invalid syntax.
VtErrorInvalidTypeConversion	Requested type conversion is not supported.
VtErrorLoadPicture	Could not load requested picture.
VtErrorNoDisplayResources	The **MSChart** control does not have enough display resources to properly dis play the chart.
VtErrorNoMemory	There is not enough memory to accomplish the requested action.
VtErrorNotFound	Cannot find the item for which the function is looking.
VtErrorNotImplemented	Feature is not yet implemented.

VtErrorOSVersion	Version of Windows is not supported.
VtErrorStreamIo	An error was encountered when trying to read or write a file.
VtErrorTooSmall	The returned result is longer than the return buffer size. A NULL string is placed in the buffer.
VtErrorUnableToLoadString	Unable to load a string; the string may have been too long.
VtErrorUnexpectedEOS	Encountered unexpected end of string.
VtErrorUnrecognizedFunction	Encountered unrecognized function.
VtErrorUserIo	An attempt to write a file to a user-created function failed.
VtFail	A general failure error.
VtOk	No error occurred.

Weighting Object

Axis Object

Represents an axis on a chart.

Syntax

Axis

Remarks

Three axes are available: *x*, *y*, and *z*. The *z* axis is visible only when the chart is a 3D chart.

Example

The following example reads the number of label levels present on the *x* axis using the *x* **Axis** object.

```
Private Sub Command1_Click()
   Dim XAxis As Object
   Dim NumberOfLevels As Integer
   ' Read the number of label level present on the X
   ' Axis.
   Set XAxis = MSChart1.Plot.Axis(VtChAxisIdX, 1)
   NumberOfLevels = XAxis.LabelLevelCount
   MsgBox "Number of Label Levels = " _
   & Str(NumberOfLevels)
End Sub
```

AxisGrid Object

Represents the planar area surrounding a chart axis.

Syntax

AxisGrid

Example

The following example changes the appearance of the y **AxisGrid** line style.

```
Private Sub Command1_Click()
   With MSChart1.Plot.Axis(VtChAxisIdY)
      .CategoryScale.Auto = False
      .ValueScale.MajorDivision = 10
      .ValueScale.MinorDivision = 5
      .AxisGrid.MajorPen.Style = VtPenStyleSolid
      .AxisGrid.MajorPen.VtColor.Green = 255
      .AxisGrid.MajorPen.Width = 2
      .AxisGrid.MinorPen.Style = VtPenStyleDashed
      .AxisGrid.MinorPen.VtColor.Red = 255
      .AxisGrid.MinorPen.Width = 1
      .AxisGrid.MinorPen.Cap = VtPenCapRound
   End With
End Sub

AxisScale Object

Controls how chart values are plotted on an axis.

Syntax

AxisScale

Example

The following examples sets the *x* and *y* axes to a percent scale for a two-dimensional line chart. To try the example, draw an **MSChart** and a **CommandButton** control on a form. Paste the code into the **Form** object's code module and run the project.

```
Private Sub Command1_Click()
   ' Change both x and y axes to Percent scale for 2D
   ' Line chart.
   Dim axisID As VtChAxisId
   MSChart1.ChartType = VtChChartType2dLine
   For AxisId = VtChAxisIdX To VtChAxisIdY
      With MSChart1.Plot.Axis(AxisId).AxisScale
         .Type = VtChScaleTypePercent
         .PercentBasis = VtChPercentAxisBasisSumChart
      End With
   Next
End Sub
```

AxisTitle Object

Represents an axis title on a chart.

Syntax

AxisTitle

Example

The following example makes the axis title visible for all axes of a three-dimensional chart.

```
Private Sub Command1_Click()
   ' Makes Axis title visible for all axes of a
   ' 3D chart.
   Dim axisID As VtChAxisId
   MSChart1.chartType = VtChChartType3dBar
   For axisId = VtChAxisIdX To VtChAxisIdZ
      With MSChart1.Plot.axis(axisId, 1)
         .AxisTitle.VtFont.Size = 14
         .AxisTitle.Visible = True
         Select Case axisId
            Case 0
               .AxisTitle.text = "X Axis Title"
            Case 1
               .AxisTitle.text = "Y Axis Title"
            Case 2
               .AxisTitle.text = "2nd Y Axis Title"
            Case 3
               .AxisTitle.text = "Z Axis Title"
         End Select
      End With
   Next
End Sub
```

DataGrid Object

Represents a virtual matrix containing labels and data points for the **MSChart** control.

Syntax

DataGrid

Remarks

The **DataGrid** object is configured as rows and columns. You can add and subtract rows, columns, and labels to this matrix to change the appearance of the chart.

Example

The following example sets the chart parameters for a three-dimensional bar chart, fills the chart with random data and labels the data grid columns.

```
Private Sub Command1_Click()
   Dim rowLabelCount, columnLabelCount, rowCount As Integer
   Dim columnCount, labelIndex, Column, Row As Integer
   MSChart1.ChartType = VtChChartType3dBar
   With MSChart1.DataGrid
   ' Set Chart parameters using methods.
      rowLabelCount = 2
      columnLabelCount = 2
      rowCount = 6
      columnCount = 6
      .SetSize RowLabelCount, columnLabelCount, _
      RowCount, ColumnCount
      ' Randomly fill in the data.
      .RandomDataFill
      ' Then assign labels to second Level.
      labelIndex = 2
      column = 1
      .ColumnLabel(column, labelIndex) = "Product 1"
      column = 4
      .ColumnLabel(column, labelIndex) = "Product 2"
      row = 1
      .RowLabel(row, labelIndex) = "1994"
      row = 4
      .RowLabel(row, labelIndex) = "1995"
   End With
End Sub
```

DataPoint Object

A member of the **DataPoints** collection that describes the attributes of an individual data point on a chart.

Syntax

DataPoint

Remarks

The **DataPoints** collection is accessed through the **SeriesCollection** object.

> **Caution** The DataPoints collection contains only one member at this time. To access it, you must use the –1, as shown below:

```
MSChart1.Plot.SeriesCollection(1).DataPoints(-1) _
.Brush.FillColor.Set 0, 255, 255
```

Example

The following example assigns a variable to a data point and sets the data point color and marker.

```
Private Sub Command1_Click()
   ' Change the color and marker of First DataPoint in
   ' the First Series.
   With MSChart1.Plot.SeriesCollection(1).DataPoints(-1)
      ' Change Data Point color to blue.
      .Brush.Style = VtBrushStyleSolid
      ' Set Color=Blue.
      .Brush.FillColor.Set 0, 255, 255
      ' Set DataPoint marker visible.
      .Marker.Visible = True
   End With
End Sub
```

DataPoints Collection

A group of chart data points.

Syntax

object.**DataPoints.**(*index*)

The **DataPoints** collection syntax has these parts:

Part	Description
object	An object expression that evaluates to an object the Applies To list.
index	Identifies a specific data point within the current series. For this version of the chart, –1 is the only valid valu e for this argument. This allows you two make changes to the default settings for all data points in the series. Settings cannot be changed for individual data points within the series.

Example

The following example sets the markers for a data point in a chart.

```
Private Sub Command1_Click()
   With MSChart1.Plot.SeriesCollection(1).DataPoints(-1)
   ' Set DataPoint marker visible.
      .Marker.Visible = True
      .Marker.Style = VtMarkerStyleDiamond
   End With
End Sub
```

The **Datapoints** collection **Item** method takes a special –1 argument to designate default properties for all data points of the series. The **Datapoint** object returned by **Item**(–1) can be manipulated just like a normal **Datapoint** object. A property set on this default data point affects every data point in the series, except those data points that have had that property set individually. In the example, the data point label for each series is set at three different locations. It makes no difference whether individual data point settings come before or after default settings; the individual settings always override the default settings. The **ResetCustom** method can be used to remove any individual settings for a data point and cause it to use the default settings for the series.

```
Private Sub Command1_Click()
   With MSChart1.Plot
      .SeriesCollection(1).DataPoints.Item(-1) _
      .DataPointLabel.LocationType = VtChLabelLocationTypeAbovePoint

      .SeriesCollection(2).DataPoints.Item(-1) _
      .DataPointLabel.LocationType = VtChLabelLocationTypeCenter

      .SeriesCollection(3).DataPoints.Item(-1) _
      .DataPointLabel.LocationType = VtChLabelLocationTypeBase
   End With
End Sub
```

Fill Object

Describes the type and appearance of an object's backdrop in a chart.

Syntax

Fill

Example

The following example sets a gradient backdrop for a chart using the **Fill** object.

```
Private Sub Command1_Click()
   With MSChart1.backdrop.Fill
      ' Set a brush pattern backdrop.
      .Style = VtFillStyleBrush
      .Brush.Style = VtBrushPattern50Percent

Intersection Object

The point at which an axis intersects an intersecting axis on a chart.

Syntax

Intersection

Example

The following example sets manual intersection position properties and displays labels with the axis.

```
Private Sub Command1_Click()
      With MSChart1.Plot.Axis(VtChAxisIdX).Intersection
      ' Set Intersection Properties.
      .Auto = False   ' Set positioning to manual.
      .Point = 20      ' Set intersection with the Y
                     ' Axis to 20.
      .LabelsInsidePlot = True   ' Display Labels
                                 ' with Axis not at
                                 ' the base.

Light Object

Represents the light source illuminating a three-dimensional chart.

Syntax

Light

Example

The following example sets the ambient light and edge lighting intensity for a chart. To try the example, draw an **MSChart** and two **ComboBox** controls on a form. Paste the code into the **Form** object's code module and run the project. Click the ComboBox controls to see the change of ambient light and edge intensity.

```
Private Sub Form_Load()
    ' Configure the chart.
   With MSChart1
      .Title = "Hold down Control and mousedown on chart"
      .chartType = VtChChartType3dBar
      .Plot.Light.AmbientIntensity = 1   ' 100 % Intensity.
      .Plot.Light.EdgeIntensity = 0.5        ' 50 % Intensity.
      .Plot.Light.EdgeVisible = True
   End With
   'Configure ComboBoxe controls.
   ConfigCombo Combo1
   ConfigCombo Combo2
End Sub

Private Sub ConfigCombo(cmb As ComboBox)
   ' Populate a combobox with values.
   Dim i As Single
   For i = 0 To 1 Step 0.1
      cmb.AddItem i
   Next i
   cmb.ListIndex = 0
End Sub

Private Sub Combo1_Click()
   MSChart1.Plot.Light.AmbientIntensity = Combo1.Text
End Sub

Private Sub Combo2_Click()

LightSources Collection

A group of **LightSource** objects in a chart.

Syntax

object.**LightSources**(*index*)

The **LightSources** collection syntax has the following parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	Integer. A number that uniquely identifies a member of the collection.

Example

The following example sets the coordinates and intensity for a light source, then adds a light source from a chart. To try the example, draw an **MSChart**, and two **CommandButton** controls on a form. Paste the code into the **Form** object's code module and run the project. Click the buttons to change the light sources.

```
Option Explicit

Private Sub Form_Load()
   ' Configure the chart and its light source.
   With MSChart1
      .chartType = VtChChartType3dBar
      .Plot.Light.AmbientIntensity = 0.01 ' 1 % Intensity.
      .Plot.Light.EdgeIntensity = 0.5      ' 50 % Intensity.
      .Plot.Light.EdgeVisible = True
   End With
End Sub

Private Sub Command1_Click()
   Dim LightSource As Object
   Set LightSource = _
   MSChart1.Plot.Light.LightSources(1)
   ' Set coordinates for Light Source 1 as well as its
   ' intensity.
   LightSource.X = 1
   LightSource.y = 0.5
   LightSource.Z = 1
   LightSource.Intensity = 1
End Sub

Private Sub Command2_Click()
   ' Add a new light source.

Location Object

Represents the current position of a textual chart element such as the title, legend, or footnote.

Syntax

Location

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Example

The following example sets the title location for a chart using the **Location** object. To try the example, draw an **MSChart** and a **ComboBox** control on a form. Paste the code into the **Form** object's code module, and run the project. Click the **ComboBox** to change the title location.

```
Option Explicit

Private Sub Combo1_Click()
   MSChart1.Title.Location.LocationType = Combo1.ListIndex
End Sub

Private Sub Form_Load()
   ' Set Title Text.
   With MSChart1
      .TitleText = "Test Title Location"
      .Title.Location.Visible = True
   End With

   ' Add LocationType constants to ComboBox.
   With Combo1
      .AddItem "VtChLocationTypeTopLeft"     ' 0

Marker Object

A marker that identifies a data point on a chart.

Syntax

Marker

Example

The following example sets a blue X marker style for a chart series.

```
Option Explicit
Option Base 1
Private Sub Command1_Click()
   ' Display Markers for Series 1.
   Dim i As Integer
   For i = 1 To MSChart1.Plot.SeriesCollection.Count
      With MSChart1.Plot.SeriesCollection _
      .Item(i).DataPoints.Item(-1).Marker
         .Visible = True
         .Size = 20
         .Style = VtMarkerStyleX
         .FillColor.Automatic = False
         .FillColor.Set 0, 0, 255
      End With
   Next i
End Sub

Pen Object

Describes the color and pattern of lines or edges on a chart.

Syntax

Pen

Example

The following example sets the pen attributes for a two-dimensional xy chart series. The **GuideLinePen** property returns a reference to a **Pen** object.

```
Private Sub Command1_Click()
   ' Set Guide Lines for 2D XY chart Series 1.
   MSChart1.ChartType = VtChChartType2dXY
   MSChart1.Plot.SeriesCollection.Item(1) _
   .ShowGuideLine(VtChAxisIdX) = True
   With _
   MSChart1.Plot.SeriesCollection.Item(1).GuideLinePen
      ' Set Pen attributes.
      .VtColor.Set 255, 255, 0
      .Width = 10
      .Style = VtPenStyleDashDot
      .Join = VtPenJoinRound
      .Cap = VtPenCapRound
   End With
End Sub

Plot Object

Represents the area upon which a chart is displayed.

Syntax

Plot

Remarks

The **Plot** object allows you to program the following objects:

1. **Axis** object — represents the *x*, *y*, and *z* axis of the chart. The *z* axis is only visible on 3D charts.
2. **BackDrop** object — the area behind the axes.
3. **Light** object — the ambient and edge light of the plot.
4. **LocationRect** object — the location of the plot.
5. **SeriesCollection** object — the collection of series sets.
6. **View3D** object — the elevation and rotation of the 3D image.
7. **Wall** object — the area behind the plot.

Example

The following example sets the chart viewing distance and axis division spacing.

```
Private Sub Command1_Click()
   ' Change the chart type to 3D Bar.
   MSChart1.ChartType = VtChChartType3dBar
   With MSChart1.Plot
      ' Changes 3d bar chart's viewing.
      .DepthToHeightRatio = 2
      .WidthToHeightRatio = 2
      ' Changes the spacing between divisions on the
      ' X-Axis.
      .xGap = 0
      ' Changes the spacing between divisions on the
      ' Z-Axis.
      .zGap = 0.8
   End With
End Sub
```

PlotBase Object

The area beneath a chart.

Syntax

PlotBase

Example

The following example sets the chart base parameters on a three-dimensional bar chart.

```
Private Sub Command1_Click()
   ' Change the chart type to 3D.
   MSChart1.ChartType = VtChChartType3dBar
   With MSChart1.Plot.PlotBase
      ' Change the base height.

Rect Object

Defines a coordinate location.

Syntax

Rect

Example

The example increases the size of the chart plot using the **LocationRect** property and the x and y properties of the **Rect** object.

```
Private Sub Command1_Click()
   ' Increase the size of the chart plot.
   MSChart1.Plot.AutoLayout = False
   With MSChart1.Plot.LocationRect
      .Min.x = .Min.x * 1.2
      .Min.y = .Min.y * 1.2
      .Max.x = .Max.x * 1.2

Series Collection

A collection of chart series.

Syntax

Series (*index*)

The **Series** collection syntax has these parts:

Part	Description
index	Integer. Identifies the series of the chart. Series are identified in the order of data grid columns, beginning with 1.

Example

The following example hides all the series in a chart.

```
Private Sub Command1_Click()
   Dim serX As Series
   ' Hides All Series.
   For Each serX In MSChart1.Plot.SeriesCollection
      serX.Position.Hidden = True

Series Object

An item from a **SeriesCollection** collection that represents a group of data points on a chart.

Syntax

Series

Example

The following example changes the appearance of the lines for all series in a three-dimensional line chart.

```
Private Sub Command1_Click()
   Dim serX As Series
   ' Change the chart type to 3D line and smoothing
   ' each line.
   MSChart1.chartType = VtChChartType3dLine
   MSChart1.ColumnCount = 4
   For Each serX In MSChart1.Plot.SeriesCollection
      serX.ShowGuideLine(VtChAxisIdY) = True
      serX.GuideLinePen.Style = VtPenStyleDitted
      serX.Pen.Style = 4
   Next
End Sub

SeriesMarker Object

Describes a marker that identifies all data points within one series on a chart.

Syntax

SeriesMarker

Example

The following example sets marker parameters for all series in a chart.

```
Private Sub Command1_Click()
   Dim serX As series
   ' Show markers and unshow the lines for all series.
   MSChart1.chartType = VtChChartType2dLine
   For Each serX In MSChart1.Plot.SeriesCollection
      serX.SeriesMarker.Show = True

StatLine Object

Describes how statistic lines are displayed on a chart.

Syntax

StatLine

Example

The following example sets the color and pen parameters for a chart statistics line.

```
Private Sub Command1_Click()
   ' Show all statistic lines for series 2.
   MSChart1.chartType = VtChChartType2dLine
   With MSChart1.plot.SeriesCollection(2).StatLine
      .VtColor.Set 128, 128, 255
      .Flag = VtChStatsMinimum Or VtChStatsMaximum _
      Or VtChStatsMean Or VtChStatsStddev Or _

ValueScale Object

Scale used to display a value axis.

Syntax

ValueScale

Example

The following example sets the major and minor grid line color for a two-dimensional bar chart using the **ValueScale** object.

```
Private Sub Command1_Click()
   ' Set chart type to 2d bar.
   MSChart1.ChartType = VtChChartType2dBar
   ' Use manual scale to display y axis (value axis).
   With MSChart1.Plot.Axis(VtChAxisIdY).ValueScale
      .Auto = False
      .MajorDivision = 2
      .MinorDivision = 5
   End With
   ' Show major grid line in red and minor grid line
   ' in blue.
   With MSChart1.Plot.Axis(VtChAxisIdY).AxisGrid
      .MajorPen.VtColor.Set 255, 0, 0
      .MajorPen.Width = 4
      .MinorPen.VtColor.Set 0, 0, 255

VtColor Object

Describes a drawing color in a chart.

Syntax

VtColor

Example

The following example sets the fill color for a chart backdrop brush. The **FillColor** property returns a reference to the **VtColor** object.

```
Private Sub Command1_Click()
' Sets Backdrop to Fill - Brush Style.
   MSChart1.Backdrop.Fill.Style = VtFillStyleBrush
   ' Sets chart fill color to red.
   With MSChart1.Backdrop.Fill.Brush.FillColor
      .Red = 255   ' Use properties to set color.

ActiveSeriesCount Property

Returns the number of series that appear on a chart based on the number of columns in the **DataGrid** object and the type of chart being drawn.

Syntax

*object.***ActiveSeriesCount**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

DataGrid Object

Applies To: MSChart Control

AllowDithering Property

Returns or sets a value that determines whether to disable color dithering for charts on 8-bit color monitors in order to enable use of **MSChart** control's own color palette and enhance the chart display.

Syntax

object.**AllowDithering** [=*boolean*]

The **AllowDithering** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether a color dithering is allowed, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	Color dithering is allowed.
False	(Default) MSChart control's color palette is used for enhanced color matching and display .

See Also

Applies To: MSChart Control

AllowDynamicRotation Property

Returns or sets a value that indicates whether users can interactively rotate three-dimensional charts by holding down the control key to display the rotation cursor.

Syntax

object.**AllowDynamicRotation** [= *boolean*]

The **AllowDynamicRotation** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether a dynamic rotation is allowed, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The user can interactively rotate the chart with the cursor .
False	The user cannot interactively rotate the chart with the cursor.

See Also

Applies To: MSChart Control

AllowSelections Property

Returns or sets a value that indicates whether or not users can select chart objects.

Syntax

object.**AllowSelections** [= *boolean*]

The **AllowSelections** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether selections can be made, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The user can interactively select chart objects .
False	The user cannot select chart objects.

See Also

Applies To: MSChart Control

AllowSeriesSelection Property

Returns or sets a value that indicates whether a series is selected when a user clicks on an individual chart data point.

Syntax

object.**AllowSeriesSelection** [= *boolean*]

The **AllowSeriesSelection** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether series are selected, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) Users can select a series by clicking a data point.
False	Clicking a data point selects only that data point, not the entire series .

See Also

Applies To: MSChart Control

AmbientIntensity Property

Returns or sets the percentage of ambient light illuminating a three-dimensional chart.

Syntax

object.**AmbientIntensity** [= *intensity*]

The **AmbientIntensity** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
intensity	Single. The chart light intensity. Valid values are 0 to 1. If set to 1, all sides of the chart elements are fully illuminated no matter what light sources are turned on. If set at 0, there is no contribution fro m ambient light; only the sides of the chart elements facing active light sources are illuminated.

See Also

Applies To: Light Object

AngleUnit Property

Returns or sets the unit of measure used for all chart angles.

Syntax

object.**AngleUnit** [= *unit*]

The **AngleUnit** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
unit	Integer. A VtAngleUnits constant describing the unit of measure. The angles can be measured in degrees, radians, or grads.

See Also

AngleUnits Constants

Applies To: Plot Object

AngleUnits Constants

VtAngleUnits provides the valid units for measuring chart angles.

Constants	Description
VtAngleUnitsDegrees	Chart angles are measured in degrees.
VtAngleUnitsRadians	Chart angles are measured in radians.
VtAngleUnitsGrads	Chart angles are measured in grads.

See Also

AngleUnit Property

Auto Property (CategoryScale)

Returns or sets a value that indicates whether the axis is automatically scaled.

Syntax

object.**Auto** [= *boolean*]

The **Auto** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether the item is displayed, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The axis is automatically scaled based on the data being charted.
False	The axis is not automatically scaled. Values in **DivisionsPerLabel** and **DivisionsPerTick** are used to determine the scale.

Auto Property (Intersection) | Auto Property (Label) | Auto Property (SeriesMarker) | Auto Property (ValueScale) | DivisionsPerLabel Property | DivisionsPerTick Property | LabelTick Property

Applies To: CategoryScale Object

Auto Property (Intersection)

Returns or sets a value that determines whether or not the **Intersection** object uses the value of the **Point** property to position the axis.

Syntax

object.**Auto** [= *boolean*]

The **Auto** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether the item is displayed, as described in Settings.

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The axis is positioned in its standard location.
False	The intersecting axis is positioned at the value indicated by **Point**.

See Also

Auto Property (CategoryScale) | Auto Property (Label) | Auto Property (SeriesMarker) | Auto Property (ValueScale)

Applies To: Intersection Object

Auto Property (Label)

Returns or sets a value that determines whether axis labels are automatically rotated to improve the chart layout.

Syntax

object.**Auto** [= *boolean*]

The **Auto** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies how axis labels will be positioned, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The labels may be rotated.
False	The labels are not rotated. Long labels may not display properly .

See Also

Auto Property (CategoryScale) | Auto Property (Intersection) | Auto Property (SeriesMarker) | Auto Property (ValueScale)

Applies To: Label Object

Auto Property (SeriesMarker)

Returns or sets a value that determines if the **SeriesMarker** object assigns the next available marker to all data points in the series.

Syntax

object.**Auto** [= *boolean*]

The **Auto** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls how markers are assigned, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The **SeriesMarker** object assigns the marker .
False	You can assign a custom marker.

Remarks

Set this property to **False** if you wish to change the series marker type.

This property is automatically set to **False** if the **Marker** property of the **DataPoint** object is set.

See Also

Auto Property (CategoryScale) | Auto Property (Intersection) | Auto Property (Label) | Auto Property (ValueScale)

Applies To: SeriesMarker Object

Auto Property (ValueScale)

Returns or sets a value that determines whether automatic scaling is used to draw the value axis.

Syntax

object.**Auto** [= *boolean*]

The **Auto** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that determines whether automatic scaling is used, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The scale is automatically set based on the data being charted.
False	The values in the **Minimum**, **Maximum**, **MajorDivisions** and **MinorDivisions** properties are used to scale the axis.

See Also

Auto Property (CategoryScale) | Auto Property (Intersection) | Auto Property (Label) | Auto Property (SeriesMarker)

Applies To: ValueScale Object

AutoIncrement Property

Returns or sets a value that determines if the properties that set the current data point are incremented during data entry without manually setting the **Column** and **Row** properties.

Syntax

object.**AutoIncrement** [= *boolean*]

The **AutoIncrement** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether the current data point is incremented, as described in Settings.

Settings

The settings for *boolean* are:

Setting	Description
True	When the **Data** property is changed, the **Row** property updates to the next row in the column. If you are at the end of a column, the **Column** property increments to the next column.
False	(Default) The current data point is not incremented.

See Also

Applies To: MSChart Control

AutoLayout Property

Returns or sets a value that determines whether or not a **Plot** object is in manual or automatic layout mode.

Syntax

object.**AutoLayout** [= *boolean*]

The **AutoLayout** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies the layout mode, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The **Plot** object automatically determines the proper size and position of the plot based on the size and position of other elements.
False	The coordinates specified by **Plot** object's **LocationRect** property are used to position the plot.

See Also

Applies To: Plot Object

Automatic Property

Returns or sets a value that determines whether the color is calculated automatically. This is only used for edge pens on chart elements.

Syntax

object.**Automatic** [= *boolean*]

The **Automatic** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that determines whether the color is calculated automatically, as described in Setting s.

Settings

The settings for *boolean* are:

Setting	Description
True	Color automatically picks up the brush color used on the chart series .
False	The color is determined based on the settings of **Value**.

See Also

Applies To: VtColor Object

Axis Property

Returns a reference to an **Axis** object that describes an axis on a chart.

Syntax

object.**Axis**(*axisID*)

The **Axis** property syntax has these parts:

Part	Description
object	Required. An object expression that evaluates to an object in the Applies To list.
axisID	Required. An integer or VtChAxisId constant that identifies a specific axis.
index	Optional. Reserved for future use. Identifies the specific axis when there is more than one axis with the same *axisID*.

Remarks

Three axes are available: *x*, *y*, and *z*. The *z* axis is visible only when the chart is a 3D chart.

See Also

AxisId Constants

Applies To: Plot Object

AxisGrid Property

Returns a reference to an **AxisGrid** object that represents the planar area surrounding a chart axis.

Syntax

object.**AxisGrid**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Axis Object

AxisId Property

Returns a specific axis that intersects with the current axis.

Syntax

object.**AxisId**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Return Value

The return value is an integer that identifies the intersecting axis.

See Also

AxisId Constants

Applies To: Intersection Object

AxisId Constants

The **VtChAxisId** constants provide options for identifying a chart axis.

Constants	Description
VtChAxisIdX	Identifies the *x* axis.
VtChAxisIdY	Identifies the *y* axis.
VtChAxisIdY2	Identifies the secondary *y* axis.
VtChAxisIdZ	Identifies the *z* axis.

See Also

Axis Property | AxisId Property | GetSelectedPart Method | SelectPart Method | ShowGuideLine Property | TwipsToChartPart Method

AxisScale Property

Returns a reference to an **AxisScale** object that describes how chart values are plotted on an axis.

Syntax

object.**AxisScale**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

AxisScale Object

Applies To: Axis Object

AxisTitle Property

Returns a reference to an **AxisTitle** object associated with the axis of a chart.

Syntax

*object.***AxisTitle**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Axis Object

Backdrop Property

Returns a reference to a **Backdrop** object that describes the shadow, pattern, or picture behind a chart or chart element.

Syntax

object.**Backdrop**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: AxisTitle Object | DataPointLabel Object | Footnote Object | Label Object | Legend Object | MSChart Control | Plot Object | Title Object

BarGap Property

Returns or sets the spacing of two-dimensional bars or clustered three-dimensional bars within a category.

Syntax

object.**BarGap** [= *value*]

The **BarGap** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
value	Single. The bar spacing value. This is measured as a percentage of the bar width. A value of 0 results in the bars touching. A value of 100 means the gap between the bars is as wide as the bars.

See Also

Applies To: Plot Object

BaseHeight Property

Returns or sets the height of the three-dimensional chart base in points.

Syntax

object.**BaseHeight** [= *height*]

The **BaseHeight** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
height	Single. The base height.

See Also

Applies To: PlotBase Object

Basis Property

Returns or sets the type of weighting used to determine pie size on a chart.

Syntax

object.**Basis** [= *type*]

The **Basis** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
type	A **VtChPieWeightBasis** constant that identifies the weighting type.

See Also

PieWeightBasis Constants

Applies To: Weighting Object

PieWeightBasis Constants

The **VtChPieWeightBasis** constants provide options for displaying pie chart slices.

Constant	Description
VtChPieWeightBasisNone	All pies are drawn the same size.
VtChPieWeightBasisTotal	The slice values in each pie are totaled and the pie with the highest total identified. The size of each pie in the chart is determined by the ratio of its total value compared to the largest pie.
VtChPieWeightBasisSeries	The first column of data in the data grid holds the relative size index. In other words, if you have 5 categories, you can control the size of the pies representing each category by using the first column of the data grid to number the rows 1 through 5. The size of the pie is determined by the ratio of its first column value and the largest value in the first column. The pie containing the 1 is the largest pie; the one containing the 5 the smallest. It is most common to exclude this first column of data so that the values are not drawn as a pie slice.

See Also

Basis Property | Set Method (Weighting)

Blue Property

Returns or sets the blue component of the RGB value in a chart.

Syntax

object.**Blue [=***b***]**

The **Blue** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
b	Integer. The blue value.

Remarks

RGB specifies the relative intensity of red, green, and blue to cause a specific color to be displayed. The valid range for a normal RGB color is 0 to 16,777,215. The value for any argument to RGB that exceeds 255 is assumed to be 255.

See Also

Applies To: VtColor Object

Brush Property

Returns a reference to a **Brush** object that describes the fill type used to display a chart element.

Syntax

object.**Brush**

The *object* placeholder represents an object expression that evaluates to an object in the Applies To list.

Example

See Brush Object.

See Also

Brush Object

Applies To: DataPoint Object | Fill Object | PlotBase Object | Shadow Object | Wall Object

Cap Property

Returns or sets a value that determines how line ends are capped.

Syntax

object.**Cap** [= *type*]

The **Cap** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
type	Integer. A VtPenCap constant that describes the line pen cap style.

See Also

PenCap Constants

Applies To: Pen Object

PenCap Constants

VtPenCap provides methods for displaying line endings.

Constant	Description
VtPenCapButt	The line is squared off at the endpoint.
VtPenCapRound	A semicircle with the diameter of the line thickness is drawn at the end of the line.
VtPenCapSquare	The line continues beyond the endpoint for a distance equal to half the line thickness a nd is squared off.

See Also

Cap Property

CategoryScale Property

Returns a reference to a **CategoryScale** object that describes the scale information for a category axis.

Syntax

object.**CategoryScale**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

ValueScale Property

Applies To: Axis Object

Chart3d Property

Returns a value that specifies whether or not a chart is three dimensional.

Syntax

object.**Chart3D**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Return Values

Setting	Description
True	The chart is a three-dimensional chart.
False	The chart is not a three-dimensional chart.

Remarks

Whether or not a chart is three-dimensional depends on the **ChartType** property's setting.

See Also

Applies To: MSChart Control

ChartData Property

Returns or sets an array that contains the values that will be displayed by the chart.

Syntax

object.**ChartData** [= *data*]

The **ChartData** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
data	Variant. A two-dimensional array that holds the data used to draw the chart .

Remarks

If the first series of a multi-dimensional array contains strings, those strings will become the labels of the chart.

ChartData is the default property for the MSChart control.

Example

The following example uses a Visual Basic array to load the chart data grid directly. To try the example, draw a **MSChart** control on a form, paste the code into the **Form** object's code module, and run the project.

```
Private Sub Form_Load()
    Dim arrData(3, 1 To 3)
    arrData(1, 1) = "Jan"   ' Set the labels in the first series.
    arrData(2, 1) = "Feb"
    arrData(3, 1) = "Mar"

    arrData(1, 2) = 8
    arrData(2, 2) = 4
    arrData(3, 2) = 0.3

    arrData(1, 3) = 0.2
    arrData(2, 3) = 3
    arrData(3, 3) = 6.3
    MSChart1.ChartData = arrData
End Sub
```

In this example, the lower subscript bound was declared as 1 using the **Option Base 1** statement, rather than the default of 0. We use a **Variant** array where the first series values are set to string variables and the second and third series' values are set to numeric values. This allows both the chart's labels and data to be set simultaneously. Note that declaring the array as type **String** works too, as long as the second and third series contain numeric values. If you wish only to set the chart's data, the array can be of the numeric types **Integer**, **Long**, **Single** or **Double**. Note that doing this will replace the existing chart labels with default row/column labels. Also, a one-dimensional array will work as well as a two-dimensional one as long as the last values are either numeric or text representations of numeric values.

The following example returns data from the chart. The example contains a loop to print out the array returned from the chart. Note the use of the **Lbound** and **Ubound** functions to determine the array bounds from the chart. To try the example, draw a **CommandButton** control onto a form with a **MSChart** control. Paste the code into the code module, run the project, and click the button.

```
Private Sub Command1_Click()
   Dim y() As Variant
   Dim i, j As Integer
   y = MSChart1.ChartData
   For i = LBound(y, 2) To UBound(y, 2)
      Debug.Print
      For j = LBound(y, 1) To UBound(y, 1)
         Debug.Print y(j, i)
```

```
        Next j
    Next i
End Sub
```

The returned array lower bound values are equal to 0. The returned array will always be a two-dimensional array of type **Variant**. Since **ChartData** is the default property for the chart, the object name alone, such as MSChart1, can be substituted for MSChart1.ChartData. So you could use MSChart1 = data or data = MSChart1.

See Also

Applies To: MSChart Control

ChartType Property

Returns or sets the chart type being used to display a chart.

Syntax

object.**ChartType** [= *type*]

The **ChartType** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
type	Integer. A VtChChartType constant that describes the chart type.

See Also

ChartType Constants

Applies To: MSChart Control

ChartType Constants

VtChChartType provides chart type options.

Constant	Description
VtChChartType3dBar	3D Bar
VtChChartType2dBar	2D Bar
VtChChartType3dLine	3D Line
VtChChartType2dLine	2D Line
VtChChartType3dArea	3D Area
VtChChartType2dArea	2D Area
VtChChartType3dStep	3D Step
VtChChartType2dStep	2D Step
VtChChartType3dCombination	3D Combination
VtChChartType2dCombination	2D Combination
VtChChartType2dPie	2D Pie
VtChChartType2dXY	2D XY

See Also

ChartType Property | TypeByChartType Method

Clockwise Property

Returns or sets a value that specifies whether pie charts are drawn in a clockwise direction.

Syntax

object.**Clockwise** [= *boolean*]

The **Clockwise** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls the direction used to draw pie charts, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) Pie charts are drawn in a clockwise direction .
False	The charts are drawn in a counterclockwise direction.

See Also

Applies To: Plot Object

Column Property (MSChart Control)

Returns or sets the current data column in the data grid.

Syntax

object.**Column** [= *col*]

The **Column** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
col	Integer. The current data column.

Remarks

You must select a column before you can use other properties to change the column's corresponding chart series or any data point within the series.

See Also

Applies To: MSChart Control

ColumnCount Property

Returns or sets the number of columns in the current data grid associated with a chart.

Syntax

object.**ColumnCount** [= *count*]

The **ColumnCount** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
count	The number of data columns.

See Also

SetSize Method

Applies To: DataGrid Object | MSChart Control

ColumnLabel Property (DataGrid Object)

Returns or sets the label on a data column in the grid associated with a chart.

Syntax

object.**ColumnLabel**(*column*, *labelIndex*) [= *text*]

The **ColumnLabel** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
column	Integer. Identifies a specific data column. Columns are numbered from left to right beginning with 1. Any columns containing labels are not counted as data columns.
labelIndex	Integer. Identifies a specific label. If more than one level of column labels exist for the column, you must identify one of them. Column labels are numbered from bottom to top beginning at 1.
text	String. The column label text.

Example

See ColumnLabel Property (MSChart).

See Also

ColumnLabel Property (MSChart) | RowLabel Property (DataGrid Object)

Applies To: DataGrid Object

ColumnLabel Property (MSChart)

Returns or sets the label text associated with a column in the data grid of a chart.

Syntax

object.**ColumnLabel** [= *text*]

The **ColumnLabel** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
text	String. Label text associated with a column in the data grid.

Remarks

This property sets the label for the column currently identified by the **Column** property.

Example

The example adds three column labels to the z axis of a chart. To try the example, draw an **MSChart** control on a form. Paste the code into the **Form** object's code module, and run the project. Click the form to see the labels.

```
Private Sub Form_Click()
   With MSChart1
      .chartType = VtChChartType3dLine

      .Plot.Axis(VtChAxisIdZ).Labels(1).VtFont.Size = 24
      .DataGrid.ColumnLabel(1, 1) = "Label Z1"
      .DataGrid.ColumnLabel(2, 1) = "Label Z2"
      .DataGrid.ColumnLabel(3, 1) = "Label Z3"
   End With
End Sub

Private Sub Form_Load()
   ' The first series contains labels for the X axis.
   Dim arrData(4, 1 To 4)
   arrData(1, 1) = "Jan"
   arrData(2, 1) = "Feb"
   arrData(3, 1) = "Mar"
   arrData(4, 1) = "Apr"

   arrData(1, 2) = 8
   arrData(2, 2) = 4
   arrData(3, 2) = 0.3
   arrData(4, 2) = 3

   arrData(1, 3) = 0.2
   arrData(2, 3) = 3
   arrData(3, 3) = 6.3
   arrData(4, 3) = 2

   arrData(1, 4) = 5
   arrData(2, 4) = 7
   arrData(3, 4) = 2
   arrData(4, 4) = 9
   MSChart1.ChartData = arrData
End Sub
```

See Also

ColumnLabel Property (DataGrid Object) | RowLabel Property (MSChart)

Applies To: MSChart Control

ColumnLabelCount Property

Returns or sets the number of levels of labels on the columns in the data grid associated with a chart.

Syntax

object.**ColumnLabelCount** [= *count*]

The **ColumnLabelCount** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
count	Integer. The number of column label levels. Set this property to add or delete levels of labels on data grid columns.

Remarks

Column label levels are numbered from bottom to top, beginning at 1. Levels are added or subtracted from the top.

See Also

SetSize Method

Applies To: DataGrid Object | MSChart Control

ColumnLabelIndex Property

Returns or sets a specific level of column labels associated with a chart.

Syntax

object.**ColumnLabelIndex** [= *index*]

The **ColumnLabelIndex** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
index	Integer. Identifies a column label level.

Remarks

To set a label on a column with more than one level of labels, or to return the current value for a label, you must first identify which level you want to affect. Column label levels are numbered from bottom to top, beginning at 1.

See Also

Applies To: MSChart Control

Component Property

Returns or sets the type of label to be used to identify the data point.

Syntax

object.**Component** [= *type*]

The **Component** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. A VtChLabelComponent constant that identifies the label type .

See Also

LabelComponent Constants

Applies To: DataPointLabel Object

LabelComponent Constants

The **VtChLabelComponent** constants provide options for displaying chart labels.

Constant	Description
VtChLabelComponentValue	The value of the data point appears in the label. Data points in XY, Pola r, and Bubble charts actually have two or three values. The default label for these chart types display all values in a standard format. You can cu stomize this format to highlight an individual data value.
VtChLabelComponentPercent	The value of the data point is displayed in the label as a percentage of t he total value of the series.
VtChLabelComponentSeriesName	The series name is used to label the data point. This name is taken fro m the label associated with the column in the data grid.
VtChLabelComponentPointName	The data point name is used to label the data point.

See Also

Component Property

CompositeColumnLabel Property

Returns the multilevel label string that identifies a column in the data grid associated with a chart.

Syntax

object.**CompositeColumnLabel**(*column*)

The **CompositeColumnLabel** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
column	Integer. Identifies a specific data column. Columns are numbered from left to right beginning with 1. Any columns containing labels are not counted as data columns.

See Also

CompositeRowLabel Property

Applies To: DataGrid Object

CompositeRowLabel Property

Returns the multilevel label string that identifies a row in the data grid associated with a chart.

Syntax

object.**CompositeRowLabel** (*row*)

The **CompositeRowLabel** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
row	Integer. Identifies a specific data row. Rows are numbered from top to bottom beginning with 1. Any rows containing labels are not counted as data rows.

See Also

CompositeColumnLabel Property

Applies To: DataGrid Object

Custom Property

Returns or sets a value that determines if custom text is used to label a data point on a chart.

Syntax

object.**Custom** [= *boolean*]

The **Custom** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether custom text is used, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The label contains custom text.
False	(Default) Information specified by the **DataPointLabel** object's **Components** property is used to label t he data point.

See Also

Applies To: DataPointLabel Object

Data Property (MSChart)

Returns or sets a value that is inserted into the current data point in the data grid of a chart.

Syntax

object.**Data** [= *value*]

The **Data** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
value	Integer. The data point value.

Remarks

If the current data point already contains a value, it is replaced by the new value. The chart is redrawn to reflect the new value for the current data point.

See Also

Applies To: MSChart Control

DataGrid Property

Returns a reference to a **DataGrid** object that describes the data grid associated with a chart.

Syntax

object.**DataGrid**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: MSChart Control

DataPointLabel Property

Returns a reference to a **DataPointLabel** object that describes a label on an individual chart data point.

Syntax

object.**DataPointLabel**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: DataPoint Object

DataPoints Property

Returns a reference to a **DataPoint** Collection that describes the data points within a chart series.

Syntax

object.**DataPoints**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Series Object

DataSeriesInRow Property

Returns or sets a value that indicates whether series data is being read from a row or a column in a data grid associated with a chart.

Syntax

object.**DataSeriesInRow** [= *boolean*]

The **DataSeriesInRow** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls how series data is read, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	Series data is being read from a row in a data grid .
False	(Default) Series data is being read from a column.

See Also

Applies To: Plot Object

DefaultPercentBasis Property

Returns the default axis percentage basis for the chart.

Syntax

object.**DefaultPercentBasis**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Return Value

An integer that specifies the default axis percentage basis. Possible return values are VtChPercentAxisBasis constants.

See Also

Applies To: Plot Object

DepthToHeightRatio Property

Returns or sets the percentage of the chart height to be used as the chart depth.

Syntax

object.**DepthToHeightRatio** [= *pctg*]

The **DepthToHeightRatio** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
pctg	Single. The chart height percentage.

Remarks

This property has an effect only on 3 dimensional chart types.

See Also

Applies To: Plot Object

DivisionsPerLabel Property

Returns or sets the number of divisions to skip between labels.

Syntax

object.**DivisionsPerLabel** [= *num*]

The **DivisionsPerLabel** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
num	Integer. An integer representing the number of divisions.

Remarks

If this property is set, the object's **Auto** property is automatically set to **False**.

See Also

Auto Property (CategoryScale) | DivisionsPerTick Property

Applies To: CategoryScale Object

DivisionsPerTick Property

Returns or sets the number of divisions to skip between major tick marks.

Syntax

object.**DivisionsPerTick** [= *num*]

The **DivisionsPerTick** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
num	Integer. An integer representing the number of divisions.

Remarks

If this property is set, the object's **Auto** property is automatically set to **False**.

See Also

Auto Property (CategoryScale) | DivisionsPerLabel Property

Applies To: CategoryScale Object

DoSetCursor Property

Returns or sets a value that indicates whether or not the cursor can be set by a chart. The **DoSetCursor** property determines whether or not the application can control what the mouse pointer looks like.

Syntax

object.**DoSetCursor** [= *boolean*]

The **DoSetCursor** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether custom text is used, as described in Settings.

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The application can control the mouse pointer appearance .
False	The application cannot control the mouse pointer appearance.

See Also

Applies To: MSChart Control

DrawMode Property (MSChart)

Returns or sets a value that determines when and how a chart is repainted.

Syntax

object.**DrawMode** [= *mode*]

The **DrawMode** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mode	Integer. A value that determines how and when the chart will be redrawn, as shown in Settings .

Settings

The settings for *mode* are:

Constant	Value	Description
VtChDrawModeDraw	0	Draws directly to the display device.
VtChDrawModeBlit	1	Blits an offscreen drawing to the display device.

See Also

DrawMode Constants

Applies To: MSChart Control

DrawMode Constants

The **VtChDrawMode** constants provide options for redisplaying a chart after it has been altered.

Constants	Description
VtChDrawModeDraw	Draw mode. The chart is redrawn on the screen every time you change a setting.
VtChDrawModeBlit	Blit mode. The chart is redrawn off the screen and displayed after the redraw is complete.

Blit mode stores a bitmap copy of the chart in memory when the chart is laid out. Repainting the chart uses the bitmap and draws very quickly. It requires more memory than Draw mode, but can save time waiting for the chart to redraw on screen. Blit mode is particularly useful when working with charts that contain many elements.

EdgeIntensity Property

Returns or sets the intensity of light used to draw the edges of objects in a three-dimensional chart.

Syntax

object.**EdgeIntensity** [= *edgeint*]

The **EdgeIntensity** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
edgeint	Single. The edge light intensity. Valid values are 0 to 1.0. An intensity of 0 turns edges off, drawing the edges as black lines; and an intensity of 1 fully illuminates the edges using the element's pen color.

Remarks

If this property is set, then the **Light** object's **EdgeVisible** property is automatically set to **True**.

See Also

Applies To: Light Object

EdgePen Property

Returns the **Pen** object used to draw the edge of the data point on a chart.

Syntax

object.**EdgePen**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: DataPoint Object

EdgeVisible Property

Returns or sets a value that determines whether edges are displayed on the elements in a three-dimensional chart.

Syntax

object.**EdgeVisible** [= *boolean*]

The **EdgeVisible** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies edges are displayed, as described in Settings.

Settings

The settings for *boolean* are:

Setting	Description
True	Edges are visible.
False	Edges are not displayed on elements in the three-dimensional chart.

See Also

Applies To: Light Object

Effect Property

Returns or sets the font effects in a chart.

Syntax

object.**Effect** [= *effects*]

The **Effect** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
effects	Integer. A **VtFontEffect** constant describing the font effect.

See Also

FontEffect Constants

Applies To: VtFont Object

FontEffect Constants

VtFontEffect provides methods of altering fonts for the desired effect.

Constant	Description
VtFontEffectStrikeThrough	Applies the strike-through attribute to the font.
VtFontEffectUnderline	Applies the underscore attribute to the font.

See Also

Effect Property

Elevation Property

Returns or sets a value that describes the degree of elevation from which a three-dimensional chart is viewed.

Syntax

object.**Elevation** [= *degree*]

The **Elevation** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
degree	Single. The degree of elevation. Elevation can be any number from 0 to 90 degrees. If you set the elevation to 90 degrees, you look directly down onto the top of the chart. If you set the elevation to 0, you look directly at the side of the chart. The de fault elevation is 30 degrees. By default, degrees are used to measure elevation. However, these settings us e the current settings for the AngleUnit property. The other options are: Grads and Radians.

See Also

Applies To: View3D Object

Excluded Property

Returns or sets a value that determines whether a series is included on the chart.

Syntax

object.**Excluded** [= *boolean*]

The **Excluded** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls whether a series is included on the chart, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The chart is drawn without including the series.
False	(Default) The series is included when the chart is drawn. A series may be included in a chart, but still not display because it is **Hidden**.

See Also

Hidden Property (MSChart)

Applies To: SeriesPosition Object

Fill Property

Returns a reference to a **Fill** object that describes the type and appearance of a chart object's backdrop.

Syntax

object.**Fill**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Example

See Fill Object.

See Also

Fill Object

Applies To: Backdrop Object

FillColor Property

Returns a reference to a **VtColor** object that describes the color used to fill a chart element.

Syntax

object.**FillColor**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

If the **FillColor** property of the **Marker** object is set, then the **Marker** object's **Visible** property is automatically set to **True**.

Example

See VtColor Object.

See Also

FillStyle Constants (MSChart Control)

Applies To: Brush Object | Marker Object

Flag Property

Returns or sets which statistic lines are being displayed for a series.

Syntax

object.**Flag** [= *lines*]

The **Flag** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
lines	Integer. A VtChStats constant used to describe the stat line. If more than one statistics line is displayed, the constants are combined with an OR operator.

See Also

StatsType Constants

Applies To: StatLine Object

Font Property (MSChart)

Returns a reference to a standard **Font** object that describes the font used to display text on the chart.

Syntax

object.**Font**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: AxisTitle Object | DataPointLabel Object | Footnote Object | Label Object | Legend Object | Title Object

Footnote Property

Returns a reference to a **Footnote** object that provides information about the descriptive text used to annotate a chart.

Syntax

object.**Footnote**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Footnote Object

Applies To: MSChart Control

FootnoteText Property

Returns or sets the text used as the footnote.

Syntax

object.**FootnoteText** [= *text*]

The **FootnoteText** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
text	String. The footnote text.

Remarks

The same results can be achieved by using the **Text** property of the **Footnote** object.

See Also

Applies To: MSChart Control

Format Property (Label Object)

Returns or sets the characters that define the format used to display the axis label.

Syntax

object.**Format** [= *format*]

The **Format** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
format	String. Defines the format used to display the axis label.

See Also

Applies To: Label Object

FormatLength Property

Returns the length of the format string.

Syntax

object.**FormatLength**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Return Value

Integer

See Also

Applies To: Label Object

Frame Property

Returns a reference to a **Frame** object that describes the appearance of the frame around a chart element.

Syntax

object.**Frame**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Frame Object

Applies To: Backdrop Object

FrameColor Property

Returns a reference to a **VtColor** object that specifies the color used to frame a chart element.

Syntax

*object.***FrameColor**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Example

See Frame Object.

See Also

SpaceColor Property

Applies To: Frame Object

Green Property

Returns or sets the green component of the RGB value in a chart.

Syntax

object.**Green [**=*g***]**

The **Green p**roperty syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
g	Integer. The green value.

Remarks

RGB specifies the relative intensity of red, green, and blue to cause a specific color to be displayed. The valid range for a normal RGB color is 0 to 16,777,215. The value for any argument to RGB that exceeds 255 is assumed to be 255.

See Also

Applies To: VtColor Object

GuidelinePen Property

Returns a reference to a **Pen** object that describes the pattern of line and color used to display guidelines.

Syntax

*object.***GuidelinePen**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

Setting this property automatically sets the **ShowGuideLines** property to **True**.

Example

See Pen Object.

See Also

Applies To: Series Object

Hidden Property (MSChart)

Returns or sets a value that determines whether a series is displayed on the chart.

Syntax

object.**Hidden** [= *boolean*]

The **Hidden** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls whether a series is displayed on the chart, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The chart is drawn without displaying the series. However, any space allocated for the serie s still exists.
False	(Default) The series is displayed.

See Also

Applies To: SeriesPosition Object

Hide Property

Returns or sets a value that determines whether the axis on a chart is hidden.

Syntax

object.**Hide** [= *boolean*]

The **Hide** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether the axis is hidden, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The axis scale, line, ticks and title are hidden .
False	(Default) The axis appears on the chart.

See Also

Applies To: AxisScale Object

HorzAlignment Property

Returns or sets the method of horizontal alignment of text.

Syntax

object.**HorzAlignment** [= *type*]

The **HorzAlignment** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. A VtHorizontalAlignment constant used to describe the horizontal alignment method of text .

See Also

HorizontalAlignment Constants

Applies To: TextLayout Object

HorizontalAlignment Constants

The **VtHorizontalAlignment** constants provide options for text alignment.

Constant	Description
VtHorizontalAlignmentLeft	All lines of text are aligned on the left margin.
VtHorizontalAlignmentRight	All lines of text are aligned on the right margin .
VtHorizontalAlignmentCenter	All lines of text are centered horizontally.

See Also

HorzAlignment Property

Index Property (Brush)

Returns or sets the pattern or hatch used in the brush if its **Style** property is set to **VtBrushStylePattern** or **VtBrushStyleHatch**.

Syntax

object.**Index** [= *num*]

The **Index property syntax has** these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
num	A VtBrushPattern constant or VtBrushHatch constant describing the brush pattern .

See Also

BrushHatch Constants | BrushPattern Constants | Index Property (Intersection)

Applies To: Brush Object

Index Property (Intersection)

Returns which axis intersects another axis when there is more than one axis with the same index.

Syntax

object.**Index**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Return Value

The return value is an integer that specifies the index of the intersecting axis. Currently, 1 is the only valid value for this argument.

See Also

Index Property (Brush)

Applies To: Intersection Object

Intensity Property

Returns or sets the strength of the light coming from the light source.

Syntax

object.**Intensity** [= *strength*]

The **Intensity** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
strength	Single. The light strength. If the intensity is set to 100 percent (1), chart surfaces facing the light source are fully illuminated. If the light is set at 50 percent (.5), these surfaces receive 50 percent illumination from th is light. Valid range is 0 to 1.

Remarks

Intensity is the default property of the **LightSource** object.

See Also

Applies To: LightSource Object

Intersection Property

Returns a reference to an **Intersection** object that describes the point at which an axis intersects another axis on a chart.

Syntax

object.**Intersection**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Intersection Object

Applies To: Axis Object

Item Property (MSChart)

Returns a reference to an object within a collection that describes a chart element.

Syntax

object.**Item** (*index*)

The **Item** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
index	An unique integer that identifies the member of the collection.

See Also

Applies To: DataPoints Collection | Labels Collection | LightSources Collection | SeriesCollection Collection

Join Property

Returns or sets a value that determines how line segments are formed.

Syntax

object.**Join** [= *type*]

The **Join** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
type	Integer. A VtPenJoin constant that describes the style of pen join.

See Also

PenJoin Constants

Applies To: Pen Object

PenJoin Constants

The **VtPenJoin** constants provide options for joining line segments in a series.

Constant	Description
VtPenJoinMiter	The outer edges of the two lines are extended until they meet.
VtPenJoinRound	A circular arc is drawn around the point where the two lines meet .
VtPenJoinBevel	The notch between the ends of two joining lines is filled.

See Also

Join Property

LabelLevelCount Property

Returns the number of levels of labels for a given axis. Not available at design time.

Syntax

object.**LabelLevelCount** [= *count*]

The **LabelLevelCount** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
count	Integer. An integer that describes the number of labels.

See Also

Applies To: Axis Object

Labels Property

Returns a reference to a **Labels** collection that describes the labels on a chart axis.

Syntax

object.**Labels**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Label Object | Labels Collection

Applies To: Axis Object

LabelsInsidePlot Property

Returns or sets a value that determines whether to leave the axis labels at the normal location or move them with the axis to the new intersection point.

Syntax

object.**LabelsInsidePlot** [= *boolean*]

The **LabelsInsidePlot** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies where to display the axis labels, as described in Settings.

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The axis labels remain at the normal location.
False	The labels move inside the plot to the new intersection point.

Remarks

If this property is set, then the Intersection object's **Auto** property is automatically set to **False**.

See Also

Applies To: Intersection Object

LabelTick Property

Returns or sets a value that indicates whether category axis labels are centered on an axis tick mark.

Syntax

object.**LabelTick** [= *boolean*]

The **LabelTick** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether the item is displayed, as described in Settings.

Settings

The settings for *boolean* are:

Setting	Description
True	The labels are centered on a tick mark.
False	(Default) The labels are centered between two tick marks.

Remarks

If this property is set, the object's **Auto** property is automatically set to **False**.

See Also

Auto Property (CategoryScale)

Applies To: CategoryScale Object

Legend Property

Returns a reference to a **Legend** object that contains information about the appearance and behavior of the graphical key and accompanying text that describes the chart series.

Syntax

object.**Legend**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: MSChart Control

LegendText Property

Returns or sets the text that identifies the series in the legend of a chart.

Syntax

object.**LegendText** [= *text*]

The **LegendText** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
text	String. The text that identifies the current series in the legend.

Remarks

By default, this text is the same as the **Text** property of the **ColumnLabel** object.

See Also

Applies To: Series Object

Length Property (MSChart)

Returns or sets the length of axis tick marks, measured in points.

Syntax

object.**Length** [**=** *length*]

The **Length** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
length	Integer. The axis tick mark length.

See Also

Applies To: Tick Object

Light Property

Returns a reference to a **Light** object that provides information about the light illuminating a three-dimensional chart.

Syntax

object.**Light**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Plot Object

LightSources Property

Returns a reference to a **LightSources** collection that describes all light sources used to illuminate a three-dimensional chart.

Syntax

object.**LightSources**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

LightSources Collection

Applies To: Light Object

Limit Property

Returns or sets the joint limit, in points, of the line.

Syntax

object.**Limit** [= *joint*]

The **Limit** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
joint	Single. A joint limit as a multiple of the line width. If two lines meet at a sharp angle, a mitered join results in a corner point that extends beyond the actual corner. If the distance from the inner join point to the outer join point exceeds the value in this variable, the join automatically changes to a bevel.

See Also

Applies To: Pen Object

LineStyle Property (DataPointLabel Object)

Returns or sets the type of line used to connect a data point to a label on a chart.

Syntax

object.**LineStyle** [= *type*]

The **LineStyle** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. A VtChLabelLineStyle constant identifying the connecting line.

See Also

LabelLineStyle Constants

Applies To: DataPointLabel Object

LabelLineStyle Constants

The **VtChLabelLineStyle** constants provide options for displaying lines connecting a label and series.

The following table lists the valid constants for **VtChLabelLineStyle**:

Constants	Description
VtChLabelLineStyleNone	No line connects the label and series.
VtChLabelLineStyleStraight	A straight line connects the label and series.
VtChLabelLineStyleBent	A bent line connects the label and series.

See Also

LineStyle Property (DataPointLabel Object)

Location Property

Returns a reference to a **Location** object that describes the position of textual chart elements.

Syntax

object.**Location**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Location Object

Applies To: Footnote Object | Legend Object | Title Object

LocationRect Property

Returns a reference to a **Rect** object that specifies the location of the chart plot using *x* and *y* coordinates.

Syntax

*object.***LocationRect**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

The values of this property are used to position the plot if **AutoLayout** is **False.**

If this property is set, then the **AutoLayout** property is automatically set to **False**.

Example

See Rect Object.

See Also

Applies To: Plot Object

LocationType Property

Returns or sets the standard position used to display a chart element.

Syntax

object.**LocationType** [=*type*]

The **LocationType** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. For the **DataPointLabel** object, a VtChLabelLocationType constant identifying label position . For a **Location** object, a VtChLocationType constant describing the location of text.

See Also

LocationType Constants

Applies To: DataPointLabel Object | Location Object

LocationType Constants

VtChLocationType provides location options for chart elements.

Constant	Example
VtChLocationTypeTop	Top
VtChLocationTypeTopLeft	Top Left
VtChLocationTypeTopRight	Top Right
VtChLocationTypeLeft	Left
VtChLocationTypeRight	Right
VtChLocationTypeBottom	Bottom
VtChLocationTypeBottomLeft	Bottom Left
VtChLocationTypeBottomRight	Bottom Right
VtChLocationTypeCustom	Custom

See Also

LocationType Property

LabelLocationType Constants

The **VtChLabelLocationType** constants provide options for determining series label location.

The following table lists the valid constants for **VtChLabelLocationType**:

Constants	Description
VtChLabelLocationTypeNone	No label displayed.
VtChLabelLocationTypeAbovePoint	The label is displayed above the data point.
VtChLabelLocationTypeBelowPoint	The label is displayed below the data point.
VtChLabelLocationTypeCenter	The label is displayed centered on the data point.
VtChLabelLocationTypeBase	The label is displayed at the base along the category axis, dir ectly beneath the data point.
VtChLabelLocationTypeInside	The label is displayed inside a pie slice.
VtChLabelLocationTypeOutside	The label is displayed outside a pie slice.
VtChLabelLocationTypeLeft	The label is displayed to the left of the data point.
VtChLabelLocationTypeRight	The label is displayed to the right of the data point.

LogBase Property

Returns or sets the logarithm base used to plot chart values on a logarithmic axis.

Syntax

object.**LogBase** [= *base*]

The **LogBase** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
base	Integer. An integer that identifies the logarithm base. The default base is 10. The valid range is 2 to 100 .

Remarks

This property has an effect only when the **Type** property is set to **VtChScaleTypeLogarithmic**.

See Also

Applies To: AxisScale Object

MajorDivision Property

Returns or sets the number of major divisions displayed on the axis.

Syntax

object.**MajorDivision** [= *num*]

The **MajorDivision** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
num	Integer. Number of divisions.

Remarks

If this property is set, then the **ValueScale** object's **Auto** property is automatically set to **False**.

See Also

MinorDivision Property

Applies To: ValueScale Object

MajorPen Property

Returns a reference to a **Pen** object that describes the appearance of the major axis grid lines.

Syntax

*object.***MajorPen**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

MinorPen Property

Applies To: AxisGrid Object

Marker Property

Returns a reference to a **Marker** object that describes the icon used to identify a data point on a chart.

Syntax

object.**Marker**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: DataPoint Object

Max Property (MSChart)

Returns a reference to a **Coor** object that specifies the ending corner of a rectangle.

Syntax

object.**Max**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Min Property (MSChart)

Applies To: Rect Object

Maximum Property

Returns or sets the highest or ending value on the chart value axis.

Syntax

object.**Maximum** [= *value*]

The **Maximum** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
value	Double. The highest axis value.

Remarks

If this property is set, then the **ValueScale** object's **Auto** property is automatically set to **False**.

The **Maximum** property should be set before the **Minimum** property to avoid a chart display error.

See Also

Minimum Property

Applies To: ValueScale Object

Min Property (MSChart)

Returns a reference to a **Coor** object that specifies the starting corner of a rectangle.

Syntax

object.**Min**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Max Property (MSChart)

Applies To: Rect Object

Minimum Property

Returns or sets the lowest or beginning value on the chart value axis.

Syntax

object.**Minimum** [= *value*]

The **Minimum** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
value	Double. The lowest axis value.

Remarks

If this property is set, then the **ValueScale** object's **Auto** property is automatically set to **False**.

The **Maximum** property should be set before the **Minimum** property to avoid a chart display error.

See Also

MajorDivision Property

Applies To: ValueScale Object

MinorDivision Property

Returns or sets the number of minor divisions displayed on the axis.

Syntax

object.**MinorDivision** [= *num*]

The **MinorDivision** property syntax has these parts:

Part	Description
Object	An object expression that evaluates to an object in the Applies To list .
num	Integer. Number of minor divisions.

Remarks

If this property is set, then the **ValueScale** object's **Auto** property is automatically set to **False**.

See Also

Applies To: ValueScale Object

MinorPen Property

Returns a reference to a **Pen** object that describes the appearance of the minor axis grid lines.

Syntax

*object.***MinorPen**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

MajorPen Property

Applies To: AxisGrid Object

MousePointer Property (MSChart)

Returns or sets a value indicating the type of mouse pointer displayed when the mouse is over a particular part of an object at run time.

Syntax

object.**MousePointer** [= *value*]

The **MousePointer** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
value	Integer. A VtMousePointer constant that specifies the type of mouse pointer displayed.

See Also

MousePointer Constants

Applies To: MSChart Control

MousePointer Constants

The **VtMousePointer** constants provide the following types of pointers.

Constant	Description
VtMousePointerArrow	Arrow pointer
VtMousePointerArrowHourGlass	Arrow and hourglass
VtMousePointerArrowQuestion	Arrow and question mark
VtMousePointerCross	Crosshair pointer
VtMousePointerDefault	Default chart pointer
VtMousePointerHourGlass	Hourglass pointer
VtMousePointerIbeam	Ibeam pointer
VtMousePointerIcon	Small square within a square pointer
VtMousePointerNoDrop	No drop pointer
VtMousePointerSize	Sizing arrows
VtMousePointerSizeAll	Sizing in all directions arrows
VtMousePointerSizeNESW	Double arrow pointing northeast and southwest
VtMousePointerNS	Double arrow pointing north and south
VtMousePointerNWSE	Double arrow pointing northwest and southeast
VtMousePointerWE	Double arrow pointing east and west
VtMousePointerUpArrow	Arrow pointing up

See Also

MousePointer Property (MSChart)

Name Property (VtFont)

Returns or sets the name of the font. This is the default property of the **VtFont** object.

Syntax

object.**Name** [= *text*]

The **Name** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
text	Integer. The text containing the font name.

See Also

Applies To: MSChart Control | VtFont Object

Offset Property

Returns or sets the distance that a chart element is offset or pulled away from its default location.

Syntax

object.**Offset** [= *offset*]

The **Offset** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
offset	For the **DataPoint** object, this is an integer describing the offset distance. Offset is measured in inches or centimeters depending upon your default Windows settings. For the **DataPointLabel** and **Shadow** objects, this is a reference to a **Coor** object that describe the *x* and *y* values of the offset.

Remarks

For the **DataPointLabel** object, this property indicates the distance that a data point label is offset or pulled away from one of the predefined (standard) label positions. The offset is added to the position calculated for the point based on the **DataPointLabel** object's **LocationType** setting.

See Also

Applies To: DataPoint Object | DataPointLabel Object | Shadow Object

Order Property

Returns or sets the position of the series in the chart. If the position in order matches another series, the series are stacked.

Syntax

object.**Order** [= *order*]

The **Order** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
order	Integer. The position order.

See Also

Applies To: SeriesPosition Object

Orientation Property (MSChart)

Returns or sets the method of orientation for text.

Syntax

object.**Orientation** [= *type*]

The **Orientation** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. A VtOrientation constant used to describe the orientation method .

See Also

Orientation Constants

Applies To: TextLayout Object

Orientation Constants

The **VtOrientation** constants provide options for positioning text.

Constant	Description
VtOrientationHorizontal	The text is displayed horizontally.
VtOrientationVertical	The letters of the text are drawn one on top of each other from the top down .
VtOrientationUp	The text is rotated to read from bottom to top.
VtOrientationDown	The text is rotated to read from top to bottom.

See Also

Orientation Property (MSChart)

PatternColor Property

Returns a reference to a **VtColor** object that describes the pattern color used to fill a chart element.

Syntax

object.**PatternColor**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Brush Object

Pen Property

Returns or sets a reference to a **Pen** object that describes the color and pattern of lines or edges on chart elements.

Syntax

object.**Pen**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Pen Object

Applies To: Axis Object | Marker Object | PlotBase Object | Series Object | Wall Object

PercentBasis Property

Returns or sets the type of percentage used to plot chart values on a percent axis.

Syntax

object.**PercentBasis** [= *type*]

The **PercentBasis** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	A VtChPercentAxisBasis constant used to describe the percentage used to plot percent axis values .

Remarks

This property has an effect only when the **Type** property is set to **VtChScaleTypePercent**.

See Also

PercentAxisBasis Constants | Type Property (MSChart)

Applies To: AxisScale Object

PercentAxisBasis Constants

VtChPercentAxisBasis provides methods of displaying percentage axes.

Constant	Description
VtChPercentAxisBasisMaxChart	The largest value in the chart is considered 100 percent and all other values on the chart are displayed as percentages of that value.
VtChPercentAxisBasisMaxRow	The largest value in each row is considered 100 percent and all other values in that row are displayed as percentages of that value.
VtChPercentAxisBasisMaxColumn	The largest value in each series is considered 100 percent and all other values in that series are displayed as percentages of that value.
VtChPercentAxisBasisSumChart	All values in the chart are added together, and that value is considered 100 percent. All other values are displayed as percentages of that value.
VtChPercentAxisBasisSumRow	All values in each row are added together and the total value for each row is considered 100 percent. All other values in that same row are displayed as percentages of that value. This is the basis for 100 percent stacked charts.
VtChPercentAxisBasisSumColumn	All values in each series are added together to give a total value for each series. All values are displayed as a percentage of their series total value.

See Also

PercentBasis Property

PercentFormat Property

Returns or sets a string that describes the format used to display the label as a percent.

Syntax

object.**PercentFormat** [= *format*]

The **PercentFormat** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
format	String. Describes the format used to display a label as a percent.

Remarks

Use the **DataPointLabel** object's **Component** property to change the label type.

The following table lists several examples of percentage format strings. The values listed at left are the valid formats.

	3	-3	.3
0%	300%	-300%	30%
0.0%	300.0%	-300.0%	30.0%
0.00%	300.00%	-300.00%	30.00%

See Also

Applies To: DataPointLabel Object

Plot Property

Returns a reference to a **Plot** object that describes the area upon which a chart is displayed.

Syntax

object.**Plot**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: MSChart Control

PlotBase Property

Returns a reference to a **PlotBase** object that describes the appearance of the area beneath a chart.

Syntax

object.**PlotBase**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Plot Object

Point Property

Returns or sets the point where the current axis intersects with another axis.

Syntax

object.**Point** [= *point*]

The **Point** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
point	Double. The point on an axis where the current axis intersects.

Remarks

If this property is set, then the Intersection object's **Auto** property is automatically set to **False**.

See Also

Applies To: Intersection Object

Position Property (MSChart)

Returns a reference to a **SeriesPosition** object that describes the location of one series in relation to other chart series.

Syntax

object.**Position**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

SeriesPosition Object

Applies To: Series Object

Projection Property

Returns or sets the type of projection used to display the chart.

Syntax

object.**Projection** [= *type*]

The **Projection** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. A VtProjectionType constant used to describe the type of chart projection .

Remarks

The **Projection** property determines the appearance of 3 dimensional charts.

Example

The example allows you to see the different effects obtainable by setting the **Projection** property. To try the example, draw an **MSChart** and a **ComboBox** control on a form. Paste the code into the Declarations section, and press F5. Click the **ComboBox** to see the different settings.

```
Option Explicit

Private Sub Combo1_Click()
   ' Change the projection when clicked.
   MSChart1.Plot.Projection = Combo1.ListIndex
End Sub

Private Sub Form_Load()
   ' Set the chart to a 3D type.
   MSChart1.chartType = VtChChartType3dBar
   ' Configure the ComboBox by adding the valid settings.
   With Combo1
      .AddItem "VtProjectionTypePerspective" ' 0
      .AddItem "VtProjectionTypeOblique"      ' 1
      .AddItem "VtProjectionTypeOrthogonal"  ' 2
      .AddItem "VtProjectionTypeFrontal"      ' 3
      .AddItem "VtProjectionTypeOverhead"    ' 4
      .ListIndex = 0
   End With
End Sub
```

See Also

ProjectionType Constants

Applies To: Plot Object

ProjectionType Constants

VtProjectionType provides viewpoint and perspective options for displaying and viewing a chart.

Constants	Description
VtProjectionTypePerspective	This provides the most realistic three-dimensional appearance. Objects farther away from you converge toward a vanishing point. This is the default projection.
VtProjectionTypeOblique	This is sometimes referred to as 2.5 dimensional. The chart does have depth, but the xy plane does not change when the chart is rotated or elevated.
VtProjectionTypeOrthogonal	Perspective is not applied in this three-dimensional view. The major advantage of using this type of projection is that vertical lines remain vertical, making some charts easier to read.

See Also

Projection Property

RandomFill Property

Indicates whether the data for a chart data grid was randomly generated.

Syntax

object.**RandomFill** [= *boolean*]

The **RandomFill** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls how data is generated, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) Random data is used to draw the chart.
False	No random data is generated. The user provides the data for the chart .

See Also

RandomDataFill Method | RandomFillColumns Method | RandomFillRows Method

Applies To: MSChart Control

Rect Property

Returns a reference to a **Rect** object that defines a coordinate location.

Syntax

object.**Rect**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Rect Object

Applies To: Location Object

Red Property

Returns or sets the red component of the RGB value in a chart.

Syntax

object.**Red [=***r***]**

The **Red** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
r	Integer. The red value.

Remarks

RGB specifies the relative intensity of red, green, and blue to cause a specific color to be displayed. The valid range for a normal RGB color is 0 to 16,777,215. The value for any argument to RGB that exceeds 255 is assumed to be 255.

See Also

Applies To: VtColor Object

Repaint Property

Returns or sets a value that determines if the **MSChart** control is repainted after a change is made to the chart.

Syntax

object.**Repaint** [= *boolean*]

The **Repaint** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls whether the chart is repainted, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) Refreshes the control.
False	Does not allow the control to repaint when a change is made to the chart. This is useful when several operations are performed on the chart and you do not want the chart to continually repaint during the process.

See Also

Applies To: MSChart Control

Rotation Property

Returns or sets a value that describes the degree of rotation from which a three-dimensional chart is viewed.

Syntax

object.**Rotation** [= *degree*]

The **Rotation** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
degree	Single. The degree of rotation. Rotation can range from 0 to 360 degrees. By default, degrees are used to measure rotation. However, thes e settings use the current settings for the AngleUnit property. The other options are: Grads and Radians.

See Also

Applies To: View3D Object

Row Property (MSChart)

Returns or sets a specific row in the current column of a data grid associated with a chart.

Syntax

object.**Row** [= *num*]

The **Row** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
num	Integer. A row number in the current column. Rows are numbered from top to bottom beginning with 1 .

See Also

Applies To: MSChart Control

RowCount Property (MSChart)

Returns or sets how many rows there are in each column of a data grid associated with a chart.

Syntax

object.**RowCount** [= *count*]

The **RowCount** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
count	Integer. The number of rows in a column.

Remarks

The virtual data grid is represented by the **DataGrid** object.

See Also

Applies To: DataGrid Object | MSChart Control

RowLabel Property (DataGrid Object)

Returns or sets a specific row label in the current data grid associated with a chart.

Syntax

object.**RowLabel** (*row*, *labelIndex*) [= *text*]

The **RowLabel** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
row	Integer. Specifies a row. Rows are numbered from top to bottom beginning at 1.
labelIndex	Integer. Specifies a specific level of row labels. Row labels are numbered from left to right beginning at 1.
text	String. Text of the row label.

See Also

RowLabel Property (MSChart)

Applies To: DataGrid Object

RowLabel Property (MSChart)

Returns or sets a data label that can be used to identify the current data point in a chart.

Syntax

object.**RowLabel** [= *text*]

The **RowLabel** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
text	String. The text for a row label. The label you specify sets the label for the data points identified by the **Row** property. This label appears along the category axis for most chart types and is used as the label for each in dividual pie in a pie chart. Label text may not be displayed if it is too long to fit on a chart.

See Also

RowLabel Property (DataGrid Object)

Applies To: MSChart Control

RowLabelCount Property

Returns or sets the number of levels of labels on the rows in a data grid associated with a chart.

Syntax

object.**RowLabelCount** [= *count*]

The **RowLabelCount** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
count	Integer. The number of label levels. Set this property to add or delete levels of labels from data grid rows. Row label levels are numbered from right to left, beginning at 1. Levels are added or subtracted from the left.

See Also

SetSize Method

Applies To: DataGrid Object | MSChart Control

RowLabelIndex Property

Returns or sets a value that specifies a level of row labels.

Syntax

object.**RowLabelIndex** [= *index*]

The **RowLabelIndex** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
index	Integer. A row label level. To set a label on a row with more than one level of labels, or to return the current value for a label, you must first identify which level you want to affect. Row label levels are numbered from right to left, beginning at 1.

See Also

Applies To: MSChart Control

SecondaryAxis Property

Returns or sets a value that determines whether the series is charted on the secondary axis.

Syntax

object.**SecondaryAxis** [= *boolean*]

The **SecondaryAxis** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls whether the series is charted on the secondary axis, as described in Settings.

Settings

The settings for *boolean* are:

Setting	Description
True	The series is charted on the secondary axis.
False	(Default) The series is not charted on the secondary axis.

See Also

Applies To: Series Object

SeriesCollection Property

Returns a reference to a **SeriesCollection** collection that provides information about the series that make up a chart.

Syntax

object.**SeriesCollection**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Plot Object

SeriesColumn Property

Returns or sets the column position for the current series data.

Syntax

object.**SeriesColumn** [= *pos*]

The **SeriesColumn** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
pos	Integer. The position of the column containing the current series data. You can use this property to reorder series. If two series are assigned the same position, they are stacked.

See Also

Applies To: MSChart Control

SeriesMarker Property

Returns a reference to a **SeriesMarker** object that describes a marker that identifies all data points within one series on a chart.

Syntax

object.**SeriesMarker**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Series Object

SeriesType Property

Returns or sets the type used to display the current series.

Syntax

object.**SeriesType** [= *type*]

The **SeriesType** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. A VtChSeriesType constant describing the method used to display the series. You must select the series to change using the **Column** property before using the **SeriesType** property.

See Also

SeriesType Constants

Applies To: MSChart Control | Series Object

SeriesType Constants

The **VtChSeriesType** constants provide options for types of series.

Constant	Series Type
VtChSeriesType3dBar	3D Bar
VtChSeriesType2dBar	2D Bar
VtChSeriesType3dLine	3D Line
VtChSeriesType2dLine	2D Line
VtChSeriesType3dArea	3D Area
VtChSeriesType2dArea	2D Area
VtChSeriesType3dStep	3D Step
VtChSeriesType2dStep	2D Step
VtChSeriesType2dXY	XY
VtChSeriesType2dPie	2D Pie

See Also

SeriesType Property | TypeByChartType Method

Shadow Property

Returns a reference to a **Shadow** object that describes the appearance of a shadow on chart elements.

Syntax

object.**Shadow**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Backdrop Object

Show Property

Returns or sets a value that determines whether series markers are displayed on a chart.

Syntax

object.**Show** [= *boolean*]

The **Show** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls whether series markers are displayed, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	Series markers are displayed
False	(Default) Series markers are not displayed .

See Also

Applies To: SeriesMarker Object

ShowGuideLine Property

Returns or sets a value that determines whether or not the connecting data point lines on a chart are displayed for a series.

Syntax

object.**ShowGuideLines** (*axisId*, *index*) [= *boolean*]

The **ShowGuideLine** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. A VtChAxisId constant describing the series axis you want to set this property for.
index	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid value for this argument.
boolean	A Boolean expression that controls whether the series is charted on the secondary axis, as described in Settings.

Settings

The settings for *boolean* are:

Setting	Description
True	The series guidelines are displayed.
False	(Default) The series guidelines are not displayed.

See Also

AxisId Constants

Applies To: Series Object

ShowLegend Property

Returns or sets a value that indicates whether a legend is visible for a chart.

Syntax

object.**ShowLegend** [= *boolean*]

The **ShowLegend** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls whether a legend is displayed on the chart, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The legend appears on the chart in the position indicated by the **Location** object.
False	(Default) The legend is not displayed on the chart. The default legend location is to the right side of the chart.

Remarks

The default legend location is to the right side of the chart.

See Also

Applies To: MSChart Control

ShowLine Property

Returns or sets a value that determines whether the lines connecting data points on a chart are visible.

Syntax

object.**ShowLine** [= *boolean*]

The **ShowLine** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls whether lines are displayed, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The lines connecting data points appear on the chart .
False	The data point lines do not appear.

See Also

Applies To: Series Object

Size Property (MSChart)

Returns or sets the size of a chart element in points.

Syntax

object.**Size** [= *size*]

The **Size** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
size	Single. Size of the chart element in points.

Applies To: Marker Object | VtFont Object

Sort Property (MSChart)

Returns or sets the type of sort order used in a pie chart.

Syntax

object.**Sort** [= *type*]

The **Sort** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
type	Integer. A VtSortType constant used to describe the plot sort order.

See Also

SortType Constants

Applies To: Plot Object

SortType Constants

The **VtSortType** constants provide options for sorting pie charts.

Constant	Description
VtSortTypeNone	Pie slices are drawn in the order the data appears in the data grid.
VtSortTypeAscending	Pie slices are drawn, in order, from the smallest to the largest slice, starting at the defined starting angle and in the defined plot direction.
VtSortTypeDescending	Pie slices are drawn, in order, from the largest to the smallest slice, starting at the defined starting angle and in the defined plot direction.

See Also

Sort Property (MSChart)

SpaceColor Property

Returns a reference to a **VtColor** object that specifies the color used fill the space between double frames around a chart element.

Syntax

object.**SpaceColor**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Example

See Frame Object.

See Also

FrameColor Property

Applies To: Frame Object

Stacking Property

Sets a value that determines whether all the series in the chart are stacked.

Syntax

object.**Stacking** [= *boolean*]

The **Stacking** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls whether all chart series are stacked, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	All chart series are stacked.
False	(Default) Chart series are not stacked .

See Also

Applies To: MSChart Control

StackOrder Property

Returns or sets in what position the current series is drawn if it is stacked with other series.

Syntax

object.**StackOrder** [= *position*]

The **StackOrder** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
position	Integer. The order of the series if stacked with other series. Lower stack orders are on the bottom of the stack.

See Also

Applies To: SeriesPosition Object

Standing Property

Returns or sets a value that specifies whether axis labels are displayed horizontally in the *x* or *z* plane or vertically on the text baseline in the *y* plane.

Syntax

object.**Standing** [= *boolean*]

The **Standing** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies how to display the axis labels, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The axis labels are displayed vertically on the text baseline in the *y* plane .
False	(Default) The axis labels are displayed horizontally in the *x* or *z* plane.

See Also

Applies To: Label Object

StartingAngle Property

Returns or sets the position where you want to start drawing pie charts.

Syntax

object.**StartingAngle** [= *angle*]

The **StartingAngle** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
angle	Single. This angle can be measured in degrees, radians, or grads, depending on the current AngleUnits setting. A value of 0 degrees indicates the 3 o'clock position. Setting the starting angle to 90 degrees moves the starting position to 12 o'clock if the Clockwise property is set to counterclockwise, or to 6 o'clock if it is set to clockwise. Valid values range from -360 to 360 degrees.

Applies To: Plot Object

StatLine Property

Returns a reference to a **StatLine** object that describes how statistic lines are displayed on a chart.

Syntax

object.**StatLine**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Series Object

Style Property (MSChart Control)

Returns or sets the style used to draw certain chart elements

Syntax

object.**Style** [=*style*]

The **Style** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
style	For the **Brush** object, a VtBrushStyle constant describing the brush pattern. For the **Fill** object, a VtFillStyle constant that describes the style of fill. A fill can have a brush, which is a solid color or patterned fill. For the **Frame** object, a VtFrameStyle constant that describes the type of frame. For the **Marker** object, a VtMarkerStyle constant that lists the marker type. For the **Pen** object, a VtPenStyle constant that describes the style of pen. For the **Shadow** object, a VtShadowStyle constant used to describe the shadow type. For the **Tick** object, a VtChAxisTickStyle constant used to describe the axis tick position. For the **VtFont** object, a VtFontStyle constant describing the style of font. For the **Weighting** object, a VtChPieWeightStyle constant that identifies the weighting factor meth od.

See Also

AxisTickStyle Constants | BorderStyle Constants (MSChart) | FillStyle Constants (MSChart Control) | FontStyle Constants | FrameStyle Constants | MarkerStyle Constants | PenStyle Constants | PieWeightStyle Constants | ShadowStyle Constants | StatsType Constants | Style Property (StatLine)

Applies To: Brush Object | Fill Object | Frame Object | Marker Object | Pen Object | Shadow Object | Tick Object | VtFont Object | Weighting Object

AxisTickStyle Constants

The **VtChAxisTickStyle** constants provide options for indicating axis tick mark location.

Constants	Description
VtChAxisTickStyleNone	No tick marks are displayed on the axis.
VtChAxisTickStyleCenter	Tick marks are centered across the axis.
VtChAxisTickStyleInside	Tick marks are displayed inside the axis.
VtChAxisTickStyleOutside	Tick marks are displayed outside the axis.

See Also

Style Property (MSChart Control)

BorderStyle Constants (MSChart)

The **VtBorderStyle** constants provide options for the type of border to be placed around the chart control.

Constant	Description
VtBorderStyleFixedSingle	A single border is placed around the chart control .
VtBorderStyleNone	No border is placed around the chart control.

BrushHatch Constants

VtBrushHatch provides valid brush types if **VtBrushStyle** is set to **VtBrushStyleHatch**.

Constant	Description
VtBrushHatchHorizontal	Horizontal hatch lines
VtBrushHatchVertical	Vertical hatch lines
VtBrushHatchDownDiagonal	Down diagonal hatch lines
VtBrushHatchUpDiagonal	Up diagonal hatch lines
VtBrushHatchCross	Cross hatch lines
VtBrushHatchDiagonalCross	Diagonal cross hatch lines

See Also

Index Property (Brush)

BrushStyle Constants

VtBrushStyle provides valid brush types.

Constant	Description
VtBrushStyleNull	No brush (background shows through)
VtBrushStyleSolid	Solid color brush
VtBrushStylePattern	Bitmap patterned brush
VtBrushStyleHatched	Hatched brush

See Also

Style Property (MSChart Control)

BrushPattern Constants

VtBrushPattern provides valid brush types if **VtBrushStyle** is set to **VtBrushStylePattern**.

Constant	Description
VtBrushPattern94percent	94 percent pattern color
VtBrushPattern88percent	88 percent pattern color
VtBrushPattern75percent	75 percent pattern color
VtBrushPattern50percent	50 percent pattern color
VtBrushPattern25percent	25 percent pattern color
VtBrushPatternBoldHorizontal	Bold horizontal lines
VtBrushPatternBoldVertical	Bold vertical lines
VtBrushPatternBoldDownDiagonal	Bold down diagonal lines
VtBrushPatternBoldUpDiagonal	Bold up diagonal lines
VtBrushPatternChecks	Checks pattern
VtBrushPatternWeave	Weave pattern
VtBrushPatternHorizontal	Horizontal lines
VtBrushPatternVertical	Vertical lines
VtBrushPatternDownDiagonal	Down diagonal lines
VtBrushPatternUpDiagonal	Up diagonal lines
VtBrushPatternGrid	Grid pattern
VtBrushPatternTrellis	Trellis pattern
VtBrushPatternInvertedTrellis	Inverted trellis pattern

See Also

Index Property (Brush)

FillStyle Constants (MSChart Control)

The **VtFillStyle** constants provide options for indicating the type of fill used to paint a backdrop.

Constant	Description
VtFillStyleNull	No fill (background shows through)
VtFillStyleBrush	A solid color or pattern fill

Remarks

The **FillStyle** constants are used with the **Style** property of the Fill object.

An example of the constant usage is shown below:

```
With MSChart1.Backdrop.Fill
   .Style = VtFillStyleBrush
   .Brush.FillColor.Set 0, 200, 250 ' Set the color of the fill.
End With
```

See Also

Brush Object | Fill Object | FillColor Property | Style Property (MSChart Control)

FontStyle Constants

VtFontStyle provides valid font attribute options.

Constant	Description
VtFontStyleBold	Applies the bold attribute to the font.
VtFontStyleItalic	Applies the italic attribute to the font.
VtFontStyleOutline	Applies the outline attribute to the font .

See Also

Style Property (MSChart Control)

FrameStyle Constants

The **VtFrameStyle** constants provide options for displaying backdrop frames.

Constant	Description
VtFrameStyleNull	No frame.
VtFrameStyleSingleLine	A single line encloses the backdrop.
VtFrameStyleDoubleLine	Two equal width lines enclose the backdrop.
VtFrameStyleThickInner	A thick inner line and a thin outer line enclose the backdrop.
VtFrameStyleThickOuter	A thin inner line and a thick outer line enclose the backdrop.

See Also

Frame Object | Frame Property | FrameColor Property | Style Property (MSChart Control)

MarkerStyle Constants

The **VtMarkerStyle** constants provide options for displaying data point markers.

Constant	Description
VtMarkerStyleNull	Suppressed
VtMarkerStyleDash	Dash marker
VtMarkerStylePlus	Plus marker
VtMarkerStyleX	X marker
VtMarkerStyleStar	Star marker
VtMarkerStyleCircle	Circle marker
VtMarkerStyleSquare	Square marker
VtMarkerStyleDiamond	Diamond marker
VtMarkerStyleUpTriangle	Triangle marker
VtMarkerStyleDownTriangle	Down triangle marker
VtMarkerStyleFilledCircle	Filled circle marker
VtMarkerStyleFilledSquare	Filled square marker
VtMarkerStyleFilledDiamond	Filled diamond marker
VtMarkerStyleFilledUpTriangle	Filled triangle marker
VtMarkerStyleFilledDownTriangle	Filled down triangle marker
VtMarkerStyle3dBall	Three-dimensional ball marker

See Also

Style Property (MSChart Control)

PenStyle Constants

The **VtPenStyle** constants provide options for the pen used to draw chart lines.

Constant	Description
VtPenStyleNull	No pen is applied
VtPenStyleSolid	Solid line pen
VtPenStyleDashed	Dashed line pen
VtPenStyleDotted	Dotted line pen
VtPenStyleDashDot	Dash-dot line pen
VtPenStyleDashDotDot	Dash-dot-dot line pen
VtPenStyleDitted	Ditted line pen
VtPenStyleDashDit	Dash-ditted line pen
VtPenStyleDashDitDit	Dash-dit-dit line pen

See Also

Style Property (MSChart Control) | Style Property (StatLine)

PieWeightStyle Constants

The **VtChPieWeightStyle** constants provide options for displaying individual pies within a single chart.

Constant	Description
VtChPieWeightStyleArea	The area of the individual pies changes, based on their weighting.
VtChPieWeightStyleDiameter	The diameter of the individual pies changes, based on their weighting.

See Also

Set Method (Weighting) | Style Property (MSChart Control)

ShadowStyle Constants

The **VtShadowStyle** constants provides shadow options.

Constant	Description
VtShadowStyleNull	No shadow.
VtShadowStyleDrop	Drop shadow.

See Also

Style Property (MSChart Control)

Style Property (StatLine)

Returns or sets the line type used to display the statistic line.

Syntax

object.**Style** (*type*)[= *style*]

The **Style** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
type	Integer. A VtChStats constant used to describe the line type.
style	Integer. A VtPenStyle constant used to describe the stat line style.

See Also

PenStyle Constants | Style Property (MSChart Control)

Applies To: StatLine Object

StatsType Constants

The **VtChStats** constants provide methods of displaying statistic lines on a chart.

Constant	Description
VtChStatsMinimum	Shows the minimum value in the series.
VtChStatsMaximum	Shows the maximum value in the series.
VtChStatsMean	Shows the mathematical mean of the values in the series .
VtChStatsStddev	Shows the standard deviation of the values in the series.
VtChStatsRegression	Shows a trend line indicated by the values in a series.

See Also

Flag Property | Style Property (StatLine)

SubPlotLabelPosition Property

Returns or sets the position used to display a label on each pie in a chart.

Syntax

object.**SubPlotLabelPosition** [= *pos*]

The **SubPlotLabelPosition** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
pos	Integer. A VtChSubPlotLabelLocationType constant used to describe the position of the chart label .

See Also

SubPlotLabelLocationType Constants

Applies To: Plot Object

SubPlotLabelLocationType Constants

The **VtSubPlotLabelLocationType** constants provide methods for displaying the subplot label.

Constant	Description
VtChSubPlotLabelLocationTypeNone	No subplot label is displayed.
VtChSubPlotLabelLocationTypeAbove	The subplot label is displayed above the pie .
VtChSubPlotLabelLocationTypeBelow	The subplot label is displayed below the pie .
VtChSubPlotLabelLocationTypeCenter	The subplot label is centered on the pie.

See Also

SubPlotLabelPosition Property

Text Property (MSChart)

Returns or sets the text used to display a chart element such as an axis title, data point label, footnote, or chart title.

Syntax

object.**Text** [= *text*]

The **Text** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
text	String. A string that contains the text used for the chart element.

Remarks

The **Text** property is the default property for each of the objects to which it applies.

See Also

Applies To: AxisTitle Object | DataPointLabel Object | Footnote Object | Title Object

TextOutputType Constants

The **VtTextOutputType** constants provide methods of outputting text.

Constant	Description
VtTextOutputTypeHardware	Device context type Null.
VtTextOutputTypePolygon	Device context type Metafile.

TextLayout Property

Returns a reference to a **TextLayout** object that describes text positioning and orientation.

Syntax

object.**TextLayout**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: AxisTitle Object | DataPointLabel Object | Footnote Object | Label Object | Legend Object | Title Object

TextLength Property

Returns or sets the number of characters in the text of a chart axis title, data point label, footnote, or chart title.

Syntax

object.**TextLength** [= *size*]

The **TextLength** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
size	Integer. The number of characters in the text.

See Also

Applies To: AxisTitle Object | DataPointLabel Object | Footnote Object | Title Object

TextLengthType Property

Returns or sets a value that specifies how text is drawn to optimize the appearance either on the screen or printed page.

Syntax

object.**TextLengthType** [= *type*]

The **TextLengthType** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. A VtTextLengthType constant indicating the method used to draw text .

See Also

TextLengthType Constants

Applies To: MSChart Control

TextLengthType Constants

The **VtTextLengthType** constants provide options for optimizing text layout for the screen or for the printer.

Constant	Description
VtTextLengthTypeVirtual	Choose this constant to use TrueType virtual font metrics to optimize text layout for printing. TrueType virtual font metrics may not be very accurate for text displayed on the screen. Text displayed on the screen may be a larger or smaller than the virtual metrics requested. Larger text may not fit where it is supposed to and part of a character, a whole character, or even in some cases words may be clipped.
VtTextLengthTypeDevice	Choose this constant to optimize text layout for the screen. Text in charts laid out for screen display always fits correctly within its chart area. The printed text is generally a bit smaller and so the text may appear in slightly different places.

See Also

TextLengthType Property

Tick Property

Returns a reference to a **Tick** object that describes a marker indicating a division along a chart axis.

Syntax

object.**Tick**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Axis Object

Title Property (MSChart)

Reference to a **Title** object that describes the text used to title a chart.

Syntax

object.**Title**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: MSChart Control

TitleText Property

Returns or sets the text displayed as the chart title.

Syntax

object.**TitleText** [= *text*]

The **TitleText** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
text	The text used to display a chart title.

Remarks

This property provides a simple means to set or return the chart title. This property is functionally identical to using `MSChart.Title.Text`.

See Also

Applies To: MSChart Control

Type Property (MSChart)

Returns or sets the scale type of an axis.

Syntax

object.**Type** [= *type*]

The **Type** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
type	A VtChScaleType constant describing the axis scale type.

See Also

ScaleType Constants

Applies To: AxisScale Object

ScaleType Constants

VtChScaleType provides methods for plotting chart values and displaying the chart scale.

Constant	Description
VtChScaleTypeLinear	Chart values are plotted in a linear scale with values ranging from the minimum to the maximum chart range value.
VtChScaleTypeLogarithmic	Chart values are plotted in a logarithmic scale with values based on a specific log scale set with the *logBase* argument of this function.
VtChScaleTypePercent	Chart values are plotted in a linear scale with values based on the percentages of the chart range values.

See Also

Type Property (MSChart)

UniformAxis Property

Returns or sets a value that specifies whether the unit scale for all value axes in a chart is uniform.

Syntax

object.**UniformAxis** [= *boolean*]

The **UniformAxis** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that controls the unit scale, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	(Default) The unit scale for all value axes is uniform.
False	The unit scale is not uniform. The unit scale is determined by the plot size and positioning s et according to the AutoLayout or LocationRect property. If **AutoLayout** is **True**, the plot si ze and position are based on the size and position of other automatically laid out elements. If **False**, the coordinates specified by **LocationRect** are used to position the plot and deter mine the axes unit scale.

See Also

Applies To: Plot Object

ValueFormat Property

Returns or sets the format used to display the label as a value.

Syntax

object.**ValueFormat** [= *format*]

The **ValueFormat** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
format	String. Describes the format used to display a label as a value.

Remarks

Use the **DataPointLabel** object's **Component** property to change the label type.

See Also

Applies To: DataPointLabel Object

ValueScale Property

Returns a reference to a **ValueScale** object that describes the scale used to display a value axis.

Syntax

object.**ValueScale**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

CategoryScale Property

Applies To: Axis Object

VertAlignment Property

Returns or sets the method used to vertically align text.

Syntax

object.**VertAlignment** [= *type*]

The **VertAlignment** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
type	Integer. A VtVerticalAlignment constant used to describe the vertical alignment method of text .

See Also

VerticalAlignment Constants

Applies To: TextLayout Object

VerticalAlignment Constants

The **VtVerticalAlignment** constants provide methods of vertically aligning text.

Constant	Description
VtVerticalAlignmentTop	All lines of text are aligned at the top margin.
VtVerticalAlignmentBottom	All lines of text are aligned at the bottom margin .
VtVerticalAlignmentCenter	All lines of text are centered vertically.

See Also

VertAlignment Property

View3D Property

Returns a reference to a **View3D** object that describes the physical orientation of a three-dimensional chart.

Syntax

object.**View3D**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Plot Object

Visible Property (MSChart)

Returns or sets a value that determines whether a chart element is displayed.

Syntax

object.**Visible** [= *boolean*]

The **Visible** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that specifies whether the item is displayed, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	The chart, axis title, label, or marker are displayed .
False	The elements are hidden.

See Also

Applies To: AxisTitle Object | Location Object | Marker Object | MSChart Control

VtColor Property

Returns a reference to a **VtColor** object that describes a drawing color in a chart.

Syntax

object.**VtColor**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Pen Object | StatLine Object | VtFont Object

VtFont Property

Returns a reference to a **VtFont** object that describes the font used to display chart text.

Syntax

object.**VtFont**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: AxisTitle Object | DataPointLabel Object | Footnote Object | Label Object | Legend Object | Title Object

Wall Property

Returns a reference to a **Wall** object that describes the planar area depicting the y axes on a three-dimensional chart.

Syntax

object.**Wall**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Plot Object

Weighting Property

Returns a reference to a **Weighting** object that describes the size of a pie in relation to other pies in the same chart.

Syntax

object.**Weighting**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Plot Object

Width Property (MSChart)

Returns or sets the width of a chart element, in points.

Syntax

object.**Width** [= *width*]

The **Width** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
width	Single. The width of the chart element.

See Also

Applies To: Frame Object | MSChart Control | Pen Object | StatLine Object | Wall Object

WidthToHeightRatio Property

Returns or sets the percentage of the chart height to be used as the chart width.

Syntax

object.**WidthToHeightRatio** [= *pctg*]

The **WidthToHeightRatio** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
pctg	Single. The chart height percentage.

See Also

Applies To: Plot Object

WordWrap Property (MSChart)

Returns or sets a value that determines whether text wraps.

Syntax

object.**WordWrap** [= *boolean*]

The **WordWrap** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
boolean	A Boolean expression that determines whether text wraps, as described in Settings .

Settings

The settings for *boolean* are:

Setting	Description
True	Text wraps.
False	(Default) Text does not wrap .

See Also

Applies To: TextLayout Object

X Property

Returns or sets the *x* value in a floating coordinate pair for a chart.

Syntax

object.**X** [= *x*]

The **X** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
x	Single. (Long for **LCoor** object.) Identifies the *x* value of the coordinate .

See Also

Set Method (Coor, LCoor) | Y Property

Applies To: Coor Object | LCoor Object | LightSource Object

XGap Property

Returns or sets the spacing of bars between divisions on the *x* axis. This space is measured as a percentage of the bar width.

Syntax

object.**xGap** [= *spacing*]

The **xGap** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
spacing	Single. The bar width percentage. A value of 0 results in the series of bars touching .

See Also

Applies To: Plot Object

Y Property

Returns or sets the *y* value in a floating coordinate pair for a chart.

Syntax

object.**Y** [= *y*]

The **Y** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
y	Single. (Long for **LCoor** object.) Identifies the *y* value of the coordinate .

See Also

Set Method (Coor, LCoor) | X Property

Applies To: Coor Object | LCoor Object | LightSource Object

Z Property

Returns or sets the *z* value in a coordinate location.

Syntax

object.**Z** [= *z*]

The **Z** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
z	Single. (Long for **Lcoor** object.) Identifies the *z* value of the coordinate .

See Also

X Property | Y Property

Applies To: LightSource Object

ZGap Property

Returns or sets the spacing of three-dimensional bars between divisions on the *z* axis. This space is measured as a percentage of the bar depth.

Syntax

object.**zGap** [= *spacing*]

The **zGap** property syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
spacing	Single. The bar depth percentage. A value of 0 results in the series of bars touching along the *z* axis .

TypeByChartType Method

Add Method (LightSources Collection)

Adds a **LightSource** object to the **LightSources** collection.

Syntax

*object.***Add** (*x,y,z,intensity)*

The **Add** method syntax has these parts:

Part	Description
collection	A object expression that evaluates to an object in the Applies To list.
x, y, z	Integers. Indicate the light source location.
intensity	Single. Indicates the light source intensity.

Remarks

Setting *x*, *y*, and *z* to zero generates a **VtChInvalidArgument** error.

See Also

Applies To: LightSources Collection

Count Method

Returns the number of objects in a collection.

Syntax

*object.***Count**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: Series Collection | SeriesCollection Collection

DeleteColumnLabels Method

Deletes levels of labels from the data columns in a data grid associated with a chart.

Syntax

object.**DeleteColumnLabels** (*labelIndex*, *count*)

The **DeleteColumnLabels** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
labelIndex	Integer. Identifies the number of the first level of labels you want to delete. Column label levels are n umbered bottom to top, beginning with 1.
count	Integer. Specifies the number of label levels you want to delete. The number of columns being delete d is calculated from the column identified in *labelIndex* up.

See Also

DeleteColumns Method | DeleteRowLabels Method | DeleteRows Method

Applies To: DataGrid Object

DeleteColumns Method

Deletes columns of data and their associated labels from the data grid associated with a chart.

Syntax

*object.***DeleteColumns** (*column, count)*

The **DeleteColumns** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
column	Integer. Identifies a specific data column. Columns are numbered from left to right beginning with 1 .
count	Integer. Specifies the number of columns you want to delete.

See Also

DeleteColumnLabels Method | DeleteRowLabels Method | DeleteRows Method

Applies To: DataGrid Object

DeleteRowLabels Method

Deletes levels of labels from the data rows in a data grid associated with a chart.

Syntax

object.**DeleteRowLabels** (*labelIndex*, *count*)

The **DeleteRowLabels** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
labelIndex	Integer. Identifies the number of the first level of labels you want to delete. Row labels are numbered right to left, beginning with 1.
count	Integer. Specifies the number of label levels you want to delete. Row labels are deleted from the row identified by *labelIndex* to the left.

See Also

DeleteColumnLabels Method | DeleteColumns Method | DeleteRows Method

Applies To: DataGrid Object

DeleteRows Method

Deletes rows of data and their associated labels from the data grid associated with a chart.

Syntax

object.**DeleteRows** (*row*, *count*)

The **DeleteRows** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
row	Integer. Identifies a specific data row. Rows are numbered from top to bottom beginning with 1 .
count	Integer. Specifies the number of rows you want to delete.

See Also

DeleteColumnLabels Method | DeleteColumns Method | DeleteRowLabels Method

Applies To: DataGrid Object

EditCopy Method

Copies a picture of the current chart to the clipboard in Windows metafile format. It also copies the data being used to create the chart to the clipboard.

Syntax

object.**EditCopy**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

This method allows you to paste the chart's data or a picture of the chart itself into another application. Since both the data and the picture of the chart are stored on the clipboard, what gets pasted into the new application varies depending on the type of application. For example, if you execute the chart's **EditCopy** method in your code and then go to an Excel spreadsheet and select **Edit Paste**, the chart data set is placed in the spreadsheet. To insert the picture of the chart into the spreadsheet, select **Edit Paste Special** and select the **Picture** type.

See Also

EditPaste Method

Applies To: MSChart Control

EditPaste Method

Pastes a Windows metafile graphic or tab-delimited text from the clipboard into the current selection on a chart.

Syntax

object.**EditPaste**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

The chart can accept several types of information from the clipboard, depending on the currently selected chart element when **EditPaste** is called. If the entire chart is selected, the chart looks for data on the clipboard and attempts to use this new data to redraw the chart. If an item that can accept a picture, such as a bar or chart backdrop is selected, the chart looks for a metafile on the clipboard. If it finds a metafile, it uses that metafile to fill the selected object.

See Also

EditCopy Method

Applies To: MSChart Control

GetData Method (MSChart)

Returns the value currently stored in a specific data point in the data grid associated with a chart.

Syntax

object.**GetData** (*row*, *column*, *dataPoint*, *nullFlag*)

The **GetData** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
row	Integer. Identifies the row containing the data point value.
column	Integer. Identifies the column containing the data point value.
dataPoint	Double. The data point value.
nullFlag	Integer. Indicates whether or not the data point value is a null.

See Also

Applies To: DataGrid Object

GetSelectedPart Method

Identifies the currently selected chart element.

Syntax

object.**GetSelectedPart** (*part*, *index1*, *index2*, *index3*, *index4*)

The **GetSelectedPart** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
part	Integer. Specifies the chart element. Valid constants are VtChPartType.
index1	Integer. If element refers to a series or a data point, this argument specifies which series. Series are numbered in the order their corresponding columns appear in the data grid from left to right, beginning with 1. If element refers to an axis or axis label, this argument identifies the axis type with a VtChAxisId constant.
Index2	Integer. If element refers to a data point, this argument specifies which data point in the series identified by index1.
index3	Integer. If element refers to an axis label, this argument refers to the level of the label. Axis label levels are numbered from the axis out, beginning with 1. If element is not an axis label, the argument is unused.
index4	Integer. This argument is unused at this time.

See Also

AxisId Constants | PartType Constants

Applies To: MSChart Control

InitializeLabels Method

Assigns each label in the first level of data grid labels a unique identifier.

Syntax

*object.***InitializeLabels**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: DataGrid Object

InsertColumnLabels Method

Inserts levels of labels for the data columns in a data grid associated with a chart.

Syntax

object.**InsertColumnLabels** (*labelIndex*, *count*)

The **InsertColumnLabels** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
labelIndex	Integer. Identifies the number of the first level of labels you want to insert. Column label levels are numbered bottom to top, beginning with 1.
count	Integer. Specifies the number of label levels you want to insert. The number of columns being inserted is calculated from the column identified in *labelIndex* up.

See Also

InsertColumns Method | InsertRowLabels Method | InsertRows Method

Applies To: DataGrid Object

InsertColumns Method

Adds one or more data columns to the data grid associated with a chart.

Syntax

object.**InsertColumns** (*column, count*)

The **InsertColumns** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
column	Integer. Identifies a specific data column. Columns are numbered from left to right beginning with 1 .
count	Integer. Specifies the number of columns you want to insert.

See Also

InsertColumnLabels Method | InsertRowLabels Method | InsertRows Method

Applies To: DataGrid Object

InsertRowLabels Method

Inserts levels of labels from the data rows in a data grid associated with a chart.

Syntax

object.**InsertRowLabels** (*labelIndex*, *count*)

The **InsertRowLabels** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
labelIndex	Integer. Identifies the number of the first level of labels you want to insert. Row labels are numbered right to left, beginning with 1.
count	Integer. Specifies the number of label levels you want to insert. Row labels are inserted from the row identified by *labelIndex* to the left.

See Also

InsertColumnLabels Method | InsertColumns Method | InsertRows Method

Applies To: DataGrid Object

InsertRows Method

Adds one or more data rows to the data grid associated with a chart.

Syntax

object.**InsertRows** (*row, count*)

The **InsertRows** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
row	Integer. Identifies a specific data row. Rows are numbered from top to bottom beginning with 1.
count	Integer. Specifies the number of rows you want to insert. Rows contain null data until you fill them with d ata.

See Also

InsertColumnLabels Method | InsertColumns Method | InsertRowLabels Method

Applies To: DataGrid Object

Layout Method

Lays out a chart, forcing recalculation of automatic values.

Syntax

object.**Layout**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Remarks

A chart is laid out the first time it is drawn. When any chart settings change, the chart is again laid out at the next draw. There are a number of settings the chart calculates, such as the axis minimum and maximum values, based on the chart type or some other setting. These values are not determined until the chart is laid out. If you attempt to "get" these automatic values before the chart is properly laid out, they will not reflect the new values.

See Also

Applies To: MSChart Control

MoveData Method

Moves a range of data within a data grid associated with a chart.

Syntax

object.**MoveData** (*top*, *left*, *bottom*, *right*, *overOffset*, *downOffset*)

The **MoveData** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
top	Integer. Identifies the first row in the range to move.
left	Integer. Identifies the first column in the range to move.
bottom	Integer. Identifies the last row in the range to move.
right	Integer. Identifies the last column in the range to move.
overOffset	Integer. Identifies the horizontal direction data should be moved. A positive value moves data to the right; a negative value moves data to the left.
downOffset	Integer. Identifies the vertical direction data should be moved. A positive value moves data down, a negative value moves data up.

See Also

Applies To: DataGrid Object

RandomDataFill Method

Fills the data grid associated with a specific chart with randomly generated data.

Syntax

*object.***RandomDataFill**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

MoveData Method | RandomFill Property | RandomFillColumns Method | RandomFillRows Method

Applies To: DataGrid Object

RandomFillColumns Method

Fills a number of data grid columns associated with a chart with random values.

Syntax

object.**RandomFillColumns** (*column, count*)

The **RandomFillColumns** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
column	Integer. Identifies the first column you wish to fill. Columns are numbered from left to right beginning with 1.
count	Integer. Specifies the number of columns you want to fill with random data.

See Also

RandomDataFill Method | RandomFill Property | RandomFillRows Method

Applies To: DataGrid Object

RandomFillRows Method

Fills a number of data grid rows associated with a chart with random values.

Syntax

object.**RandomFillRows** (*row*, *count*)

The **RandomFillRows** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
row	Integer. Identifies the first row you wish to fill. Rows are numbered from top to bottom beginning with 1 .
count	Integer. Specifies the number of rows you want to fill with random data.

See Also

MoveData Method | RandomDataFill Method | RandomFill Property | RandomFillColumns Method

Applies To: DataGrid Object

Remove Method (LightSources Collection)

Removes a **LightSource** from the **LightSources** collection.

Syntax

object.**Remove** (*index*)

The **Remove** method syntax has these parts:

Part	Description
collection	A object expression that evaluates to an object in the Applies To list.
index	Integer. A specific light source by position in the list of light sources .

Applies To: LightSources Collection

ResetCustom Method

Resets any custom attributes placed on a data point to the series default.

Syntax

object.**ResetCustom**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: DataPoint Object

ResetCustomLabel Method

Resets any custom attributes placed on a data point label in a chart to the series default.

Syntax

*object.***ResetCustomLabel**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: DataPointLabel Object

Select Method

Selects the specified chart element.

Syntax

object.**Select**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

Applies To: DataPoint Object | DataPointLabel Object | Footnote Object | Legend Object | Series Object | Title Object

SelectPart Method

Selects the specified chart part.

Syntax

object.**SelectPart** (*part*, *index1*, *index2*, *index3*, *index4*)

The **SelectPart** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
part	Integer. Specifies the chart part. Valid constants are VtChPartType.
index1	Integer. If *part* refers to a series or a data point, this argument specifies which series. Series are numbered in the order their corresponding columns appear in the data grid from left to right, beginning with 1. If *part* refers to an axis or axis label, this argument identifies the axis type with a VtChAxisId constant.
index2	Integer. If *part* refers to a data point, this argument specifies which data point in the series is identified by index1. Data points are numbered in the order their corresponding rows appear in the data grid from top to bottom, beginning with 1. If *part* refers to an axis, axis title, or axis label, this argument refers to the axis index which is currently not used. In this case, the only valid value for this argument is 1.
index3	Integer. If *part* refers to an axis label, this argument refers to the level of the label. Axis label levels are numbered from the axis out, beginning with 1. If *part* is not an axis label, the argument is unused.
index4	Integer. This argument is unused at this time.

See Also

AxisId Constants | PartType Constants

Applies To: MSChart Control

PartType Constants

The **VtChPartType** constants provide options for chart elements.

Constant	Description
VtChPartTypeChart	Identifies the chart control.
VtChPartTypeTitle	Identifies the chart title.
VtChPartTypeFootnote	Identifies the chart footnote.
VtChPartTypeLegend	Identifies the chart legend.
VtChPartTypePlot	Identifies the chart plot.
VtChPartTypeSeries	Identifies a chart series.
VtChPartTypePoint	Identifies an individual data point .
VtChPartTypePointLabel	Identifies a data point label.
VtChPartTypeAxis	Identifies an axis.
VtChPartTypeAxisLabel	Identifies an axis label.
VtChPartTypeAxisTitle	Identifies an axis title.

See Also

GetSelectedPart Method | SelectPart Method | TwipsToChartPart Method

Set Method (Coor, LCoor)

Sets the *x* and *y* coordinate values for a chart.

Syntax

object.**Set** (*x*,*y*)

The **Set** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
x	Single. (Long for **LCoor** object.) Identifies the *x* value of the coordinate.
y	Single. (Long for **LCoor** object.) Identifies the *y* value of the coordinate .

See Also

X Property | Y Property

Applies To: Coor Object | LCoor Object

Set Method (LightSource)

Sets the *x*, *y*, and *z* coordinates and the intensity for the **LightSource** object location.

Syntax

object.**Set** (*x*,*y*,*z*, *intensity*)

The **Set** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
x, *y*, *z*	Integers. Indicate the light source location.
intensity	Single. Indicate the light source intensity.

See Also

Applies To: LightSource Object

Set Method (View3D)

Sets the rotation and degree of elevation for a three-dimensional chart.

Syntax

object.**Set** (*rotation*, *elevation*)

The **Set** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
rotation	Single. The degree of rotation. Rotation can range from 0 to 360 degrees. By default, degrees are used to measure rotation. However, thes e settings use the current settings for the **AngleUnit** property. The other options are: Grads and Radians.
elevation	Single. The degree of elevation. Elevation can be any number from 0 to 90 degrees. If you set the elevation to 90 degrees, you look directly down onto the top of the chart. If you set the elevation to 0, you look directly at the side of the chart. The de fault elevation is 30 degrees. By default, degrees are used to measure elevation. However, these settings us e the current settings for the **AngleUnits** property. The other options are: Grads and Radians.

Applies To: View3D Object

Set Method (VtColor)

Sets the red, green and blue values of the **VtColor** object.

Syntax

object.**Set** (*red*,*green*,*blue*)

The **Set** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
red, *green*, *blue*	Integer. The values for the red, green and blue components of color.

Remarks

RGB specifies the relative intensity of red, green, and blue to cause a specific color to be displayed. The valid range for a normal RGB color is 0 to 16,777,215. The value for any argument to RGB that exceeds 255 is assumed to be 255.

See Also

Applies To: VtColor Object

Set Method (Weighting)

Sets the basis and style of the **Weighting** object.

Syntax

object.**Set** (*basis, style*)

The **Set** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
basis	A VtChPieWeightBasis constant that identifies the weighting type.
style	A VtChPieWeightStyle constant that identifies the weighting factor method .

See Also

PieWeightBasis Constants | PieWeightStyle Constants

SetData Method (MSChart)

Sets the value for a specific data point in the data grid associated with a chart.

Syntax

object.**SetData** *(row, column, dataPoint, nullFlag)*

The **SetData** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
row	Integer. Identifies the row containing the data point value.
column	Integer. Identifies the column containing the data point value.
dataPoint	Double. The data point value.
nullFlag	Integer. Indicates whether or not the data point value is a null.

See Also

Applies To: MSChart Control

SetSize Method

Resizes the number of data columns and rows, as well as the number of levels of column labels and row labels of a data grid associated with a chart at one time.

Syntax

object.**SetSize** (*rowLabelCount*, *columnLabelCount*, *dataRowCount*, *columnLabelCount*)

The **SetSize** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
rowLabelCount	Integer. Returns or sets the number of levels of row labels you want on the data grid.
columnLabelCount	Integer. Returns or sets the number of levels of column labels you want on the data grid.
dataRowCount	Integer. Returns or sets the number of data rows you want on the data grid.
columnLabelCount	Integer. Returns or sets the number of data columns you want on the data grid.

Remarks

This method can be used in place of **RowCount**, **ColumnCount**, **RowLabelCount** and **ColumnLabelCount**.

If you reduce the size of the data grid, data in deleted rows or columns is destroyed.

See Also

Applies To: DataGrid Object

ToDefaults Method

Returns the chart to its initial settings.

Syntax

*object.***ToDefaults**

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: MSChart Control

TwipsToChartPart Method

Identifies a chart part by using the x and y set of coordinates on to identify that part.

Syntax

object.**TwipsToChartPart** (*xVal*, *yVal*, *part*, *index1*, *index2*, *index3*, *index4*)

The **TwipsToChartPart** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
xVal,*yVal*	Long. The horizontal and vertical coordinates of the point.
part	Integer. A VtChPartType constant that identifies the chart part that is located at the *xVal* and *yVal* coordinates.
index1	Integer. If *part* refers to a series or a data point, this argument specifies which series. Series are numbered in the order their corresponding columns appear in the data grid from left to right, beginning with 1. If part refers to an axis or axis label, this argument identifies the axis type using the VtChAxisId constant.
index2	Integer. If *part* refers to a data point, this argument specifies which data point in the series identified by index1. Data points are numbered in the order their corresponding rows appear in the data grid from top to bottom, beginning with 1. If part refers to an axis, axis title, or axis label, this argument refers to the axis index which is currently not used. In this case, the only valid value for this argument is 1.
index3	Integer. If *part* refers to an axis label, this argument refers to the level of the label. Axis label levels are numbered from the axis out, beginning with 1. If *part* is not an axis label, the argument is unused.
index4	Integer. This argument is unused at this time.

Applies To: MSChart Control

TypeByChartType Method

Returns the series type used to draw a series if the chart type is set to *chType*. This method allows you to get the series type information based on a specified chart type without actually setting the chart type.

Syntax

object.**TypeByChartType** (*chtype*)

The **TypeByChartType** method syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list .
chtype	Integer. A VtChChartType constant describing the chart type.

Return Values

Depending on the chart type specified by the *chtype* argument, the **TypeByChartType** method returns one of the **VtChSeriesType** values, as shown below:

Constant	Value	Description
VtChSeriesTypeDefault	-1	Default
VtChSeriesType3dBar	0	3D Bar
VtChSeriesType2dBar	1	2D Bar
VtChSeriesType3dLine	5	3D Line
VtChSeriesType2dLine	6	2D Line
VtChSeriesType3dArea	7	3D Area
VtChSeriesType3dStep	9	3D Step
VtChSeriesType2dStep	10	2D Step
VtChSeriesType2dXY	11	XY
VtChSeriesType2dPie	24	2D Pie

AxisActivated Event

Occurs when the user double clicks on a chart axis.

Syntax

Private Sub *object*_**AxisActivated** (*axisId* **As Integer**, *axisIndex* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The AxisActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis, as described in Settings.
axisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid val ue for this argument.
mouseFlags	Integer. An integer that indicates whether a key is held down when the mouse button is clicked, as de scribed in Settings.
cancel	Integer. An integer that is not used at this time.

Settings

The event handler determines which axis is activated and sets *axisId* to:

Constants	Description
VtChAxisIdX	If the *x* axis is affected.
VtChAxisIdY	If the *y* axis is affected.
VtChAxisIdY2	If the secondary *y* axis is affected .
VtChAxisIdZ	If the *z* axis is affected.

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

AxisLabelActivated Event

Occurs when the user double clicks on an axis label.

Syntax

Private Sub *object*_**AxisLabelActivated** (*axisId* **As Integer**, *axisIndex* **As Integer**, *labelSetIndex* **As Integer**, *labelIndex* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The AxisLabelActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis, as described in Settings.
axisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid value for this argument.
labelSetIndex	Integer. An integer that identifies the level of labels you are double clicking on. Levels of labels ar e numbered from the axis out, beginning with 1.
labelIndex	Integer. An integer that is currently unused.
mouseFlags	Integer. An integer that indicates if a key is held down when the mouse button is clicked.
cancel	Integer. An integer that is not used at this time.

Settings

The event handler determines which axis label is activated and sets *axisId* to:

Constants	Description
VtChAxisIdX	If the *x* axis is affected.
VtChAxisIdY	If the *y* axis is affected.
VtChAxisIdY2	If the secondary *y* axis is affected.
VtChAxisIdZ	If the *z* axis is affected.

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

AxisLabelSelected Event | AxisLabelUpdated Event | UpdateFlags Constants

Applies To: MSChart Control

AxisLabelSelected Event

Occurs when the user clicks an axis label.

Syntax

Private Sub *object*_**AxisLabelSelected** (*axisId* **As Integer**, *axisIndex* **As Integer**, *labelSetIndex* **As Integer**, *labelIndex* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The AxisLabelSelected event syntax has these parts.

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis, as described in Settings.
axisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid v alue for this argument.
labelSetIndex	Integer. An integer that identifies the level of labels you are double clicking on. Levels of labels are numbered from the axis out, beginning with 1.
labelIndex	Integer. An integer that is currently unused.
mouseFlags	Integer. An integer that indicates if a key is held down when the mouse button is clicked, as describ ed in Settings.
cancel	Integer. An integer that is not used at this time.

Settings

The event handler determines which axis label is selected and sets *axisId* to:

Constants	Description
VtChAxisIdX	If the *x* axis is affected.
VtChAxisIdY	If the *y* axis is affected.
VtChAxisIdY2	If the secondary *y* axis is affected.
VtChAxisIdZ	If the *z* axis is affected.

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

AxisLabelActivated Event | AxisLabelUpdated Event

Applies To: MSChart Control

AxisLabelUpdated Event

Occurs when an axis label has changed.

Syntax

Private Sub *object*_**AxisLabelUpdated** (*axisId* **As Integer**, *axisIndex* **As Integer**, *labelSetIndex* **As Integer**, *labelIndex* **As Integer**, *updateFlags* **As Integer**)

The AxisLabelUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis, as described in Settings.
axisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid value for this argument.
labelSetIndex	Integer. An integer that identifies the level of labels you are double clicking on. Levels of labels ar e numbered from the axis out, beginning with 1.
labelIndex	Integer. An integer that is currently unused.
updateFlags	Integer. An integer provides information about the update of the label, as described in Settings.

Settings

The event handler determines which axis label is updated and sets *axisId* to:

Constants	Description
VtChAxisIdX	If the *x* axis is affected.
VtChAxisIdY	If the *y* axis is affected.
VtChAxisIdY2	If the secondary *y* axis is affected .
VtChAxisIdZ	If the *z* axis is affected.

The event handler determines the affect of the update, and sets *updateFlags* to:

Constants	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

AxisLabelActivated Event | AxisLabelSelected Event

Applies To: MSChart Control

AxisSelected Event

Occurs when the user clicks on a chart axis.

Syntax

Private Sub *object*_**AxisSelected** (*axisId* **As Integer**, *axisIndex* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The AxisSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis, as described in Settings.
axisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid value for this argument.
mouseFlags	Integer. An integer that indicates whether key is held down when the mouse button is clicke d, as described in Settings.
cancel	Integer. An integer that is not used at this time.

Settings

The event handler determines which axis is selected and sets *axisId* to:

Constants	Value	Description
VtChAxisIdX	0	If the *x* axis is affected.
VtChAxisIdY	1	If the *y* axis is affected.
VtChAxisIdY2	2	If the secondary *y* axis is affected.
VtChAxisIdZ	3	If the *z* axis is affected.
VtChAxisIDNone	4	No axis.

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

AxisTitleActivated Event

Occurs when the user double clicks on an axis title.

Syntax

Private Sub *object*_**AxisTitleActivated** (*axisId* **As Integer**, *axisIndex* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The AxisTitleActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis.
AxisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid v alue for this argument.
mouseFlags	Integer. An integer that indicates whether a key is held down when the mouse button is clicked.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines which axis title is activated and sets *axisId* to:

Constants	Value	Description
VtChAxisIdX	0	If the *x* axis is affected.
VtChAxisIdY	1	If the *y* axis is affected.
VtChAxisIdY2	2	If the secondary *y* axis is affected.
VtChAxisIdZ	3	If the *z* axis is affected.
VtChAxisIDNone	4	No axis.

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

AxisTitleSelected Event | AxisTitleUpdated Event

Applies To: MSChart Control

AxisTitleSelected Event

Occurs when the user clicks on an axis title.

Syntax

Private Sub *object*_**AxisTitleSelected** (*axisId* **As Integer**, *axisIndex* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The AxisTitleSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis.
AxisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid v alue for this argument.
mouseFlags	Integer. An integer that indicates whether a key is held down when the mouse button is clicked.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines which axis title is selected and sets *axisId* to:

Constants	Value	Description
VtChAxisIdX	0	If the *x* axis is affected.
VtChAxisIdY	1	If the *y* axis is affected.
VtChAxisIdY2	2	If the secondary *y* axis is affected.
VtChAxisIdZ	3	If the *z* axis is affected.
VtChAxisIDNone	4	No axis.

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

AxisTitleActivated Event | AxisTitleUpdated Event

Applies To: MSChart Control

AxisTitleUpdated Event

Occurs when an axis title has changed.

Syntax

Private Sub *object*_**AxisTitleUpdated** (*axisId* **As Integer**, *axisIndex* **As Integer**, *updateFlags* **As Integer**)

The AxisTitleUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis.
axisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid value for this argument.
updateFlags	Integer. An integer that provides information about the update of the title.

Settings

The event handler determines which axis title is updated and sets *axisId* to:

Constants	Value	Description
VtChAxisIdX	0	If the *x* axis is affected.
VtChAxisIdY	1	If the *y* axis is affected.
VtChAxisIdY2	2	If the secondary *y* axis is affected.
VtChAxisIdZ	3	If the *z* axis is affected.
VtChAxisIDNone	4	No axis.

The following table lists the constants for *updateFlags*.

Constants	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

Applies To: MSChart Control

AxisUpdated Event

Occurs when an axis has changed.

Syntax

Private Sub *object*_**AxisUpdated** (*axisId* **As Integer**, *axisIndex* **As Integer**, *updateFlags* **As Integer**)

The AxisUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
axisId	Integer. An integer that identifies a specific axis.
axisIndex	Integer. An integer reserved for future use. For this version of MSChart control, 1 is the only valid value for this argument.
updateFlags	Integer. An integer that provides information about the update of the axis.

Settings

The event handler determines which axis is updated and sets *axisId* to:

Constants	Value	Description
VtChAxisIdX	0	If the *x* axis is affected.
VtChAxisIdY	1	If the *y* axis is affected.
VtChAxisIdY2	2	If the secondary *y* axis is affected.
VtChAxisIdZ	3	If the *z* axis is affected.
VtChAxisIDNone	4	No axis.

The following table lists the constants for *updateFlags*.

Constants	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

Applies To: MSChart Control

ChartActivated Event

Occurs when the user double clicks the Microsoft Chart control, but not on a specific element in the chart.

Syntax

Private Sub *object*_**ChartActivated** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The ChartActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

ChartSelected Event | ChartUpdated Event

Applies To: MSChart Control

ChartSelected Event

Occurs when the user clicks the Microsoft Chart control, but not on a specific element in the chart.

Syntax

Private Sub *object*_**ChartSelected** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The ChartSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in S ettings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

ChartActivated Event | ChartUpdated Event

Applies To: MSChart Control

ChartUpdated Event

Occurs when the chart has changed.

Syntax

Private Sub *object*_**ChartUpdated** (*updateFlags* **As Integer**)

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
updateFlags	Integer. Provides information about the update of the chart, as described in Settings .

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

See Also

ChartActivated Event | ChartSelected Event | UpdateFlags Constants

Applies To: MSChart Control

DataUpdated Event

Occurs when the chart data grid has changed.

Syntax

Private Sub *object*_**DataUpdated** (*row* **As Integer**, *column* **As Integer**, *labelRow* **As Integer**, *labelColumn* **As Integer**, *labelSetIndex* **As Integer**, *updateFlags* **As Integer**)

The DataUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
row	Integer. Indicates the row in the data grid.
column	Integer. Indicates the column in the datagrid.
labelRow	Integer. Indicates the row label.
labelColumn	Integer. Indicates the column label.
labelSetIndex	Integer. Identifies the level of labels. Levels of labels are numbered from the axis out, beginning with 1.
updateFlags	Integer. Provides information about the update of the data, as described in Settings.

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

Remarks

If row and column are nonzero, the change occurs to the indicated data cell. If *labelRow* or *labelColumn*, along with *labelSetIndex*, are nonzero, the indicated row or column label changes. If none of these are nonzero, no specific information about the change is available.

DonePainting Event

Occurs immediately after the chart repaints or redraws.

Syntax

Private Sub *object*_**DonePainting** ()

The object placeholder represents an object expression that evaluates to an object in the Applies To list.

See Also

Applies To: MSChart Control

FootnoteActivated Event

Occurs when the user double clicks the chart footnote.

Syntax

Private Sub *object*_**FootnoteActivated**(*mouseFlags* **As Integer**, *cancel* **As Integer**)

The FootnoteActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

FootnoteSelected Event | FootnoteUpdated Event

Applies To: MSChart Control

FootnoteSelected Event

Occurs when the user clicks the chart footnote.

Syntax

Private Sub *object*_**FootnoteSelected** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The FootnoteSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

FootnoteActivated Event | FootnoteUpdated Event

Applies To: MSChart Control

FootnoteUpdated Event

Occurs when the chart footnote changes.

Syntax

Private Sub *object*_**FootnoteUpdated** (*updateFlags* **As Integer**)

The FootnoteUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
updateFlags	Integer. Provides information about the update of the footnote, as described in Settings .

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

LegendActivated Event

Occurs when the user double clicks on the chart legend.

Syntax

Private Sub *object*_**LegendActivated** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The LegendActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in S ettings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down .

See Also

Applies To: MSChart Control

LegendSelected Event

Occurs when the user clicks on the chart legend.

Syntax

Private Sub *object*_**LegendSelected** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The LegendSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked .
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down .

See Also

Applies To: MSChart Control

LegendUpdated Event

Occurs when the chart legend has changed.

Syntax

Private Sub *object*_**LegendUpdated** (*updateFlags* **As Integer**)

The LegendUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
updateFlags	Integer. Provides information about the update of the legend, as described in Settings .

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

See Also

UpdateFlags Constants

Applies To: MSChart Control

PlotActivated Event

Occurs when the user double clicks the chart plot.

Syntax

Private Sub *object*_**PlotActivated** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The PlotActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

PlotSelected Event

Occurs when the user clicks the chart plot.

Syntax

Private Sub *object*_**PlotSelected** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The PlotSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in S ettings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

PlotUpdated Event

Occurs when the chart plot has changed.

Syntax

Private Sub *object*_**PlotUpdated** (*updateFlags* **As Integer**)

The PlotUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
updateFlags	Integer. Provides information about the update of the plot, as described in Settings.

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

UpdateFlags Constants

Applies To: MSChart Control

PointActivated Event

Occurs when the user double clicks on a data point.

Syntax

Private Sub *object*_**PointActivated** (*series* **As Integer**, *dataPoint* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The PointActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that their columns appear in the data grid, beginning with 1.
dataPoint	Integer. Identifies the data point's position in the series. Points are numbered in the order that their rows appear in the data grid, beginning with 1.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

PointLabelActivated Event

Occurs when the user double clicks a data point label.

Syntax

Private Sub *object*_**PointLabelActivated** (*series* **As Integer**, *dataPoint* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The PointLabelActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that their columns appear in the data grid, beginning with 1.
dataPoint	Integer. Identifies the data point's position in the series. Points are numbered in the order that their rows appear in the data grid, beginning with 1.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

PointLabelSelected Event

Occurs when the user clicks a data point label.

Syntax

Private Sub *object*_**PointLabelSelected** (*series* **As Integer**, *dataPoint* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The PointLabelSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that their column s appear in the data grid, beginning with 1.
dataPoint	Integer. Identifies the data point's position in the series. Points are numbered in the order that their rows appear in the data grid, beginning with 1.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

PointLabelUpdated Event

Occurs when a data point label has changed.

Syntax

Private Sub *object*_**PointLabelUpdated** (*series* **As Integer**, *dataPoint* **As Integer**, *updateFlags* **As Integer**)

The PointLabelUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that their columns appear in the data grid, beginning with 1.
dataPoint	Integer. Identifies the data point's position in the series. Points are numbered in the order that their rows appear in the data grid, beginning with 1.
updateFlags	Integer. Provides information about the update of the data point label, as described in Settings.

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

PointSelected Event

Occurs when the user clicks a data point.

Syntax

Private Sub *object*_**PointSelected** (*series* **As Integer**, *dataPoint* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The PointSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that their columns appear in the data grid, beginning with 1.
dataPoint	Integer. Identifies the data point's position in the series. Points are numbered in the order that their rows appear in the data grid, beginning with 1.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

PointUpdated Event

Occurs when a data point has changed.

Syntax

Private Sub *object*_**PointUpdated** (*series* **As Integer**, *dataPoint* **As Integer**, *updateFlags* **As Integer**)

The PointUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that their columns appear in the data grid, beginning with 1.
dataPoint	Integer. Identifies the data point's position in the series. Points are numbered in the order that their rows appear in the data grid, beginning with 1.
updateFlags	Integer. Provides information about the update of the data point, as described in Settings.

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

UpdateFlags Constants

Applies To: MSChart Control

SeriesActivated Event

Occurs when the user double clicks a chart series. You can replace the standard user interface by canceling the event and displaying your own dialog box.

Syntax

Private Sub *object*_**SeriesActivated** (*series* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The SeriesActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that their columns appear in the data grid, beginning with 1.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

MouseFlag Constants

VtChMouseFlag indicates which keyboard key is being held down while the mouse button is clicked.

Constant	Description
VtChMouseFlagShiftKeyDown	The SHIFT key is held down when the mouse button is clicked.
VtChMouseFlagControlKeyDown	The CONTROL key is held down when the mouse button is clicked.

SeriesSelected Event

Occurs when the user clicks a chart series.

Syntax

Private Sub *object*_**SeriesSelected** (*series* **As Integer**, *mouseFlags* **As Integer**, *cancel* **As Integer**)

The SeriesSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that thei r columns appear in the data grid, beginning with 1.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in S ettings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

SeriesUpdated Event

Occurs when a chart series has changed.

Syntax

Private Sub *object*_**SeriesUpdated** (*series* **As Integer**, *updateFlags* **As Integer**)

The SeriesUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
series	Integer. Identifies the series containing the data point. Series are numbered in the order that thei r columns appear in the data grid, beginning with 1.
updateFlags	Integer. Provides information about the update of the series, as described in Settings.

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

See Also

UpdateFlags Constants

Applies To: MSChart Control

UpdateFlags Constants

The **UpdateFlags** constants listed below can be used in various events to determine what part of the chart is being updated.

Constant	Value	Description
VtChNoDisplay	0	Absence of update flags; the chart display is not affected .
VtChDisplayPlot	1	Update will cause the plot to repaint.
VtChLayoutPlot	2	Update will cause the plot to layout.
VtChDisplayLegend	4	Update will cause the legend to repaint.
VtChLayoutLegend	8	Update will cause the legend to layout.
VtChLayoutSeries	16	Update will cause the series to lay out.
VtChPositionSection	32	A chart section has been moved or resized.

Remarks

The constants can be used in the following events:

- AxisLabelUpdated Event
- AxisTitleUpdated Event
- AxisUpdated
- ChartUpdated Event
- DataUpdated Event
- FootnoteUpdated Event
- LegendUpdated Event
- PlotUpdated Event
- PointLabelUpdated Event
- PointUpdated Event
- SeriesUpdated Event
- TitleUpdated Event

TitleActivated Event

Occurs when the user double clicks the chart title. You can replace the standard user interface by canceling the event and displaying your own dialog box.

Syntax

Private Sub *object*_**TitleActivated** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The TitleActivated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Setti ngs.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

TitleSelected Event

Occurs when the user clicks the chart title.

Syntax

Private Sub *object*_**TitleSelected** (*mouseFlags* **As Integer**, *cancel* **As Integer**)

The TitleSelected event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
mouseFlags	Integer. Indicates whether a key is held down when the mouse button is clicked, as described in Settings.
cancel	Integer. This argument is not used at this time.

Settings

The event handler determines if a key is held down when the mouse button is clicked and sets *mouseFlags* to:

Constants	Description
VtChMouseFlagShiftKeyDown	If the SHIFT key is held down.
VtChMouseFlagControlKeyDown	If the CONTROL key is held down.

See Also

Applies To: MSChart Control

TitleUpdated Event

Occurs when the chart title has changed.

Syntax

Private Sub *object*_**TitleUpdated** (*updateFlags* **As Integer**)

The TitleUpdated event syntax has these parts:

Part	Description
object	An object expression that evaluates to an object in the Applies To list.
updateFlags	Provides information about the update of the title, as described in Settings.

Settings

The following table lists the constants for *updateFlags*.

Constant	Description
VtChNoDisplay	Absence of update flags; the chart display is not affected. (Defined as 0.)
VtChDisplayPlot	Update will cause the plot to repaint.
VtChLayoutPlot	Update will cause the plot to lay out.
VtChDisplayLegend	Update will cause the legend to repaint.
VtChLayoutLegend	Update will cause the legend to lay out.
VtChLayoutSeries	Update will cause the series to lay out.
VtChPositionSection	A chart section has been moved or resized.

Code: Redirecting to Another Page (Visual Basic)

This example uses the HttpResponse.Redirect method to redirect the browser to the specified URL.

Example

```
Response.Redirect("http://www.microsoft.com")
```

Compiling the Code

This example requires:

- A Web Forms page.

Robust Programming

The **Redirect** method is executed by the browser and therefore results in an extra round trip between server and browser.

It is up to you to make sure that the target page exists.

Security

Because the method is executed by the client, it is subject to spoofing or other tampering.

See Also

Code: Redirecting to Another Page in the Same Application (Visual Basic) | HttpResponse Class | HttpResponse.Redirect Method | Web Forms Pages | Web Applications Example Topics

Code: Overriding Control Validation on Windows Forms in the Closing Event (Visual Basic)

This example shows how to close a form even if there is validation logic in the form and one or more of the controls contain invalid data. In the example, there is validation logic for a TextBox control. Validation is overridden in the form's **Closing** event.

Example

```
Private Sub TextBox1_Validating(ByVal sender As Object, _
    ByVal e As System.ComponentModel.CancelEventArgs) _
    Handles TextBox1.Validating
    If TextBox1.Text.Length < 8 Then
            ("Value you entered is not valid;" _
            & " it must be at least 8 characters.")
        e.Cancel = True
    End If
End Sub

Private Sub Form1_Closing(ByVal sender As Object, _
    ByVal e As System.ComponentModel.CancelEventArgs) _
    Handles MyBase.Closing
    e.Cancel = False
End Sub
```

Compiling the Code

This project requires:

- A reference to the **System** namespace.
- A Windows Form.
- A **TextBox** control named TextBox1.
- Another control on the form that can receive focus to illustrate validation being overridden.

Security

User input into a Windows Forms can include potentially invalid, malformed, or malicious information. Always check that the values that a user enters conform to the requirements for your application before using the values.

See Also

Code: Validating User Input on Windows Forms (Visual Basic) | Validation of Control Data on Windows Forms | Form.Closing Event | CancelEventArgs Class | Windows Applications Example Topics

Code: Databinding a DataTable of String Values to a Windows Forms DataGrid Control (Visual Basic)

This example creates a data table with two columns and two rows and then binds it to an existing **DataGrid** control.

Example

```
Public Sub BindTableToDataGrid()
    Dim dt As New DataTable()
    dt.Columns.Add(New DataColumn("Item", GetType(String)))
    dt.Columns.Add(New DataColumn("Color", GetType(String)))
    dt.Rows.Add(New String() {"table", "brown"})
    dt.Rows.Add(New String() {"chair", "white"})
    DataGrid1.DataSource = dt
End Sub
```

Compiling the Code

This example requires:

- A reference to the **System** namespace.
- A **DataGrid** control named DataGrid1.

See Also

Code: Creating a DataTable (Visual Basic) | DataGrid Control (Windows Forms) | DataGrid.DataSource Property | DataTable Class | Windows Forms Controls Example Topics

Code: Hiding a DataColumn in a Windows Forms DataGrid Control Where the DataSource is a DataTable (Visual Basic)

This example hides the "X" column of a **DataTable** object that is displayed in an existing Windows Forms **DataGrid** control.

Example

```
Sub HideColumnOfDataSet()
    Dim points As New System.Data.DataTable("Points")
    points.Columns.Add(New DataColumn("X", GetType(Integer)))
    points.Columns.Add(New DataColumn("Y", GetType(Integer)))
    points.Rows.Add(New Object() {1, 2})
    points.Rows.Add(New Object() {3, 5})
    DataGrid1.DataSource = points

    Dim tableStyle As New DataGridTableStyle
    tableStyle.MappingName = "Points"
    DataGrid1.TableStyles.Add(tableStyle)
    DataGrid1.TableStyles("Points").GridColumnStyles("X").Width = 0
End Sub
```

Compiling the Code

This example requires:

- A Windows Form.
- A **DataGrid** control named DataGrid1.

If the data source is a **DataSet** object, set the **DataMember** property of the **DataGrid** to the table's name.

DataTable and **DataColumn** objects in typed datasets also have string-typed names. To find the name of the table, examine the table's **TableName** property. To find the name of the **DataColumn**, examine the column's **ColumnName** property.

Another method for hiding data columns is to create the **DataGridColumnStyle** objects and add them to the **GridColumnStyles** collection. With this method, you can hide a column by not adding a column style for it. For an example, see Formatting the Windows Forms DataGrid Control.

Robust Programming

The following conditions may cause an exception:

- The **MappingName** property does not match the name of the **DataTable** (NullReferenceException Class).
- Retrieving an item from the **GridColumnStyles** collection before the **TableStyle** is added to the **DataGrid.TableStyles** collection. The **GridColumnStyles** collection is filled when the **TableStyle** object is added to the **TableStyles** collection (NullReferenceException Class).
- A **TableStyle** added to the **DataGrid**.**TableStyles** collection does not have a unique **MappingName** (ArgumentException Class).
- The **DataSource** property of the **DataGrid** is not set before accessing the **GridColumnStyles** collection (NullReferenceException Class).

See Also

Windows Forms Controls Example Topics | Hiding a DataColumn in a DataGrid Where the DataSource is an Array | Hiding a DataColumn in a DataGrid Where the DataSource is an ArrayList | DataGrid Control (Windows Forms) | Formatting the Windows Forms DataGrid Control | DataGrid.TableStyles Property | DataGridTableStyle.MappingName Property | DataGridTableStyle.GridColumnStyles Property

Code: Hiding a DataColumn in a Windows Forms DataGrid Control Where the DataSource is an Array (Visual Basic)

This example hides the "X" column of a **DataGrid** that uses an array of **Point** objects as the data source.

Example

```
Sub HideColumnOfArray()
    Dim points() As System.Drawing.Point = _
        {New Point(1, 2), New Point(3, 5), New Point(5, 6)}
    DataGrid1.DataSource = points

    Dim tableStyle As New DataGridTableStyle
    Dim mappingName As String = DataGrid1.DataSource.GetType().Name
    tableStyle.MappingName = mappingName
    DataGrid1.TableStyles.Add(tableStyle)
    DataGrid1.TableStyles(mappingName).GridColumnStyles("X").Width = 0
End Sub
```

Compiling the Code

This example requires:

- A Windows Form.
- A **DataGrid** control named DataGrid1.

Another method for hiding data columns is to create the **DataGridColumnStyle** objects and add them to the **GridColumnStyles** collection. With this method, you can hide a column by not adding a column style for it. For an example, see Formatting the Windows Forms DataGrid Control.

Robust Programming

The following conditions may cause an exception:

- The **MappingName** property is not property formatted (NullReferenceException Class).
- Retrieving an item from the **GridColumnStyles** collection before the **TableStyle** is added to the **DataGrid.TableStyles** collection. The **GridColumnStyles** collection is filled when the **TableStyle** object is added to the **TableStyles** collection (NullReferenceException Class).
- A **TableStyle** added to the **DataGrid**.**TableStyles** collection does not have a unique **MappingName** (ArgumentException Class).
- The **DataSource** property of the **DataGrid** is not set before accessing the **GridColumnStyles** collection (NullReferenceException Class).

See Also

Windows Forms Controls Example Topics | Hiding a DataColumn in a DataGrid Where the DataSource is a DataTable | Hiding a DataColumn in a DataGrid Where the DataSource is an ArrayList | DataGrid Control (Windows Forms) | Formatting the Windows Forms DataGrid Control | DataGrid.TableStyles Property | DataGridTableStyle.MappingName Property | DataGridTableStyle.GridColumnStyles Property

Code: Hiding a DataColumn in a Windows Forms DataGrid Control Where the DataSource is an ArrayList (Visual Basic)

This example hides one column of a **DataGrid** that uses an **ArrayList** of **Point** objects as a data source.

Example

```
Sub HideColumnOfArrayList()
    Dim list As New System.Collections.ArrayList
    list.AddRange(New System.Drawing.Point() _
        {New Point(1, 2), New Point(3, 5), New Point(5, 6)})
    DataGrid1.DataSource = list

    Dim tableStyle As New DataGridTableStyle
    tableStyle.MappingName = "ArrayList"
    DataGrid1.TableStyles.Add(tableStyle)
    DataGrid1.TableStyles("ArrayList").GridColumnStyles("X").Width = 0
End Sub
```

Compiling the Code

This example requires:

- A Windows Form.
- A **DataGrid** control named DataGrid1.

When the data source is an **ArrayList** object, the **MappingName** is "ArrayList".

Another method for hiding data columns is to create the **DataGridColumnStyle** objects and add them to the **GridColumnStyles** collection. With this method, you can hide a column by not adding a column style for it. For an example, see Formatting the Windows Forms DataGrid Control.

Robust Programming

The following conditions may cause an exception:

- The **MappingName** property is not "ArrayList" (NullReferenceException Class).
- Retrieving an item from the **GridColumnStyles** collection before the **TableStyle** is added to the **DataGrid.TableStyles** collection. The **GridColumnStyles** collection is filled when the **TableStyle** object is added to the **TableStyles** collection (NullReferenceException Class).
- A **TableStyle** added to the **DataGrid**.**TableStyles** collection does not have a unique **MappingName** (ArgumentException Class).
- All the objects in the **ArrayList** are not of the same type of the first item or a derived type of the first item (TargetInvocationException Class).
- The **DataSource** property of the **DataGrid** is not set before accessing the **GridColumnStyles** collection (NullReferenceException Class).

See Also

Windows Forms Controls Example Topics | Hiding a DataColumn in a DataGrid Where the DataSource is a DataTable | Hiding a DataColumn in a DataGrid Where the DataSource is an Array | DataGrid Control (Windows Forms) | Formatting the Windows Forms DataGrid Control | DataGrid.TableStyles Property | DataGridTableStyle.MappingName Property | DataGridTableStyle.GridColumnStyles Property

Code: Determining Whether a Registry Key Exists (Visual Basic)

This example checks to see if the specified key, SOFTWARE\\Microsoft\\TestApp\\1.0, exists and creates it if it does not.

Example

```
Private Sub DoesKeyExist
    Dim regVersion As Microsoft.Win32.RegistryKey
    regVersion = _
Microsoft.Win32.Registry.CurrentUser.OpenSubKey("SOFTWARE\\Microsoft\\TestApp\\1.0", True)
    If regVersion Is Nothing Then
        regVersion = _
Microsoft.Win32.Registry.CurrentUser.CreateSubKey("SOFTWARE\\Microsoft\\TestApp\\1.0")
    End If
End Sub
```

Compiling the Code

This example requires:

- A reference to the **Win32** namespace.

Security

Registry calls fail if either sufficient runtime permissions are not granted (RegistryPermission Class) or if the user does not have the correct ACLs for creating or writing to settings. For example, a local application that has the code access security permission might not have operating system permission.

See Also

Code: Creating a Key In the Registry (Visual Basic) | Registry Access Changes in Visual Basic .NET | Registry Class | Registry Summary | System Input/Output Example Topics

Code: Displaying Variables in a String (Visual Basic)

This example declares the variable number and then displays it and its square in the string result.

Example

```
Private Sub DisplayTheSquare()
    Dim number As Integer = 4
    Dim result As String = _
        String.Format("{0} times {0} = {1}", _
        number, number * number)
    MsgBox(result)
End Sub
```

Compiling the Code

This example requires:

- A reference to the **System** namespace.

Robust programming

The following conditions may create an exception:

- Number is too large (OverflowException Class)
- Format string is incorrect, such as using {2} instead of {1} when there is no third element. (FormatException Class)

See Also

String Manipulation | Strings | String.Format Method | System Input/Output Example Topics

Visual C# Code Example Topics

Code example topics in the Visual C# .NET documentation are designed to present concise, real-world examples of common tasks. These topics are organized by feature area.

Code Topic Categories

Code example topics are available for the following features:

General Language Example Topics
Presents a series of specific example code topics for common tasks using language elements of Visual C# .NET.
Graphics Programming Example Topics
Presents a series of specific example code topics for common tasks in graphics and GDI+ programming with Visual C# .NET.
Web Applications Example Topics
Presents a series of specific example code topics for common tasks in Web Forms applications with Visual C# .NET.
Windows Forms Example Topics
Presents a series of specific example code topics for common tasks in Windows Forms applications with Visual C# .NET.

Other Sources For Sample Code

There are also many other places to find C# code examples for common features and tasks in the Visual Studio and .NET Framework help system. You can also find sample code in the following locations:

C# Programmer's Reference
The topics in this section contain code showing how to use basic language features such as threading, inheritance, and file IO.
Visual C# Samples
Lists compiled sample applications available to you in the documentation set.
Walkthroughs in Visual Basic and Visual C#
Lists tutorial topics that walk you through the process of creating applications and learning to use specific features.
Quickstarts and Other Samples
Lists samples available to you when you install the .NET Framework SDK.
.NET Framework Reference Information
Many topics in the .NET Framework reference contain code examples of how to use classes and their members.

General Language Example Topics

This topic is designed to help you find code that demonstrates how to perform common programming tasks in applications using Visual C#.NET.

In This Section

- Breaking Out of an Iterative Statement
- Calling a Method on an Object
- Catching an Exception
- Declaring an Array
- Declaring a Property
- Determining the Span Between Two Dates
- Displaying a Web Page in Internet Explorer
- Finding the Names of Resources in an Assembly
- Generating Multiline String Literals
- Inheriting From a Class
- Initializing an Array
- Iterating Through an Array
- Iterating Through a Collection
- Passing Object Arrays to Methods
- Reading a Text File One Line at a Time
- Reading Class Data from an XML File
- Reading From a Text File
- Reading XML From a File
- Running a Program
- Running a Program Associated with a File Type
- Searching for a String in an Array of Strings
- Searching Within a String
- Setting a Property on an Object
- Simulating Default Parameters
- Throwing an Exception
- Using PInvoke
- Writing Class Data to an XML File
- Writing to a Text File

Related Code Examples

You can also find sample code for C# applications in the following locations:

- C# Language Tour
- Visual C# Samples
- Walkthroughs in Visual Basic and Visual C#
- Quickstarts and other Samples
- .NET Framework Reference Information

Code: Breaking Out of an Iterative Statement (Visual C#)

This example uses the **break** statement to break out of a **for** loop when an integer counter reaches 10.

Example

```
for (int counter = 1; counter <= 1000; counter++)
{
    if (counter == 10)
       break;
    Console.WriteLine(counter);
}
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

See Also

break | Jump Statements | General Language Example Topics

Code: Calling a Method on an Object (Visual C#)

This example calls the **WriteLine** method on the **Console** class.

Example

```
Console.WriteLine("This line will appear in the console window");
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Robust Programming

Use the fully qualified name of the method, unless it is accessible from the same scope.

Unless the method is static, it must be referenced through an instance of the class.

When assigning an expression to a property, make sure of the following:

- That it is of a compatible data type.
- That it has a valid value, especially if the value is derived from user input.

See Also

Console Class | Console.WriteLine Method (String) | General Language Example Topics

Code: Catching an Exception (Visual C#)

This example uses the **try**-**catch** blocks to catch division by zero as an exception.

Example

```
int top = 0, bottom = 0, result = 0;
try
{
    result = top / bottom;
}
catch (System.DivideByZeroException ex)
{
    Console.WriteLine("{0} Exception caught.", ex);
}
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

See Also

Code: Throwing an Exception (Visual C#) | try-catch | try-catch-finally | DivideByZeroException Class | General Language Example Topics

Code: Declaring a Property (Visual C#)

This example declares an instance property. For more information and examples on instance and static properties, see Properties.

Example

```
private string name;
// A read-write instance property:
public string NameProperty
{
   get
   {
      return name;
   }
   set
   {
      name = value;
   }
}
```

Compiling the Code

The code must appear within a class or a struct.

Robust Programming

- You can use the **get** accessor to either return the field value or compute the value and return it, for example:

```
get
{
    return (name != null) ? name : "NA";
}
```

- Do not use the **get** accessor to change the state of the object, for example:

```
get
{
    return myNumericField++;
}
```

See Also

Property Declaration | Accessors | Interface Properties | General Language Example Topics

Code: Declaring an Array (Visual C#)

This example shows three different ways to declare different kinds of arrays: single-dimensional, multidimensional, and jagged.

Example

```
// Single-dimensional arrays.
int[] myArray1 = new int [5];
string[] myArray2 = new string[6];

// Multidimensional arrays.
int[,] myArray3 = new int[4,2];
int[,,] myArray4 = new int [4,2,3];

// Jagged array.
int[][] myArray5 = new int[3][];
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Robust Programming

Make sure you initialize the elements of the jagged array before using it, as follows:

```
myArray5[0] = new int[7];
myArray5[1] = new int[5];
myArray5[2] = new int[2];
```

See Also

Arrays | Arrays Tutorial | Array Class | Reference Types | General Language Example Topics

Code: Determining the Span Between Two Dates (Visual C#)

This example calculates the difference in days between two dates and constructs a **TimeSpan** value for that difference.

Example

```
DateTime oldDate = new DateTime(2002,7,15);
DateTime newDate = DateTime.Now;

// Difference in days, hours, and minutes.
TimeSpan ts = newDate - oldDate;
// Difference in days.
int differenceInDays = ts.Days;

Console.WriteLine("Difference in days: {0} ", differenceInDays);
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

See Also

TimeSpan Structure | DateTime Members | DateTime Subtraction Operator | DateTime.Subtract Method| TimeSpan.Days Property | General Language Example Topics

Code: Displaying a Web Page in Internet Explorer (Visual C#)

This example displays www.microsoft.com in Internet Explorer using the **Process.Start** method.

Example

```
System.Diagnostics.Process.Start(
"C:\\Program Files\\Internet Explorer\\IExplore.exe",
"www.microsoft.com");
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Replace the first parameter of **Start** with the path to IExplore.exe, if the program is installed in a different location.

See Also

Process.Start Method | Starting Processes | General Language Example Topics

Code: Finding the Names of Resources in an Assembly (Visual C#)

This example creates a string that contains the names of all the resources in an assembly.

Example

```
System.Reflection.Assembly thisExe;
thisExe = System.Reflection.Assembly.GetExecutingAssembly();
string [] resources = thisExe.GetManifestResourceNames();
string list = "";

// Build the string of resources.
foreach (string resource in resources)
   list += resource + "\r\n";
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

See Also

Assembly Class | General Language Example Topics

Code: Generating Multiline String Literals (Visual C#)

This example demonstrates two ways of constructing a multiline string literal.

Example

```
string myString1 = "This is the first line of my string.\n" +
                   "This is the second line of my string.\n" +
                   "This is the third line of the string.\n";
string myString2 = @"This is the first line of my string.
This is the second line of my string.
This is the third line of the string.";
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

See Also

string | General Language Example Topics.

Code: Inheriting From a Class (Visual C#)

This example defines the **Circle** and **Rectangle** classes, which both inherit from the **Shape** class, and the **Square** class, which inherits from the **Rectangle** class.

Example

```
public class Shape
{
    // Definitions of properties, methods, fields, and events.
}
public class Circle : Shape
{
    // Specialized properties, methods, fields, events for Circle.
}
public class Rectangle : Shape
{
    // Specialized properties, methods, fields, events for Rectangle.
}
public class Square : Rectangle
{
    // Specialized properties, methods, fields, events for Square.
}
```

Compiling the Code

- Start a new console application.
- Copy the code and paste it right before or after **Class1** declaration.

Robust Programming

Make sure the class you want to inherit is not sealed.

See Also

class | sealed | General Language Example Topics

Code: Initializing an Array (Visual C#)

This example shows three different ways to initialize different kinds of arrays: single-dimensional, multidimensional, and jagged.

Example

```
// Single-dimensional array (numbers).
int[] n1 = new int[4] {2, 4, 6, 8};
int[] n2 = new int[] {2, 4, 6, 8};
int[] n3 = {2, 4, 6, 8};
// Single-dimensional array (strings).
string[] s1 = new string[3] {"John", "Paul", "Mary"};
string[] s2 = new string[] {"John", "Paul", "Mary"};
string[] s3 = {"John", "Paul", "Mary"};

// Multidimensional array.
int[,] n4 = new int[3, 2] { {1, 2}, {3, 4}, {5, 6} };
int[,] n5 = new int[,] { {1, 2}, {3, 4}, {5, 6} };
int[,] n6 = { {1, 2}, {3, 4}, {5, 6} };

// Jagged array.
int[][] n7 = new int[2][] { new int[] {2,4,6}, new int[] {1,3,5,7,9} };
int[][] n8 = new int[][] { new int[] {2,4,6}, new int[] {1,3,5,7,9} };
int[][] n9 = { new int[] {2,4,6}, new int[] {1,3,5,7,9} };
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Robust Programming

Array members are automatically initialized to the default initial value for the array type if the array is not initialized at the time it is declared. If the array declaration is a field of a type, then when the type is instantiated, the array will be set to its default value of **null**. For more information on default values of C# types, see Default Values Table.

See Also

Arrays | Arrays Tutorial | Array Class | Reference Types | General Language Example Topics

Code: Iterating Through a Collection (Visual C#)

This example uses the **Add** method on the **Hashtable** class to add entries to a **Hashtable** collection. It then uses a **foreach** statement to iterate through the collection.

Example

```
Hashtable phones = new Hashtable();
// Add items.
phones.Add("John", "123-4567");
phones.Add("Enju", "351-8765");
phones.Add("Molly", "221-5678");
phones.Add("James", "010-4077");
phones.Add("Nelly", "110-5699");
phones.Add("Leah", "922-5699");

// Iterate through the collection.
Console.WriteLine("Name\t\tNumber");
foreach (string name in phones.Keys)
{
    Console.WriteLine(name +"\t"+ phones[name]);
}
```

Compiling the Code

- Copy the code and paste it into the **Main** method of a console application.
- Add a using directive to the **System.Collections** namespace.

See Also

Iteration Statements | foreach, in | System.Collections Namespace | Hashtable Class | Using foreach with Collections| General Language Example Topics

Code: Iterating Through an Array (Visual C#)

This example uses the **foreach** statement to access and display items of an array.

Example

```
int[] numbers = {1, 2, 3, 4, 5, 6, 7, 8, 9};
foreach (int element in numbers)
{
    System.Console.WriteLine(element);
}
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

See Also

Iteration Statements | foreach, in | Using foreach with Arrays | Using foreach with Collections | Arrays | Arrays Tutorial | General Language Example Topics

Code: Passing Object Arrays to Methods (Visual C#)

This example shows how an array of objects is passed to the **DisplayMyCollection** method, which uses the **params** keyword to accept any number of arguments.

Example

```
class MyBoxingClass
{
   public static void DisplayMyCollection(params object[] anArray)
   {
      foreach (object obj in anArray)
      {
         System.Console.Write(obj + "\t");
      }

      // Suspend the screen.
      System.Console.ReadLine();
   }

   static void Main()
   {
      DisplayMyCollection(101, "Visual C# Basics", 2002);
   }
}
```

Compiling the Code

You can compile the example directly using the command line, or paste it into a console application using the Visual Studio IDE.

See Also

params Keyword | General Language Example Topics

Code: Reading a Text File One Line at a Time (Visual C#)

This example reads the contents of a text file, one line at a time, into a string using the **ReadLine** method of the **StreamReader** class. Each text line is stored into the string `line` and displayed on the screen.

Example

```
int counter = 0;
string line;

// Read the file and display it line by line.
System.IO.StreamReader file =
   new System.IO.StreamReader("c:\\test.txt");
while((line = file.ReadLine()) != null)
{
   Console.WriteLine (line);
   counter++;
}

file.Close();

// Suspend the screen.
Console.ReadLine();
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Replace `"c:\\test.txt"` with the actual file name.

Robust Programming

The following conditions may cause an exception:

- The file may not exist (IOException).

Security

Do not make decisions about the contents of the file based on the name of the file. For example, the file myFile.cs may not be a C# source file.

See Also

Code: Writing to a Text File (Visual C#) | Code: Reading From a Text File (Visual C#) |
File Access Through StreamReader and StreamWriter Classes | StreamReader Class | General Language Example Topics

Code: Reading Class Data from an XML File (Visual C#)

This example reads the data stored in an object in the IntroToVCS.xml file using the **Deserialize** method of the **XmlSerializer** class.

Example

```
public class Book
{
   public string title;

   static void Main()
   {
      Book introToVCS  = new Book();
      System.Xml.Serialization.XmlSerializer reader = new
         System.Xml.Serialization.XmlSerializer(introToVCS.GetType());

      // Read the XML file.
      System.IO.StreamReader file=
         new System.IO.StreamReader("c:\\IntroToVCS.xml");

      // Deserialize the content of the file into a Book object.
      introToVCS = (Book) reader.Deserialize(file);
      System.Windows.Forms.MessageBox.Show(introToVCS.title,
         "Book Title");
   }
}
```

Compiling the Code

You can compile the example directly using the command line, or paste the code into a console application using the Visual Studio IDE. In the latter case, you must reference the System.Windows.Forms.dll file.

Replace `"c:\\IntroToVCS.xml"` with the actual file name.

Robust Programming

The following conditions may cause an exception:

- The path name may be too long (PathTooLongException).

See Also

Code: Writing Class Data to an XML File (Visual C#) | File Access Through StreamReader and StreamWriter Classes | StreamWriter Class | General Language Example Topics

Code: Reading From a Text File (Visual C#)

This example reads the contents of a text file into a string using the **ReadToEnd** method of the **StreamReader** class.

Example

```
// Read the file as one string.
System.IO.StreamReader myFile =
   new System.IO.StreamReader("c:\\test.txt");
string myString = myFile.ReadToEnd();

myFile.Close();

// Display the file contents.
Console.WriteLine(myString);
// Suspend the screen.
Console.ReadLine();
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Replace `"c:\\test.txt"` with the actual file name.

Robust Programming

The following conditions may cause an exception:

- The file may not exist (IOException).

Security

Do not make decisions about the contents of the file based on the name of the file. For example, the file myFile.cs may not be a C# source file.

See Also

Code: Writing to a Text File (Visual C#) | Code: Reading a Text File One Line at a Time (Visual C#) | File Access Through StreamReader and StreamWriter Classes | StreamReader Class | | General Language Example Topics

Code: Reading XML From a File (Visual C#)

This example uses the **XMLTextReader** class to extract the element names and text strings from the IntroToVCS.xml file and store the information in a string variable.

Example

```
System.Xml.XmlTextReader reader = new System.Xml.XmlTextReader("c:\\IntroToVCS.xml");
         string contents = "";
         while (reader.Read())
         {
            reader.MoveToContent();
            if (reader.NodeType == System.Xml.XmlNodeType.Element)
               contents += "<"+reader.Name + ">\n";
            if (reader.NodeType == System.Xml.XmlNodeType.Text)
               contents += reader.Value + "\n";
         }
Console.Write(contents);
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Replace `"c:\\IntroToVCS.xml"` with the actual file name.

> **Note** The XML document must be well-formed.

Robust Programming

The following conditions may cause an exception:

- The path name may be too long (PathTooLongException).

See Also

Code: Writing Class Data to an XML File (Visual C#) | Reading XML with the XmlReader | General Language Example Topics

Code: Running a Program (Visual C#)

This example loads and runs the MSPaint application using the **Process.Start** method.

Example

```
System.Diagnostics.Process.Start("mspaint.exe");
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Replace `"mspaint.exe"` with the path to the application you want to run.

Robust Programming

The following conditions may cause an exception:

- The file may not exist (IOException).

Security

The call to **Process.Start** requires full trust (SecurityException Class).

See Also

Process.Start Method | Starting Processes | General Language Example Topics

Code: Running a Program Associated With a File Type (Visual C#)

This example opens the test.txt file in Notepad using the **Process.Start** method.

Example

```
System.Diagnostics.Process.Start("c:\\test.txt");
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Replace the file "`c:\\test.txt`" with the file you want to open.

Robust Programming

The following conditions may cause an exception:

- The file may not exist (IOException).

Security

The call to **Process.Start** requires full trust (SecurityException Class).

See Also

Process.Start Method | Starting Processes | General Language Example Topics

Code: Searching for a String in an Array of Strings (Visual C#)

This example calls the **IndexOf** method on an array of strings to report the string number and index of the first occurrence of a substring.

Example

```
string[] strArray = {"ABCDEFG", "HIJKLMNOP"};
string findThisString = "JKL";
int strNumber;
int strIndex = 0;
for (strNumber = 0; strNumber < strArray.Length; strNumber++)
{
    strIndex = strArray[strNumber].IndexOf(findThisString);
    if (strIndex >= 0)
        break;
}
Console.WriteLine("String number: {0}\nString index: {1}",
    strNumber, strIndex);
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Robust Programming

The **IndexOf** method reports the location of the first character of the first occurrence of the substring. The index is 0-based, which means the first character of a string has an index of 0.

If **IndexOf** does not find the substring, it returns -1.

The **IndexOf** method is case-sensitive and uses the current culture.

If you want more control over possible exceptions, enclose the string search in a try-catch statement.

See Also

Code: Searching Within a String (Visual C#) | Exception Handling Statements | string | String.IndexOf Method (String) | General Language Example Topics

Code: Searching Within a String (Visual C#)

This example calls the **IndexOf** method on a **String** object to report the index of the first occurrence of a substring.

Example

```
string searchWithinThis = "ABCDEFGHIJKLMNOP";
string searchForThis = "DEF";
int firstCharacter = searchWithinThis.IndexOf(searchForThis);

Console.WriteLine("First occurrence: {0}", firstCharacter);
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Robust Programming

The **IndexOf** method reports the location of the first character of the first occurrence of the substring. The index is 0-based, which means the first character of a string has an index of 0.

If **IndexOf** does not find the substring, it returns -1.

The **IndexOf** method is case-sensitive and uses the current culture.

If you want more control over possible exceptions, enclose the string search in a try-catch statement.

See Also

Exception Handling Statements| string | String.IndexOf Method (String) | General Language Example Topics

Code: Setting a Property on an Object (Visual C#)

This example sets the **CurrentDirectory** property on the **Environment** class to C:\Public.

Example

```
Environment.CurrentDirectory = "C:\\Public";
```

-or-

```
Environment.CurrentDirectory = @"C:\Public";
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Robust Programming

Use the fully qualified name of the property, unless it is accessible from the same scope.

Unless the property is static, it must be referenced through an instance of the class.

When assigning an expression to a property, make sure of the following:

- That it is of a compatible data type.
- That it has a valid value, especially if the value is derived from user input.

If you want more control over possible exceptions, enclose the property assignment in a try-catch statement.

See Also

Property Declaration | Exception Handling Statements | Environment Class | Environment.CurrentDirectory Property | General Language Example Topics

Code: Simulating Default Parameters (Visual C#)

This example demonstrates the use of method overloading to simulate default parameters, which is not allowed in C#.

Example

```
class MyClass
{
    static string myMethod(string precip, string country, string location)
    {
        return string.Format("The {0} in {1} stays mainly in the {2}.",
            precip, country, location );
    }

    static string myMethod(string precip, string country )
    {
        return myMethod(precip, country, "plain");
    }

    static string myMethod()
    {
        return myMethod("rain", "Spain", "plain");
    }

    static void Main(string[] args)
    {
        Console.WriteLine(myMethod());
        Console.WriteLine(myMethod("snow", "Walla Walla"));
    }
}
```

Compiling the Code

Copy the class and paste it over `Class1` in a console application.

See Also

Comparison Between C++ and C# | Compiler Error CS0241 | General Language Example Topics

Code: Throwing an Exception (Visual C#)

This example throws the exception **System.ApplicationException**.

Example

```
throw new ApplicationException();
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Robust Programming

Unhandled exceptions cause application execution to stop.

See Also

Code: Catching an Exception (Visual C#) | throw | try-catch | ApplicationException Class | Exception Class | General Language Example Topics

Code: Using PInvoke (Visual C#)

This example shows you how to use the **DllImport** attribute to create a message box by calling **MessageBoxA** from user32.dll.

Example

```
class PlatformInvokeTest
{
   [DllImport("user32.dll")]
   public static extern int MessageBoxA(
      int h, string m, string c, int type);

   public static int Main()
   {
      return MessageBoxA(0, "Hello World!", "My Message Box", 0);
   }
}
```

Compiling the Code

- Copy the class and paste it over `Class1` in a console application.
- Add a using directive to the **System.Runtime.InteropServices** namespace.

Robust Programming

- Make sure to include the correct name of the DLL that contains the required method (user32.dll in this case).
- Make sure to use the appropriate parameters of the **MessageBoxA** function.

See Also

Platform Invoke Tutorial | Visual C# Code Example Topics

Code: Writing Class Data to an XML File (Visual C#)

This example writes the data stored in an object to the IntroToVCS.xml by means of the **Serialize** method of the **XmlSerializer** class.

Example

```
public class Book
{
   public string title;

   static void Main()
   {
      Book introToVCS = new Book();
      introToVCS.title = "Intro to Visual CSharp";
      System.Xml.Serialization.XmlSerializer writer =
         new System.Xml.Serialization.XmlSerializer(introToVCS.GetType());
      System.IO.StreamWriter file =
         new System.IO.StreamWriter("c:\\IntroToVCS.xml");

      writer.Serialize(file, introToVCS);
      file.Close();
   }
}
```

Compiling the Code

You can compile the example directly using the command line, or paste the code into a console application using the Visual Studio IDE.

Replace `"c:\\IntroToVCS.xml"` with the actual file name.

Robust Programming

The following conditions may cause an exception:

- The file exists and is read-only (IOException).
- The path name may be too long (PathTooLongException).
- The disk may be full (IOException).

Security

This example creates a new file, if the file does not already exist. If the file already exists, the application overwrites it.

See Also

Code: Reading Class Data from an XML File (Visual C#) | File Access Through StreamReader and StreamWriter Classes | StreamWriter Class | General Language Example Topics

Code: Writing to a Text File (Visual C#)

This example writes a string to a text file using the **WriteLine** method of the **StreamWriter** class.

Example

```
// Compose a string that consists of three lines.
string lines = "First line.\r\nSecond line.\r\nThird line.";

// Write the string to a file.
System.IO.StreamWriter file = new System.IO.StreamWriter("c:\\test.txt");
file.WriteLine(lines);

file.Close();
```

Compiling the Code

Copy the code and paste it into the **Main** method of a console application.

Replace `"c:\\test.txt"` with the actual file name.

Robust Programming

The following conditions may cause an exception:

- The file exists and is read-only (IOException).
- The path name may be too long (PathTooLongException).
- The disk may be full (IOException).

Security

This example creates a new file, if one does not already exist. If the file already exists, the application will overwrite it.

In order to append an existing file, set the Boolean parameter to **true**, as follows:

```
System.IO.StreamWriter file =
   new System.IO.StreamWriter("c:\\test.txt", true);
```

- Quickstarts and other Samples
- .NET Framework Reference Information

Code: Creating a Bitmap at Run Time (Visual C#)

This example creates and fills a **Bitmap** object, then displays it in an existing Windows Forms **PictureBox** control.

Example

```
void CreateBitmap()
{
    System.Drawing.Bitmap flag = new System.Drawing.Bitmap(10, 10);
    for( int x = 0; x <  flag.Height; ++x )
        for( int y = 0; y < flag.Width; ++y )
            flag.SetPixel(x, y, Color.White);
    for( int x = 0; x < flag.Height; ++x )
        flag.SetPixel(x, x, Color.Red);
    pictureBox1.Image = flag;
}
```

Compiling the Code

This example requires:

- A reference to the **System** namespace.

Robust Programming

The following conditions may cause an exception:

- Trying to set a pixel outside the bounds of the bitmap (ArgumentException Class).

Graphics Programming Example Topics | Bitmap Class

Code: Creating a Pen (Visual C#)

This example demonstrates how to create a **Pen** object.

Example

```
System.Drawing.Pen myPen;
myPen = new System.Drawing.Pen(System.Drawing.Color.Black);
```

Robust Programming

You should always call **Dispose** on any objects that consume system resources, such as **Pen** objects.

See Also

Graphics Programming Example Topics | Pen Class | Pens, Brushes, and Colors

Code: Creating a Solid Brush (Visual C#)

This example demonstrates how to create a **SolidBrush** object.

Example

```
System.Drawing.SolidBrush myBrush;
myBrush = new System.Drawing.SolidBrush(System.Drawing.Color.Black);
```

Robust Programming

You should always call **Dispose** on any objects that consume system resources, such as **Brush** objects.

See Also

Graphics Programming Example Topics | SolidBrush Class | Brush Class | Pens, Brushes, and Colors

Code: Drawing a Filled Ellipse on a Form (Visual C#)

This example demonstrates how to draw a filled ellipse on a form.

Example

```
System.Drawing.SolidBrush myBrush = new System.Drawing.SolidBrush(System.Drawing.Color.Red);
System.Drawing.Graphics formGraphics = this.CreateGraphics();
formGraphics.FillEllipse(myBrush, new Rectangle(0,0,200,300));
myBrush.Dispose();
formGraphics.Dispose();
```

Compiling the Code

This example requires:

- A Windows Application project.

The code needs to be within the scope of the **form** class. The instance of the form is represented by **this**.

Robust Programming

You should always call **Dispose** on any objects that consume system resources, such as **Brush** and **Graphics** objects.

Code: Drawing Outlined Shapes (Visual C#)

This example demonstrates how to draw outlined ellipses and rectangles on a form.

Example

```
private void DrawEllipse()
{
   System.Drawing.Pen myPen;
   myPen = new System.Drawing.Pen(System.Drawing.Color.Red);
   System.Drawing.Graphics formGraphics = this.CreateGraphics();
   formGraphics.DrawEllipse(myPen, new Rectangle(0,0,200,300));
   myPen.Dispose();
   formGraphics.Dispose();
}
private void DrawRectangle()
{
   System.Drawing.Pen myPen;
   myPen = new System.Drawing.Pen(System.Drawing.Color.Red);
   System.Drawing.Graphics formGraphics = this.CreateGraphics();
   formGraphics.DrawRectangle(myPen, new Rectangle(0,0,200,300));
   myPen.Dispose();
   formGraphics.Dispose();
}
```

Compiling the Code

This example requires

- A Windows Application project.

The code needs to be within the scope of the **form** class. The instance of the form is represented by **this**.

Robust Programming

You should always call **Dispose** on any objects that consume system resources, such as **Pen** and **Graphics** objects.

Code: Drawing Text on a Form (Visual C#)

This example demonstrates drawing text on a form.

Example

```
private void DrawString()
{
   System.Drawing.Graphics formGraphics = this.CreateGraphics();
   string drawString = "Sample Text";
   System.Drawing.Font drawFont = new System.Drawing.Font("Arial", 16);
   System.Drawing.SolidBrush drawBrush = new System.Drawing.SolidBrush(System.Drawing.Color.B
lack);
   float x = 150.0f;
   float y = 50.0f;
   formGraphics.DrawString(drawString, drawFont, drawBrush, x, y);
   drawFont.Dispose();
   drawBrush.Dispose();
   formGraphics.Dispose();
}
```

Compiling the Code

This example requires:

- A Windows Application project.

The code needs to be within the scope of the **form** class. The instance of the form is represented by **this**.

Robust Programming

You should always call **Dispose** on any objects that consume system resources, such as **Font** and **Graphics** objects.

The following conditions may cause an exception:

- The Arial font is not installed.

Code: Drawing Vertical Text on a Form (Visual C#)

This example demonstrates drawing text on a form in a vertical orientation.

Example

```
private void DrawVerticalText()
{
   System.Drawing.Graphics formGraphics = this.CreateGraphics();
   string drawString = "Sample Text";
   System.Drawing.Font drawFont = new System.Drawing.Font("Arial", 16);
   System.Drawing.SolidBrush drawBrush = new System.Drawing.SolidBrush(System.Drawing.Color.B
lack);
   float x = 150.0f;
   float y = 50.0f;
   System.Drawing.StringFormat drawFormat = new System.Drawing.StringFormat(StringFormatFlags
.DirectionVertical);
   formGraphics.DrawString(drawString, drawFont, drawBrush, x, y, drawFormat);
   drawFont.Dispose();
   drawBrush.Dispose();
   formGraphics.Dispose();
}
```

Compiling the Code

This example requires:

- A Windows Application project.

The code needs to be within the scope of the **form** class. The instance of the form is represented by **this**.

Robust Programming

You should always call **Dispose** on any objects that consume system resources, such as **Font** and **Graphics** objects.

The following conditions may cause an exception:

- The Arial font is not installed.

Code: Print Previewing the Form (Visual C#)

This example demonstrates print previewing a copy of the current form.

Example

```
[System.Runtime.InteropServices.DllImport("gdi32.dll")]
public static extern long BitBlt (IntPtr hdcDest, int nXDest, int nYDest, int nWidth, int nHe
ight, IntPtr hdcSrc, int nXSrc, int nYSrc, int dwRop);
private Bitmap memoryImage;
private void CaptureScreen()
{
   Graphics mygraphics = this.CreateGraphics();
   Size s = this.Size;
   memoryImage = new Bitmap(s.Width, s.Height, mygraphics);
   Graphics memoryGraphics = Graphics.FromImage(memoryImage);
   IntPtr dc1 = mygraphics.GetHdc();
   IntPtr dc2 = memoryGraphics.GetHdc();
   BitBlt(dc2, 0, 0, this.ClientRectangle.Width, this.ClientRectangle.Height, dc1, 0, 0, 1336
9376);
   mygraphics.ReleaseHdc(dc1);
   memoryGraphics.ReleaseHdc(dc2);
}
private void printDocument1_PrintPage(System.Object sender, System.Drawing.Printing.PrintPage
EventArgs e)
{
   e.Graphics.DrawImage(memoryImage, 0, 0);
}
private void printButton_Click(System.Object sender, System.EventArgs e)
{
   CaptureScreen();
   printPreviewDialog1.Show();
}
```

Compiling the Code

This example requires:

- A **PrintDocument** component named printDocument1 with a PrintPage event handler.
- A **PrintPreviewDialog** component named printPreviewDialog1 with its Document property set to printDocument1.
- A **Button** named printButton with a Click event handler.

The example code replaces the existing event handlers. A print preview of the form is displayed when printButton is clicked.

Robust Programming

The following conditions may cause an exception:

- You do not have permission to access the printer.
- You do not have permission to use unmanaged code.
- There is no printer installed.
- The print preview dialog box was previously disposed. This occurs after the print preview dialog box is closed.

Security

In order to run this example, you must have permission to execute unmanaged code and to access the printer.

See Also

Graphics Programming Example Topics | Printing with the PrintDocument Component | Rendering Images with GDI+ | Printing Graphics in Windows Forms | PrintDocument Class

Code: Printing a DataGrid (Visual C#)

This example demonstrates printing a **DataGrid** control.

Example

```
private void printGrid_Click(System.Object sender, System.EventArgs e)
{
   printDocument1.Print();
}
private void printDocument1_PrintPage(System.Object sender, System.Drawing.Printing.PrintPage
EventArgs e)
{
   PaintEventArgs myPaintArgs = new PaintEventArgs(e.Graphics, new Rectangle(new Point(0, 0),
this.Size));
   this.InvokePaint(dataGrid1, myPaintArgs);
}
```

Compiling the Code

This example requires:

- A **Button** control named printGrid with a Click event handler.
- A **DataGrid** control named dataGrid1.
- A **PrintDocument** component named printDocument1 with a PrintPage event handler.

The example code replaces the existing event handlers.

Robust Programming

The following conditions may cause an exception:

- You do not have permission to access the printer.
- There is no printer installed.

Security

In order to run this example, you must have permission to access the printer.

See Also

Graphics Programming Example Topics | Code Example: Printing the Form |
Introduction to the Windows Forms PrintDocument Component | Printing Graphics in Windows Forms | PrintDocument Class

Code: Printing a Text File (Visual C#)

This example demonstrates printing a text file.

Example

```
System.IO.StreamReader fileToPrint;
System.Drawing.Font printFont;
private void printButton_Click(object sender, EventArgs e)
{
   string printPath = System.Environment.GetFolderPath(Environment.SpecialFolder.Desktop);
   fileToPrint = new System.IO.StreamReader(printPath + @"\myFile.txt");
   printFont = new System.Drawing.Font("Arial", 10);
   printDocument1.Print();
   fileToPrint.Close();
}

private void printDocument1_PrintPage(object sender, System.Drawing.Printing.PrintPageEventAr
gs e)
{
   float yPos = 0f;
   int count = 0;
   float leftMargin = e.MarginBounds.Left;
   float topMargin = e.MarginBounds.Top;
   string line = null;
   float linesPerPage = e.MarginBounds.Height/printFont.GetHeight(e.Graphics);
   while (count < linesPerPage)
   {
      line = fileToPrint.ReadLine();
      if (line == null)
      {
         break;
      }
      yPos = topMargin + count * printFont.GetHeight(e.Graphics);
      e.Graphics.DrawString(line, printFont, Brushes.Black, leftMargin, yPos, new StringForma
t());
      count++;
   }
   if (line != null)
   {
      e.HasMorePages = true;
   }
}
```

Compiling the Code

This example requires:

- A **Button** control named printButton with a Click event handler.
- A **PrintDocument** component named printDocument1 with a PrintPage event handler.

This example further assumes that you have a text file named myFile.txt on your desktop. The example code replaces the existing event handlers.

Robust Programming

File operations should be enclosed within appropriate **try...catch...finally** blocks. Always call **StreamReader.Close** when you have finished using it.

The following conditions may cause an exception:

- You do not have permission to access the printer.
- You do not have permission to access the file system.

- There is no printer installed.
- The Arial font is not installed.

Security

In order to run this example, you must have permission to access the file system and the printer.

Code: Printing the Form (Visual C#)

This example demonstrates printing a copy of the current form.

Example

```
[System.Runtime.InteropServices.DllImport("gdi32.dll")]
public static extern long BitBlt (IntPtr hdcDest, int nXDest, int nYDest, int nWidth, int nHe
ight, IntPtr hdcSrc, int nXSrc, int nYSrc, int dwRop);
private Bitmap memoryImage;
private void CaptureScreen()
{
   Graphics mygraphics = this.CreateGraphics();
   Size s = this.Size;
   memoryImage = new Bitmap(s.Width, s.Height, mygraphics);
   Graphics memoryGraphics = Graphics.FromImage(memoryImage);
   IntPtr dc1 = mygraphics.GetHdc();
   IntPtr dc2 = memoryGraphics.GetHdc();
   BitBlt(dc2, 0, 0, this.ClientRectangle.Width, this.ClientRectangle.Height, dc1, 0, 0, 1336
9376);
   mygraphics.ReleaseHdc(dc1);
   memoryGraphics.ReleaseHdc(dc2);
}
private void printDocument1_PrintPage(System.Object sender, System.Drawing.Printing.PrintPage
EventArgs e)
{
   e.Graphics.DrawImage(memoryImage, 0, 0);
}
private void printButton_Click(System.Object sender, System.EventArgs e)
{
   CaptureScreen();
   printDocument1.Print();
}
```

Compiling the Code

This example requires:

- A **PrintDocument** component named printDocument1 with a PrintPage event handler.
- A **Button** named printButton with a Click event handler.

The example code replaces the existing event handlers. The form is printed when `printButton` is clicked.

Robust Programming

The following conditions may cause an exception:

- You do not have permission to access the printer.
- You do not have permission to use unmanaged code.
- There is no printer installed.

Security

In order to run this example, you must have permission to execute unmanaged code and to access the printer.

Code: Setting the Color of a Pen (Visual C#)

This example demonstrates how to change the color of a pre-existing **Pen** object.

Example

```
myPen.Color = System.Drawing.Color.PeachPuff;
```

Compiling the Code

This example requires:

- A **Pen** object named *myPen*.

Robust Programming

You should always call **Dispose** on any objects that consume system resources, such as **Pen** objects.

Web Applications Example Topics

This topic is designed to help you find code that demonstrates how to perform common programming tasks in Web applications using Visual C#.NET.

In This Section

- Adding Controls at Run Time
- Adding Items to a List Control
- Detecting the Browser Version
- Determining the Selected Item in a List Control
- Displaying Data in a Web Forms DataGrid Control
- Passing Data from One Web Forms Page to Another
- Reading a Cookie
- Reading Values From Application State
- Reading Values From Session State
- Reading a Value From View State
- Removing Items From a List Control
- Retrieving a Dataset from View State
- Redirecting to Another Page
- Redirecting to Another Page in the Same Application
- Saving Values in Application State
- Saving Values in Session State
- Saving a Dataset to View State
- Saving a Value in View State
- Selecting an Item in a List Control
- Writing a Cookie

Related Code Examples

You can also find sample code for Web applications in the following locations:

- C# Language Tour
- Visual C# Samples
- Walkthroughs in Visual Basic and Visual C#
- Quickstarts and other Samples
- .NET Framework Reference Information

Code: Adding Controls at Run Time (Visual C#)

This example adds a text box and button to a Web Forms page at run time. It also dynamically binds an event handler to the button's **Click** event. The handler displays the values of the dynamically generated text box.

The controls are added into a Panel Web server control, which acts as a placeholder. The controls are separated in the panel with line breaks (HTML <BR> elements), which are added to the panel using the LiteralControl control.

Example

```
private void Page_Load(object sender, System.EventArgs e)
{
    if (!IsPostBack)
        AddControls();
}

protected override void LoadViewState(object savedState)
{
    base.LoadViewState(savedState);
    if (ViewState["controsladded"] == null)
    AddControls();
}

private void AddControls()
{
    TextBox dynamictextbox = new TextBox();
    dynamictextbox.Text = "(Enter some text)";
    dynamictextbox.ID = "dynamictextbox";
    Button dynamicbutton = new Button();
    dynamicbutton.Click += new System.EventHandler(dynamicbutton_Click);
    dynamicbutton.Text = "Dynamic Button";
    Panel1.Controls.Add(dynamictextbox);
    Panel1.Controls.Add(new LiteralControl("<BR>"));
    Panel1.Controls.Add(new LiteralControl("<BR>"));
    Panel1.Controls.Add(dynamicbutton);
    ViewState["controlsadded"] = true;
}

private void dynamicbutton_Click(Object sender, System.EventArgs e)
{
    TextBox tb = new TextBox();
    tb = (TextBox) (Panel1.FindControl("dynamictextbox"));
    Label1.Text = tb.Text;
}
```

Compiling the Code

This example requires:

- A Web Forms page.
- A **Panel** control called Panel1.
- A **Label** control called Label1.

Security

User input in a Web Forms page can include potentially malicious client script. By default, the Web Forms page validates that user input does not include script or HTML elements. For more information, see Scripting Exploits and Protecting Against Script Exploits in a Web Application.

See Also

Adding Controls to a Web Forms Page Programmatically | Code: Reading a Value From View State (Visual C#) | Code: Saving a Value in View State (Visual C#) | Introduction to Web Forms State Management |

Code: Adding Items to a List Control (Visual C#)

This example uses the **Add** method of the ListBox.Items property to add items to the list.

Example

```
// Create a string array and assign items.
string[] ListContents = {"Enju", "Sue", "Mary"};

// Add the array items to the list box.
for (int i = 0; i <= ListContents.Length - 1; i++)
   ListBox1.Items.Add(ListContents[i]);
```

Compiling the Code

Start a new ASP.NET Web application and do the following:

- Add a list box named `ListBox1`.
- Copy the code and paste it into the **Page_Load** method.

See Also

ListBox.ObjectCollection Class | Code: Removing Items From a List Control (Visual C#) | Web Applications Example Topics

Code: Detecting the Browser Version (Visual C#)

This example examines the Request.Browser property to determine the type and version of the client's Web browser. There are many other browser attributes that can be accessed by means of the **Request.Browser** property, such as **Url**, **ServerVariables**, and **User**.

Example

```
HttpBrowserCapabilities brObject = Request.Browser;

// Display the type and version.
Response.Write("Browser Type: "+ brObject.Type);
Response.Write("<p>"+"Browser Version: "+ brObject.Version);
```

Compiling the Code

Start a new ASP.NET Web application and paste the code into the **Page_Load** method.

See Also

Detecting Browser Types in Web Forms | Request.Browser | BrowserCapabilities Class | Web Applications Example Topics

Code: Determining the Selected Item in a List Control (Visual C#)

This example uses the **SelectedIndex** and **SelectedItem** properties of a List control to access information about the selected item.

Example

```
// The index:
int ListItemIndex;
// Value of the item:
string ListItemValue;

ListItemIndex = ListBox1.SelectedIndex;
ListItemValue = ListBox1.SelectedItem.Value.ToString();
```

Compiling the Code

Start a new ASP.NET Web application and do the following:

- Add a list box named `ListBox1` and populate it with items. For details, see Code: Adding Items to a List Control (Visual C#).
- Copy the code and paste it into the **Page_Load** method.

See Also

ListBox.ObjectCollection Class | Code: Adding Items to a List Control (Visual C#) | Web Applications Example Topics

Code: Displaying Data in a Web Forms DataGrid Control (Visual C#)

This example uses the DataBind method to bind the contents of a dataset to a **DataGrid** control.

Example

```
if (!IsPostBack)
{
    sqlDataAdapter1.Fill(dataSet11);
    DataGrid1.DataBind();
}
```

Compiling the Code

This example requires:

- A Web Forms page.
- A **DataGrid** control named `DataGrid1`.
- A typed dataset named `dataSet11`, which is an instance of the typed dataset class `DataSet1`.
- A properly configured data adapter named `sqlDataAdapter1`. You can bind the **DataGrid** control to any Web Forms page data source.
- The application must have permission to access the database. For details, see Using SQL Server in Web Applications.

Robust Programming

You can specify the **DataGrid** control's **DataSource** property at design time in the Properties window. You do not have to specify it at run time, as is shown in the previous example.

You should always wrap data access calls in a **try-catch** block:

```
try
{
    sqlDataAdapter1.Fill(dataSet11);
    DataGrid1.DataBind();
}
catch
{
    Label1.Text = "Unable to connect to the database.";
}
```

You should bind the **DataGrid** control to its data source only when there is a change to the data or to the control's state. Do not data bind the control on each round trip. In the previous example, the control is bound only the first time the page runs, not on every postback.

Web Forms pages often benefit by caching a dataset rather than requerying the database. For details, see Code: Saving a Dataset to ViewState (Visual C#).

Security

If you display error information, do not include such information as a user name that a malicious user might be able to take advantage of. For details, see Displaying Safe Error Messages.

See Also

Adding DataGrid Web Server Controls to a Web Forms Page | Data Access in Web Forms Pages | Data Sources for Web Forms Pages | Introduction to Data Access in Web Forms Pages | State Management Recommendations | Web Applications Example Topics

Code: Passing Data from One Web Forms Page to Another (Visual C#)

This example stores information in session state and navigates to another page in the same application, then retrieves the stored information in the second page.

Example

```
// First part: Saves info on first page.
string firstName = "John";
string lastName = "Smith";
string city = "Seattle";
Session.Add("First", firstName);
Session.Add("Last", lastName);
Session.Add("City", city);

// Redirect to second page.
Server.Transfer("WebForm2.aspx");

// Second part: Reads info into variables on the second page.
string firstName = (string)(Session["First"]);
string lastName = (string)(Session["Last"]);
string city = (string)(Session["City"]);
```

Compiling the Code

- Start an ASP.NET application with two Web Forms pages, WebForm1.aspx and WebForm2.aspx.
- Paste the first part of the code into the **Page_Load** method (or a **Click** method) of WebForm1.aspx.
- Paste the second part of the code into the **Page_Load** method of WebForm2.aspx.

Robust Programming

Session state information is available only to pages in the same application. Storing information in session state uses server memory. For more information, see State Management Recommendations.

See Also

Code: Saving Values in Session State (Visual C#)| Introduction to Web Forms State Management |
Saving Web Forms Page Values Using View State | State Management Recommendations | ASP.NET State Management |
Web Applications Example Topics

Code: Reading a Cookie (Visual C#)

The following example uses the HttpCookie class and its properties to read a cookie with a specific name.

Example

```
HttpCookie myCookie = new HttpCookie("MyTestCookie");
myCookie = Request.Cookies["MyTestCookie"];

// Read the cookie information and display it.
if (myCookie != null)
   Response.Write("<p>"+ myCookie.Name + "<p>"+ myCookie.Value);
else
   Response.Write("not found");
```

Compiling the Code

Start a new ASP.NET Web application and paste the code into the **Page_Load** method.

Robust Programming

Replace the name `"MyTestCookie"` with the name of the cookie to be read.

Values returned from a cookie are always of type **string.**

Security

The browser can only send the data back to the server that originally created the cookie. However, malicious users can access cookies and read their contents.

See Also

Code: Writing a Cookie (Visual C#) | HttpCookie Class | Web Applications Example Topics

Code: Reading Values From Application State (Visual C#)

This example retrieves a value from the HttpApplicationState object.

Example

```
string appMsg;
appMsg = (string)(Application["Message"]);
```

Compiling the Code

Start a new ASP.NET application and paste the code into the **Page_Load** method.

Robust Programming

You must cast the data to the appropriate type, as shown in the example.

No exception is thrown if you attempt to get a value out of application state that does not exist. To be sure that the value you want is in application state, check first for the existence of the object with a test such as the following:

```
if (Application["Message"] == null)
    Response.Write("No such value in application state.");
```

If you attempt to use a non-existent application state entry in some other way (for example, to examine its type), a NullReferenceException exception is thrown.

See Also

Code: Saving Values in Application State (Visual C#) | Application State | Introduction to Web Forms State Management | State Management Recommendations | ASP.NET State Management | Web Applications Example Topics

Code: Reading Values From Session State (Visual C#)

This example accesses the HttpSessionState.Item property to retrieve the values in session state.

Example

```
string firstName = (string)(Session["First"]);
string lastName = (string)(Session["Last"]);
string city = (string)(Session["City"]);
```

Compiling the Code

Start a new ASP.NET application and paste the code into the **Page_Load** method.

Robust Programming

Session values are of type **Object**. You should cast to the appropriate type when reading them.

No exception is thrown if you attempt to get a value out of session state that does not exist. To be sure that the value you want is in session state, check first for the existence of the object with a test such as the following:

```
if (Session["City"] == null)
    Response.Write("No such value in session state.");
```

If you attempt to use a non-existent session state entry in some other way (for example, to examine its type), a NullReferenceException exception is thrown.

See Also

Code: Reading a Value From View State (Visual C#) | Introduction to Web Forms State Management | Saving Web Forms Page Values Using View State | State Management Recommendations | ASP.NET State Management | Web Applications Example Topics

Code: Reading a Value From View State (Visual C#)

This example saves the value `"yellow"` to the **Control.ViewState** property and then, when the page posts back to the server, retrieves a value of the property. For more information on **ViewState**, see Saving Web Forms Page Values Using View State.

Example

```
string strColor;
if (Page.IsPostBack)
{
   // Retrieve and display the property value.
   strColor = (string)ViewState["color"];
   Response.Write(strColor);
}
else
   // Save the property value.
   ViewState["color"] = "yellow";
```

Compiling the Code

Copy and paste the code into the **Page_Load** method of an ASP.NET Web application.

Robust Programming

As shown in the example, retrieving the **ViewState** property occurs when the Web page is posted back to the server. Otherwise, the string will be **null**.

For more information on usage recommendations, see State Management Recommendations.

See Also

Code: Saving a Value in View State (Visual C#) | State Management Recommendations | Developing High-Performance ASP.NET Applications | Web Applications Example Topics

Code: Removing Items From a List Control (Visual C#)

This example uses the **Remove** method of the ListBox.Items property to remove an item from the list.

Example

```
ListBox1.Items.Remove("Mary");
```

Compiling the Code

Start a new ASP.NET Web application and do the following:

- Add a list box named `ListBox1` and populate it with items. For details, see Code: Adding Items to a List Control (Visual C#).
- Copy the code and paste it into the **Page_Load** method.

Robust Programming

Replace `"Mary"` with the value of the item to be removed.

See Also

ListBox.ObjectCollection Class | Code: Adding Items to a List Control (Visual C#) | Web Applications Example Topics

Code: Retrieving a Dataset from View State (Visual C#)

This example retrieves the **DataSet** from a view state.

Example

```
if (Page.IsPostBack)
{
   System.IO.StringReader sr =
      new System.IO.StringReader((string)(ViewState["dSet"]));
   dSet.ReadXml(sr);
}
```

Compiling the Code

Start a new ASP.NET Web application and do the following:

- Add a **DataAdapter** named *SqlDataAdapter1*.
- Generate a **DataSet** (the default name of the **DataSet** class is **DataSet1**).
- Create an instance of **DataSet1** named *dSet*.
- Copy the code and paste it into the **Page_Load** method.

Robust Programming

As shown in the example, retrieving the **DataSet** occurs when the Web page is posted back to the server.

Security

For information about how to use a SQL Server database on other machines, see Using SQL Server in Web Applications.

See Also

Code: Saving a Dataset to ViewState (Visual C#) | Web Applications Example Topics

Code: Redirecting to Another Page (Visual C#)

This example uses the HttpResponse.Redirect method to redirect the browser to the specified URL.

Example

```
Response.Redirect("http://www.microsoft.com");
```

Compiling the Code

Start a new ASP.NET application and paste the code into the **Page_Load** method.

Robust Programming

The **Redirect** method is executed by the browser and therefore results in an extra round trip between server and browser.

Make sure that the target page exists.

Security

The method is subject to spoofing or tampering because it is executed by the client.

See Also

Code: Redirecting to Another Page in the Same Application (Visual C#) | HttpResponse Class | HttpResponse.Redirect Method | Web Forms Pages | Web Applications Example Topics

Code: Redirecting to Another Page in the Same Application (Visual C#)

This example uses the Server.Transfer method to redirect the browser to the specified page.

Example

```
Server.Transfer("WebForm2.aspx");
```

Compiling the Code

- Start an ASP.NET application with two Web Forms pages, WebForm1.aspx and WebForm2.aspx.
- Paste the code into the **Page_Load** method (or a **Click** method) of WebForm1.aspx.

Robust Programming

The page transferred to should be another Web Forms page (.aspx page) in the same application. You cannot use **Server.Transfer** to redirect to an .asp or .asmx page.

Make sure that the target page exists.

Because **Server.Transfer** is executed on the server, the browser does not have a record of the page change. Therefore, if the user refreshes the page, unexpected results can occur.

See Also

Code: Redirecting to Another Page (Visual C#) | HttpServerUtility Class | HttpServerUtility.Transfer Method | Web Forms Pages | Web Applications Example Topics

Code: Saving Values in Application State (Visual C#)

This example uses the HttpApplicationState class to save global information.

Example

```
Application["Message"] = "AppMsg";
Application["AppStartTime"] = DateTime.Now;
```

Compiling the Code

Start a new ASP.NET application and paste the code into the **Page_Load** method.

Robust Programming

Storing information in application state uses server memory. An alternative is to store information in view state. For more information, see Code: Saving a Value in View State (Visual C#) and State Management Recommendations.

See Also

Code: Reading Values From Application State (Visual C#) | Application State | Introduction to Web Forms State Management | State Management Recommendations | ASP.NET State Management | Web Applications Example Topics

Code: Saving Values in Session State (Visual C#)

This example uses the Session.Add method to persist values within an individual session.

Example

```
string firstName = "Jeff";
string lastName = "Smith";
string city = "Seattle";

Session.Add("First", firstName);
Session.Add("Last", lastName);
Session.Add("City", city);
```

Compiling the Code

Start a new ASP.NET application and paste the code into the **Page_Load** method.

Robust Programming

Storing information in session state uses server memory. An alternative is to store information in view state. For more information, see Code: Saving a Value in View State (Visual C#) and State Management Recommendations.

Server state can expire after 20 minutes of inactivity (by default) and the information that you store there can be lost.

See Also

HttpSessionState Class | Introduction to Web Forms State Management | Saving Web Forms Page Values Using View State | State Management Recommendations | ASP.NET State Management | Web Applications Example Topics

Code: Saving a Dataset to View State (Visual C#)

This example uses the **Control.ViewState** property to save a dataset.

Example

```
sqlDataAdapter1.Fill(dSet);
System.IO.StringWriter sw = new System.IO.StringWriter();

// Write the DataSet to the ViewState property.
dSet.WriteXml(sw);
ViewState["dSet"] = sw.ToString();
```

Compiling the Code

Start a new ASP.NET Web application and do the following:

- Add a **DataAdapter** named *SqlDataAdapter1*.
- Generate a dataset and then create an instance named *dSet*.
- Copy the code and paste it into the **Page_Load** method.

Security

For information about how to use a SQL Server database on other machines, see Using SQL Server in Web Applications.

See Also

Code: Retrieving a Dataset from ViewState (Visual C#) | Web Applications Example Topics

Code: Saving a Value in View State (Visual C#)

This example saves the string value `"yellow"` to the **Control.ViewState** property. For more information, see Saving Web Forms Page Values Using View State.

Example

```
ViewState["color"] = "yellow";
```

Compiling the Code

Start a new ASP.NET Web application and paste the code into the **Page_Load** method.

Robust Programming

Replace the property string with an appropriate string.

For more information on usage recommendations, see State Management Recommendations.

See Also

Code: Reading a Value From View State (Visual C#) | State Management Recommendations | Developing High-Performance ASP.NET Applications | Web Applications Example Topics

Code: Selecting an Item in a List Control (Visual C#)

This example uses the **IndexOf** method to search a list box for a specific text.

Example

```
ListBox1.SelectedIndex = ListBox1.Items.IndexOf(ListBox1.Items.FindByText("ValueToFind"));
```

Compiling the Code

Start a new ASP.NET Web application and do the following:

- Add a list box named `ListBox1` and populate it with items. For details, see Code: Adding Items to a List Control (Visual C#).
- Copy the code and paste the code into the **Page_Load** method.
- Replace "*ValueToFind*" with the text you are searching for.

See Also

ListBox.ObjectCollection Class | Code: Adding Items to a List Control (Visual C#) | Web Applications Example Topics

Code: Writing a Cookie (Visual C#)

The following example uses the HttpCookie class and its properties to write a cookie that expires after one minute.

Example

```
HttpCookie myCookie = new HttpCookie("MyTestCookie");
DateTime now = DateTime.Now;

// Set the cookie value.
myCookie.Value = now.ToString();
// Set the cookie expiration date.
myCookie.Expires = now.AddMinutes(1);

// Add the cookie.
Response.Cookies.Add(myCookie);

Response.Write("<p> The cookie has been written.");
```

Compiling the Code

Start a new ASP.NET Web application and paste the code into the **Page_Load** method.

Robust Programming

Replace the name `"MyTestCookie"` and the cookie value with a name and value of your choice.

Security

Information stored in a cookie can be lost because the user has full control over cookies and can disable cookies entirely.

See Also

Code: Reading a Cookie (Visual C#) | HttpCookie Class | Web Applications Example Topics

Windows Forms Example Topics

This topic is designed to help you find code that demonstrates how to perform common programming tasks in Windows Forms applications using Visual C#.NET.

In This Section

- Adding a Node to the Selected Node of a TreeView Control
- Adding Items to a ListBox Control
- Adding Nested Nodes to a TreeView Control
- Adding Nodes to a TreeView Control
- Changing the Background Color of a Form
- Converting the Text in a TextBox Control to an Integer
- Creating a Context Menu and Attaching it to a Control
- Creating a Group of Radio Buttons from a String Array
- Creating a Shaped Form
- Creating a ToolTip for a Control
- Databinding a DataTable of String Values to a Windows DataGrid Control
- Databinding an Array of String Values to a Windows ListBox Control
- Determining the Selected Cell in a Windows DataGrid Control
- Determining the Selected Item in a ListBox Control
- Determining the Selected Node in a TreeView Control
- Determining the Selected Text in a TextBox Control
- Determining Which Control on a Form is Selected
- Displaying a Web Page from a LinkLabel Control
- Displaying an OpenFileDialog Dynamically
- Displaying One Form from Another
- Displaying the Time in a StatusBar Control
- Drawing Graphics on a Windows Form
- Formatting Characters in Bold in a RichTextBox Control
- Getting a Value from Another Form
- Hiding a DataColumn in a DataGrid Where the DataSource is a DataTable
- Hiding a DataColumn in a DataGrid Where the DataSource is an Array
- Hiding a DataColumn in a DataGrid Where the DataSource is an ArrayList
- Populating a ListBox Control with an Array of Strings
- Retrieving an Image that is an Embedded Resource
- Retrieving the Data from the Selected Cell in a Windows DataGrid Control
- Searching for an Item in a ListBox Control
- Selecting a Range of Dates in a Calendar Control
- Selecting an Item in a ListBox Control

Related Code Examples

You can also find sample code for C# applications in the following locations:

- C# Language Tour
- Visual C# Samples
- Walkthroughs in Visual Basic and Visual C#
- Quickstarts and other Samples
- .NET Framework Reference Information

Code: Adding a Node to the Selected Node of a TreeView Control (Visual C#)

This example adds one node to the selected node of an existing **TreeView** control.

Example

```
TreeNode node = treeView1.SelectedNode;
node.Nodes.Add("New node below selected node");
```

Compiling the Code

This example requires:

- A **TreeView** control named treeView1.

Robust Programming

The following conditions may cause an exception:

- The **TreeView** control has no nodes or none of the nodes is selected (NullReferenceException Class).

See Also

Windows Forms Example Topics | Code: Adding Nodes to a TreeView Control (Visual C#) | Code: Adding Nested Nodes to a TreeView Control (Visual C#) | TreeView.SelectedNode Property | TreeView.Nodes Property | TreeView Control (Windows Forms)

Code: Adding Items to a ListBox Control (Visual C#)

This example adds the contents of a Windows Forms **TextBox** control to a **ListBox** control when the **TextBox** control loses focus.

Example

```
private void textBox_Leave(object sender, System.EventArgs e)
{
    listBox1.Items.Add(((TextBox)sender).Text);
}
```

Compiling the Code

This example requires:

- A form with a **ListBox** control named listBox1 and three **TextBox** controls named textBox1, textBox2, and textBox3. Set each TextBox's **Leave** event handler to textBox_Leave.

  Note This can also be used with a **ComboBox** control by substituting a **ComboBox** control named comboBox1 for the **ListBox** control and changing the code from listBox1 to comboBox1.

Robust Programming

To avoid duplicate entries in the list, you should search for a match before adding the contents of the **TextBox** to the list. For an example, see Code: Searching for an Item in a ListBox Control.

See Also

Windows Forms Example Topics

Code: Adding Nested Nodes to a TreeView Control (Visual C#)

This example adds a first-level node and a second-level node to an existing **TreeView** control.

Example

```
TreeNode node = treeView1.Nodes.Add("Level one node");
node.Nodes.Add("Level two node");
```

Compiling the Code

This example requires:

- A **TreeView** control named treeView1.

See Also

Windows Forms Example Topics | Code: Adding a Node to the Selected Node of a TreeView Control (Visual C#) | Code: Adding Nodes to a TreeView Control (Visual C#) | TreeView.Nodes Property | TreeView Control (Windows Forms)

Code: Adding Nodes to a TreeView Control (Visual C#)

This example adds three first-level nodes to an existing **TreeView** control.

Example

```
treeView1.Nodes.Add("First Node");
treeView1.Nodes.Add("Second Node");
treeView1.Nodes.Add("Third Node");
```

Compiling the Code

This example requires:

- A **TreeView** control named treeView1.

See Also

Windows Forms Example Topics | Code: Adding a Node to the Selected Node of a TreeView Control (Visual C#) | Code: Adding Nested Nodes to a TreeView Control (Visual C#) | TreeView.Nodes Property | TreeView Control (Windows Forms)

Code: Changing the Background Color of a Form (Visual C#)

This example changes the background color of a Windows Form programmatically.

Example

```
private void Form1_Click(object sender, System.EventArgs e)
{
    this.BackColor = System.Drawing.Color.DarkBlue;
}
```

Compiling the Code

This example requires:

- A form named Form1. Set Form1's **Click** event handler to Form1_Click.

See Also

Windows Forms Example Topics | Color Structure

Code: Converting the Text in a TextBox Control to an Integer (Visual C#)

This example demonstrates two methods of converting text data to integer data.

Example

```
int anInteger;
anInteger = Convert.ToInt32(textBox1.Text);
anInteger = int.Parse(textBox1.Text);
```

Compiling the Code

This example requires:

- A **TextBox** control named textBox1.

Robust Programming

The following conditions may cause an exception:

- The text converts to a number that is too large or too small to store as an **int** (OverflowException Class).
- The text may not represent a number (FormatException Class).

See Also

Windows Forms Example Topics | Convert Class | Int32.Parse Method

Code: Creating a Context Menu and Attaching it to a Control (Visual C#)

This example programmatically creates a Windows Forms context menu and associates it with a control.

Example

```
private void Form1_Load(object sender, System.EventArgs e)
{
    System.Windows.Forms.ContextMenu contextMenu1;
    contextMenu1 = new System.Windows.Forms.ContextMenu();
    System.Windows.Forms.MenuItem menuItem1;
    menuItem1 = new System.Windows.Forms.MenuItem();
    System.Windows.Forms.MenuItem menuItem2;
    menuItem2 = new System.Windows.Forms.MenuItem();
    System.Windows.Forms.MenuItem menuItem3;
    menuItem3 = new System.Windows.Forms.MenuItem();

    contextMenu1.MenuItems.AddRange(new System.Windows.Forms.MenuItem[] {menuItem1, menuItem2
, menuItem3});
    menuItem1.Index = 0;
    menuItem1.Text = "MenuItem1";
    menuItem2.Index = 1;
    menuItem2.Text = "MenuItem2";
    menuItem3.Index = 2;
    menuItem3.Text = "MenuItem3";

    textBox1.ContextMenu = contextMenu1;
}
```

Compiling the Code

This example requires:

- A Windows Form named Form1 and a **TextBox** control named textBox1. Set Form1's **Load** event handler to Form1_Load.

See Also

Windows Forms Example Topics | ContextMenu Component (Windows Forms)

Code: Creating a Group of Radio Buttons from a String Array (Visual C#)

This example programmatically creates a group of Windows Forms radio buttons and set their **Text** properties to values from an array of strings.

Example

```
private void button1_Click(object sender, System.EventArgs e)
{
    string [] stringArray = new string[3];

    stringArray[0] = "Yes";
    stringArray[1] = "No";
    stringArray[2] = "Maybe";

    System.Windows.Forms.RadioButton [] radioButtons = new System.Windows.Forms.RadioButton[3
];

    for(int i=0; i<3; ++i)
    {
        radioButtons[i] = new RadioButton();
        radioButtons[i].Text = StringArray[i];
        radioButtons[i].Location = new System.Drawing.Point(10, 10+i*20);
        this.Controls.Add(radioButtons[i]);
    }
}
```

Compiling the Code

This example requires:

- A Windows Form with a **Button** control named button1. Set button1's **Click** event handler to button1_Click.

See Also

Windows Forms Example Topics | RadioButton Control (Windows Forms) | RadioButton Class

Code: Creating a Shaped Form (Visual C#)

This example gives a form an elliptical shape.

Example

```
protected override void OnPaint( System.Windows.Forms.PaintEventArgs e )
{
    System.Drawing.Drawing2D.GraphicsPath shape = new System.Drawing.Drawing2D.GraphicsPath()
;
    shape.AddEllipse(0, 0, this.Width, this.Height);
    this.Region = new System.Drawing.Region(shape);
}
```

Compiling the Code

This example overrides the **OnPaint** method to change the shape of the form. To use this code, copy the method declaration as well as the drawing code inside the method.

The **Region** property of the **Form** class is an advanced member. To use this property in IntelliSense, see General, Basic, Text Editor, Options Dialog Box.

See Also

Windows Forms Example Topics | Control.OnPaint Method | Region Class | System.Drawing Namespace | GraphicsPath.AddEllipse Method | Control.Region Property

Code: Creating a ToolTip for a Control (Visual C#)

This example programmatically creates a ToolTip for a Windows Forms control.

Example

```
private void Form1_Load(object sender, System.EventArgs e)
{
    System.Windows.Forms.ToolTip ToolTip1 = new System.Windows.Forms.ToolTip();
    ToolTip1.SetToolTip(this.textBox1, "Hello");
}
```

Compiling the Code

This example requires:

- A form named Form1 with a **TextBox** control named textBox1. Set Form1's **Load** event handler to Form1_Load.

See Also

Windows Forms Example Topics

Code: Databinding a DataTable of String Values to a Windows DataGrid Control (Visual C#)

This example creates a data table with two columns and two rows and then binds it to an existing **DataGrid** control.

Example

```
DataTable dt = new DataTable();
dt.Columns.Add(new DataColumn("Item", typeof(string)));
dt.Columns.Add(new DataColumn("Color", typeof(string)));
dt.Rows.Add(new string[] {"table", "brown"});
dt.Rows.Add(new string[] {"chair", "white"});
dataGrid1.DataSource = dt;
```

Compiling the Code

This example requires:

- A **DataGrid** control named dataGrid1.

See Also

Windows Forms Example Topics | DataGrid Control (Windows Forms) | DataGrid.DataSource Property | DataTable Class

Code: Databinding an Array of String Values to a Windows ListBox Control (Visual C#)

This example adds three strings to an existing **ListBox** control.

Example

```
listBox1.DataSource = new string[] { "one", "two", "three" };
```

Compiling the Code

This example requires:

- A **ListBox** control named listBox1.

See Also

Windows Forms Example Topics | ListBox Control (Windows Forms) | ListControl.DataSource Property | ListBox.Items Property

Code: Determining the Selected Cell in a Windows DataGrid Control (Visual C#)

This example sets a reference to the selected cell of an existing **DataGrid** control.

Example

```
System.Windows.Forms.DataGridCell selectedCell = dataGrid1.CurrentCell;
```

Compiling the Code

This example requires:

- A **DataGrid** control named dataGrid1.

Robust Programming

If the **DataGrid** is not bound to a data source, or if no cell is selected, then the selected cell is the cell in row 0 and column 0.

See Also

Windows Forms Example Topics | Code: Retrieving the Data from the Selected Cell in a Windows DataGrid Control | DataGrid.CurrentCell Property | DataGrid Control (Windows Forms)

Code: Determining the Selected Item in a ListBox Control (Visual C#)

This example determines which item has been selected in a Windows Forms **ListBox** control.

Example

```
private void Form1_Load(object sender, System.EventArgs e)
{
    listBox1.Items.Add("One");
    listBox1.Items.Add("Two");
    listBox1.Items.Add("Three");
}

private void listBox1_SelectedIndexChanged(object sender, System.EventArgs e)
{
    if ((string)listBox1.SelectedItem == "Two")
        MessageBox.Show((string)listBox1.SelectedItem);
}
```

Compiling the Code

This example requires:

- A form named Form1 with a **ListBox** control named listBox1. Set Form1's **Load** event handler to Form1_Load. Set listBox1's **SelectedIndexChanged** event handler to listBox1_SelectedIndexChanged.

  Note This can also be used with a **ComboBox** control by substituting a **ComboBox** control named comboBox1 for the **ListBox** control and changing the code from listBox1 to comboBox1.

See Also

Windows Forms Example Topics

Code: Determining the Selected Node in a TreeView Control (Visual C#)

This example sets a reference to the selected node of existing **TreeView** control.

Example

```
TreeNode node = treeView1.SelectedNode;
```

Compiling the Code

This example requires:

- A **TreeView** control named treeView1.

Robust Programming

The following conditions may cause an exception:

- The **TreeView** control has no nodes or none of the nodes is selected (NullReferenceException Class).

See Also

Windows Forms Example Topics | Code: Adding Nodes to a TreeView Control (Visual C#) | Code: Adding Nested Nodes to a TreeView Control (Visual C#) | TreeView.SelectedNode Property | TreeView.Nodes Property | TreeView Control (Windows Forms)

Code: Determining the Selected Text in a TextBox Control (Visual C#)

This example programmatically selects text in a Windows Forms **TextBox** control and retrieves the selected text.

Example

```
private void button1_Click(object sender, System.EventArgs e)
{
    textBox1.Text = "Hello World";
    textBox1.Select(6, 5);
    MessageBox.Show(textBox1.SelectedText);
}
```

Compiling the Code

This example requires:

- A form with a **TextBox** control named textBox1 and a **Button** control named button1. Set button1's **Click** event handler to button1_Click.

  Note This can also be used with a **RichTextBox** control by substituting a **RichTextBox** control named richTextBox1 for the **TextBox** control and changing the code from textBox1 to richTextBox1.

Robust Programming

In this example you are setting the **Text** property before retrieving the **SelectedText** value. In most cases, you will be retrieving text entered by the user, so you will want to add error-handling code in case the text is too short.

See Also

Windows Forms Example Topics

Code: Determining Which Control on a Form is Selected (Visual C#)

This example displays the name of the currently selected Windows Forms control in a **Label** control.

Example

```
private void DisplayNameOfActiveControl()
{
    label1.Text = this.ActiveControl.Name;
}
```

Compiling the Code

This example requires:

- A form with a **Label** control named label1.

See Also

Windows Forms Example Topics

Code: Displaying a Web Page from a LinkLabel Control (Visual C#)

This example displays a Web page in the default browser when a user clicks a Windows Forms **LinkLabel** control.

Example

```
private void Form1_Load(object sender, System.EventArgs e)
{
    linkLabel1.Text = "Click here to get more info.";
    linkLabel1.Links.Add(6, 4, "www.microsoft.com");
}
private void linkLabel1_LinkClicked(object sender, System.Windows.Forms.LinkLabelLinkClickedE
ventArgs e)
{
    System.Diagnostics.Process.Start(e.Link.LinkData.ToString());
}
```

Compiling the Code

This example requires:

- A form named Form1 with a **LinkLabel** control named linkLabel1.
- An active Internet connection.

Secure programming

The call to the **Start** method requires full trust. For more information, see SecurityException Class.

See Also

Windows Forms Example Topics | LinkLabel Control (Windows Forms) | LinkLabel Class

Code: Displaying an OpenFileDialog Dynamically (Visual C#)

This example instantiates and displays an **OpenFileDialog** control.

Example

```
OpenFileDialog openFile = new OpenFileDialog();
openFile.DefaultExt = "doc";
// The Filter property requires a search string after the pipe ( | )
openFile.Filter = "Word documents (*.doc)|*.doc";
openFile.ShowDialog();
if( openFile.FileNames.Length > 0 )
{
    foreach( string filename in openFile.FileNames )
    {
        // Insert code here to process the files.
    }
}
```

Robust Programming

You can use the **FileOK** event of the **OpenFileDialog** control to be certain that the user selected a file and clicked the OK button on the dialog box.

Use the **CheckFileExists**, **CheckPathExists**, **DefaultExtension**, **Filter**, **Multiselect**, and **ValidateNames** properties of the **OpenFileDialog** control to limit run-time errors.

See Also

Windows Forms Example Topics | OpenFileDialog Class

Code: Displaying One Form from Another (Visual C#)

This example displays a second form from another Windows Form.

Example

```
private void button1_Click(object sender, System.EventArgs e)
{
    Form2 frm = new Form2();
    frm.Show();
}
```

Compiling the Code

This example requires:

- Two Windows Forms named Form1 and Form2. Form1 contains a **Button** control named button1. Set button1's **Click** event handler to button1_Click.

See Also

Windows Forms Example Topics | Windows Forms

Code: Displaying the Time in a StatusBar Control (Visual C#)

This example displays the current time in hh:mm format in a **StatusBar** control.

Example

```
private void timer1_Tick(object sender, System.EventArgs e)
{
    statusBar1.Panels[0].Text = DateTime.Now.ToShortTimeString();
}
```

Compiling the Code

The form must contain a **Timer** control with **Enabled** set to **True**, and a **StatusBar** with a **Panel** added to the **Panels** property and the **ShowPanels** property set to **True**.

The code is part of the event handler for the **Timer** control's **Tick** event, as shown.

Robust Programming

The following conditions may cause an exception:

- The **StatusBar** has no **Panel** controls (ArgumentOutOfRangeException Class).

See Also

Windows Forms Example Topics | Panel.Text Property | DateTime.ToShortTimeString Method | Timer.Tick Event

Code: Drawing Graphics on a Windows Form (Visual C#)

This example draws a circle and a square on a form.

Example

```
System.Drawing.Graphics graphics = this.CreateGraphics();
System.Drawing.Rectangle rectangle = new System.Drawing.Rectangle(100, 100, 200, 200);
graphics.DrawEllipse(System.Drawing.Pens.Black, rectangle);
graphics.DrawRectangle(System.Drawing.Pens.Red, rectangle);
```

Compiling the Code

This code is to be added to a class that derives from **System.Windows.Forms.Form**. The **this** refers to the instance of the form.

Security

To run this process, your assembly requires a privilege level granted by the UIPermission Class. If you are running in a partial-trust context, the process might throw an exception due to insufficient privileges. For more information, see Code Access Security Basics.

See Also

Windows Forms Example Topics | Graphics Class | Graphics.DrawEllipse Method | Graphics.DrawRectangle Method

Code: Formatting Characters in Bold in a RichTextBox Control (Visual C#)

This example adds the text "This text is in **bold**." to an existing **RichTextBox** control.

Example

```
richTextBox1.Rtf = @"{\rtf1\ansi This is in \b bold\b0.}";
```

Compiling the Code

This example requires:

- A **RichTextBox** control named richTextBox1.

Robust Programming

The rich text format is extremely flexible, but any errors in the format lead to errors in the displayed text. For more information, see Rich Text Format (RTF) Specification, version 1.6.

See Also

Windows Forms Example Topics | RichTextBox Control (Windows Forms)

Code: Getting a Value from Another Form (Visual C#)

This example retrieves a value from a text box on a Windows Form and displays it in a text box on another form.

Example

In Form1.cs:

```
private Form2 otherForm;
private void GetOtherFormTextBox()
{
    textBox1.Text = otherForm.TextBox1.Text;
}
```

In Form2.cs:

```
public TextBox TextBox1
{
    get
    {
        return textBox1;
    }
}
```

Compiling the Code

This example requires:

- Two forms named Form1 and Form2, each containing a **TextBox** control named textBox1. Form1 should create an instance of Form2 and assign it to otherForm; **GetOtherFormTextBox** will copy the text in Form2's textBox1 to Form1's textBox1.

See Also

Windows Forms Example Topics | Displaying One Form from Another

Code: Hiding a DataColumn in a DataGrid Where the DataSource is a DataTable (Visual C#)

This example hides the "X" column of a **DataTable** object that is displayed in an existing Windows Forms **DataGrid** control.

Example

```
private void HideColumnOfDataSet()
{
    System.Data.DataTable points = new System.Data.DataTable("Points");
    points.Columns.Add(new DataColumn("X", typeof(int)));
    points.Columns.Add(new DataColumn("Y", typeof(int)));
    points.Rows.Add(new object[]{1, 2});
    points.Rows.Add(new object[]{3, 5});
    dataGrid1.DataSource = points;

    DataGridTableStyle tableStyle = new DataGridTableStyle();
    tableStyle.MappingName = "Points";
    dataGrid1.TableStyles.Add(tableStyle);
    dataGrid1.TableStyles["Points"].GridColumnStyles["X"].Width = 0;
}
```

Compiling the Code

This example requires:

- A Windows Form with a **DataGrid** control named dataGrid1.

If the data source is a **DataSet** object, set the **DataMember** property of the **DataGrid** to the table's name.

DataTable and **DataColumn** objects in typed datasets also have string-typed names. To find the name of the table, example the table's **Name** property. To find the name of the **DataColumn**, examine the column's **Name** property.

Robust Programming

The following conditions may cause an exception:

- The **MappingName** property does not match the name of the **DataTable** (NullReferenceException Class).
- Retrieving an item from the **GridColumnStyles** collection before the **TableStyle** is added to the **DataGrid.TableStyles** collection. The **GridColumnStyles** collection is filled when the **TableStyle** object is added to the **TableStyles** collection (NullReferenceException Class).
- A **TableStyle** added to the **DataGrid**.**TableStyles** collection does not have a unique **MappingName** (ArgumentException Class).
- The **DataSource** property of the **DataGrid** is not set before accessing the **GridColumnStyles** collection (NullReferenceException Class).

See Also

Windows Forms Example Topics | Hiding a DataColumn in a DataGrid Where the DataSource is an Array | Hiding a DataColumn in a DataGrid Where the DataSource is an ArrayList | DataGrid Control (Windows Forms) | Formatting the Windows Forms DataGrid Control | DataGrid.TableStyles Property | DataGridTableStyle.MappingName Property | DataGridTableStyle.GridColumnStyles Property

Code: Hiding a DataColumn in a DataGrid Where the DataSource is an Array (Visual C#)

This example hides the "X" column of a **DataGrid** that uses an array of **Point** objects as the data source.

Example

```
private void HideColumnOfArray()
{
    System.Drawing.Point [] points = { new Point(1, 2), new Point(3, 5), new Point(5, 6)};
    dataGrid1.DataSource = points;

    DataGridTableStyle tableStyle = new DataGridTableStyle();
    tableStyle.MappingName = "Point[]";
    dataGrid1.TableStyles.Add(tableStyle);
    dataGrid1.TableStyles["Point[]"].GridColumnStyles["X"].Width = 0;
}
```

Compiling the Code

This example requires:

- A Windows Form with a **DataGrid** control named dataGrid1.

The **MappingName**, a string, is the type of the array with "[]" appended. Thus, if the data source is an array of **Point** objects, the mapping name is "Point[]".

Robust Programming

The following conditions may cause an exception:

- The **MappingName** property is not property formatted (NullReferenceException Class).
- Retrieving an item from the **GridColumnStyles** collection before the **TableStyle** is added to the **DataGrid.TableStyles** collection. The **GridColumnStyles** collection is filled when the **TableStyle** object is added to the **TableStyles** collection (NullReferenceException Class).
- A **TableStyle** added to the **DataGrid**.**TableStyles** collection does not have a unique **MappingName** (ArgumentException Class).
- The **DataSource** property of the **DataGrid** is not set before accessing the **GridColumnStyles** collection (NullReferenceException Class).

See Also

Windows Forms Example Topics | Hiding a DataColumn in a DataGrid Where the DataSource is a DataTable | Hiding a DataColumn in a DataGrid Where the DataSource is an ArrayList | DataGrid Control (Windows Forms) | Formatting the Windows Forms DataGrid Control | DataGrid.TableStyles Property | DataGridTableStyle.MappingName Property | DataGridTableStyle.GridColumnStyles Property

Code: Hiding a DataColumn in a DataGrid Where the DataSource is an ArrayList (Visual C#)

This example hides one column of a **DataGrid** that uses an **ArrayList** of **Point** objects as a data source.

Example

```
private void HideColumnOfArrayList()
{
    System.Collections.ArrayList list = new System.Collections.ArrayList();
    list.AddRange( new Point[]{ new Point(1, 2), new Point(3, 5), new Point(5, 6) } );
    dataGrid1.DataSource = list;
    DataGridTableStyle tableStyle = new DataGridTableStyle();
    tableStyle.MappingName = "ArrayList";
    dataGrid1.TableStyles.Add(tableStyle);
    object o = dataGrid1.TableStyles["ArrayList"];
    dataGrid1.TableStyles["ArrayList"].GridColumnStyles["X"].Width = 0;
}
```

Compiling the Code

This example requires:

- A Windows Form with a **DataGrid** control named dataGrid1.

When the data source is an **ArrayList** object, the **MappingName** is "ArrayList".

Robust Programming

The following conditions may cause an exception:

- The **MappingName** property is not "ArrayList"(NullReferenceException Class).
- Retrieving an item from the **GridColumnStyles** collection before the **TableStyle** is added to the **DataGrid.TableStyles** collection. The **GridColumnStyles** collection is filled when the **TableStyle** object is added to the **TableStyles** collection (NullReferenceException Class).
- A **TableStyle** added to the **DataGrid**.**TableStyles** collection does not have a unique **MappingName** (ArgumentException Class).
- All the objects in the **ArrayList** are not of the same type of the first item or a derived type of the first item (TargetInvocationException Class).
- The **DataSource** property of the **DataGrid** is not set before accessing the **GridColumnStyles** collection (NullReferenceException Class).

Code: Populating a ListBox Control with an Array of Strings (Visual C#)

This example adds an array of strings to a Windows Forms **ListBox** control.

Example

```
private void Form1_Load(object sender, System.EventArgs e)
{
    string [] myList = new string[4];

    myList[0] = "One";
    myList[1] = "Two";
    myList[2] = "Three";
    myList[3] = "Four";

    listBox1.Items.AddRange(myList);
}
```

Compiling the Code

This example requires:

- A form named Form1 with a **ListBox** control named listBox1. Set Form1's **Load** event handler to Form1_Load.

  Note This can also be used with a **ComboBox** control by substituting a **ComboBox** control named comboBox1 for the **ListBox** control and changing the code from listBox1 to comboBox1.

Robust Programming

The following conditions may cause an exception:

- The array contains one or more null values.

See Also

Windows Forms Example Topics

Code: Retrieving an Image that is an Embedded Resource (Visual C#)

This example retrieves an image that is an embedded resource of the assembly.

Example

```
System.Reflection.Assembly thisExe;
thisExe = System.Reflection.Assembly.GetExecutingAssembly();
System.IO.Stream file =
    thisExe.GetManifestResourceStream("AssemblyName.ImageFile.jpg");
this.pictureBox1.Image = Image.FromStream(file);
```

Compiling the Code

This example requires:

- A Windows Form with a **PictureBox** control named pictureBox1.

Add the image file to the project, and set the **Build Action** property to **Embedded Resource** in Solution Explorer.

Replace `"AssemblyName.ImageFile.jpg"` with the name of the resource, as it is known in the assembly. Use the **GetManifestResourceNames** method of the Assembly object to find the resource name. See Code: Finding the Names of Resources in an Assembly.

Robust Programming

The following conditions may cause an exception:

- The embedded resource does not exist in the assembly, and the call to **GetManifestResourceStream** returns **Nothing**.
- There may not be an application associated with the file type (the file extension).

See Also

Windows Forms Example Topics | Code: Finding the Names of Resources in an Assembly | Code: Running a Program | Process Class

Code: Retrieving the Data from the Selected Cell in a Windows DataGrid Control (Visual C#)

This example retrieves the selected data in an existing **DataGrid** control filled with integer values.

Example

```
System.Windows.Forms.DataGridCell selectedCell = dataGrid1.CurrentCell;
object selectedItem = dataGrid1[selectedCell.RowNumber, selectedCell.ColumnNumber];
int cellValue = Convert.ToInt32(selectedItem);
```

Compiling the Code

This example requires:

- A **DataGrid** control named dataGrid1.

Robust Programming

If the **DataGrid** is not bound to a data source, or if no cell is selected, then the selected cell is the cell in row 0 and column 0.

The following conditions may cause an exception:

- The **DataGrid** control is not bound to a data source (InvalidOperationException Class).
- The data type of the cell does not contain the type of data to which you are trying to convert (InvalidCastException Class).

See Also

Windows Forms Example Topics | Code: Determining the Selected Cell in a Windows DataGrid Control | DataGrid.CurrentCell Property | DataGrid Control (Windows Forms)

Code: Searching for an Item in a ListBox Control (Visual C#)

This example searches for a string in a Windows Forms **ListBox** control.

Example

```
private void button1_Click(object sender, System.EventArgs e)
{
    listBox1.Items.Add("One");
    listBox1.Items.Add("Two");
    listBox1.Items.Add("Three");

    if (listBox1.FindString("Two") != -1)
        MessageBox.Show("Found it!");
}
```

Compiling the Code

This example requires:

- A form with a **ListBox** control named listBox1 and a **Button** control named button1. Set button1's **Click** event handler to button1_Click.

  Note This can also be used with a **ComboBox** control by substituting a **ComboBox** control named comboBox1 for the **ListBox** control and changing the code from listBox1 to comboBox1.

Code: Selecting a Range of Dates in a Calendar Control (Visual C#)

This example selects a range of dates in a Windows Forms **MonthCalendar** control. In this example, when the user selects a date the week is selected.

Example

```
private void monthCalendar1_DateSelected(object sender, System.Windows.Forms.DateRangeEventAr
gs e)
{
    DateTime startDate = e.Start;
    startDate = startDate.AddDays(-(double)startDate.DayOfWeek);
    monthCalendar1.SelectionStart = startDate;
    monthCalendar1.SelectionEnd = startDate.AddDays(6);
}
```

Compiling the Code

This example requires:

- A Windows Form with a **MonthCalendar** control named monthCalendar1. Set monthCalendar1's **DateSelected** event handler to monthCalendar1_DateSelected.

See Also

Windows Forms Example Topics | MonthCalendar Control (Windows Forms)

Code: Selecting an Item in a ListBox Control (Visual C#)

This example selects and highlights an item in a Windows Forms **ListBox** control.

Example

```
private void button1_Click(object sender, System.EventArgs e)
{
    listBox1.Items.Add("One");
    listBox1.Items.Add("Two");
    listBox1.Items.Add("Three");
    listBox1.SelectedIndex = listBox1.FindString("Two");
}
```

Compiling the Code

This example requires:

- A form with a **ListBox** control named listBox1 and a **Button** control named button1. Set button1's **Click** event handler to button1_Click.

  Note This can also be used with a **ComboBox** control by substituting a **ComboBox** control named comboBox1 for the **ListBox** control and changing the code from listBox1 to comboBox1.

Visual Basic Sample Applications

You can access sample code in two ways:

- Browse the sample abstracts in this section. Each abstract contains a link to open or copy the sample's files.
- Browse the Visual Basic samples directory structure on the product CD or DVD. For the specific location of sample files for your version of Visual Basic .NET, see Locating Sample Files.

In the Visual Basic documentation, "sample" means a complete application, including project files, while "example" means a small block of code that demonstrates a single, limited programming task.

Console: Localized Hello World Sample
Demonstrates localizing your applications for different cultures.
Web Forms: DHTML Sample
Demonstrates that Dynamic HTML (DHTML) is still a useful tool in the world of .NET programming.
Web Forms: User Control Sample
Demonstrates how to build a custom ASP.NET User Control in Visual Basic .NET and access it from a Web Forms page.
XML Web Services: Windows Forms Client/Asynchronous XML Web Service Sample
Demonstrates how to call an XML Web service asynchronously.
Windows Forms: Calc Sample
Demonstrates how to create the equivalent of a control array in Visual Basic .NET by using common methods to handle the individual controls' click events.
Windows Forms: Localization Sample
Demonstrates how to save culture preferences to your computer that persist from run to run of your application.
Windows Forms: Multi-Threaded TCP/IP Listener Sample
Demonstrates a technique for creating a multi-threaded application that generates and listens for TCP/IP traffic.
Windows Forms: Multilingual Form Sample
Demonstrates using different culture information in a Windows Forms application.
Windows Forms: Performance Monitor Sample
Demonstrates how to monitor system performance using performance counters. This sample is also an introduction to performance counters.
Windows Forms: Process Controller Sample
Demonstrates how to build a Visual Basic Windows application for processes and services monitoring.
Windows Forms: Registry Client Sample
Demonstrates how to use the Registry classes to add a new registry key and manipulate the values associated with that key.
Windows Forms: Scribble Sample
Demonstrates a Windows Forms MDI drawing application.
Windows Forms: System Tray Sample
Demonstrates how to use the status area of the Windows taskbar in a Visual Basic .NET application.
Windows Forms: Vehicle Sample
Demonstrates inheritance by implementing a vehicle class for cars and boats.
Windows Forms: Weather Sample
Demonstrates how to use the .NET Framework's XML classes to query an XML document and retrieve the weather forecast for a specified city.
Windows Forms: Winlogger Sample
Demonstrates using a logging component to write to a text file and the Windows Application Event Log.

Console: Localized Hello World Sample

The Localized Hello World sample demonstrates creating and using satellite assemblies for console applications. It shows how to create resources for Visual Basic console applications, localize the resources, and build localized satellite assemblies.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the solution **LocalizedHelloWorld.sln**.
3. From the **Build** menu, click **Build Solution**.
4. From the **Debug** menu, click **Start Without Debugging**.
5. Type in a culture supported by the application to see the resources in that culture. This sample supports English (en), German (de), Spanish (es) French (fr) and Italian (it).

See Also

Web Forms: DHTML Sample

The Web Forms DHTML sample demonstrates using client-side script and Dynamic HTML (DHTML) within a Web Forms application. A majority of the Web Forms samples available focus on the new server-side event-handling capabilities available with ASP.NET. This sample demonstrates that client-side script is still a viable and useful tool for building Web applications in ASP.NET.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users and VS Developers groups. To debug this sample, you must be a member of the Administrators group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Use the **Copy** Link to copy the files to your hard drive. This sample will not function properly if the **Load** link is used.
2. Run the **WebFormDHTMLSetup.msi** file and follow the directions.
3. Open the **.sln** file.

   > **Note** If Visual Studio cannot open the project by means of Front Page Server Extensions, a warning dialog box will be displayed asking you to switch to file-based access. Choose **OK** to continue opening the project.

4. Press F5 to run the sample.

   > **Note** If you are prompted to set the Start Page for the application, right-click the **WebFormDHTMLDemo.aspx** item in Solution Explorer and select **Set As Start Page**.

See Also

Visual Basic Sample Applications | Visual Basic Walkthroughs | Client Script in Web Forms Pages

Web Forms: User Control Sample

The Web Forms user control sample demonstrates how to build a custom ASP.NET User Control in Visual Basic .NET and access it from a Web Forms page. This sample includes a custom paired list box user control that allows the user to move values between the available and selected list boxes. The Web Forms page that hosts the control can specify and retrieve the values from the available and selected lists.

This sample features Web Forms pages and user controls.

> **Note** This sample will not run on Windows NT 4.0; you must be running Windows 2000 or Windows XP. To install and run this sample, you must be a member of your computer's Debugger Users and VS Developers groups. To debug this sample, you must be a member of the Administrators group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Use the **Copy** Link to copy the files to your hard drive.
2. Double-click the **Setup.msi** icon, and follow the steps to install the sample on your computer.
3. Open the .sln file.
4. Set a start page by right-clicking WebForm1.aspx in Solution Explorer and choosing **Set As Start Page** on the shortcut menu.
5. Press F5.

XML Web Services: Windows Forms Client/Asynchronous XML Web Service Sample

The Asynchronous XML Web service sample demonstrates how to call an XML Web service from a Visual Basic .NET Windows Form client application by using the built-in asynchronous support of the .NET Framework. The sample XML Web service takes an input parameter — milliseconds to delay before returning to the client — and returns a random number to the caller. The Windows Form client application allows the user to specify the milliseconds to delay and demonstrates calling the XML Web service synchronously and asynchronously.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users and VS Developers groups. To debug this sample, you must be a member of the Administrators group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Use the **Copy** Link to copy the files to your hard drive. This sample will not function properly if the **Load** link is used.
2. Run the **AsyncWebServiceSetup.msi** and follow the directions.
3. After the installation completes, launch **AsyncWebService.sln**.

   > **Note** If Visual Studio cannot open the project by means of Front Page Server Extensions, a warning dialog box will be displayed asking you to switch to file-based access. Choose **OK** to continue opening the project.

4. In **Solution Explorer**, right-click **AsyncTestClient** and choose **Set as Startup Project**.
5. Press F5 to run the sample.
6. Click the **Call Web Service Sync** button.
7. Click the **Call Web Service Async** button. Do not clear to the 'Async Call Started' message in order to see the asynchronous behavior of the call.

Windows Forms: Calc Sample

The Calc sample demonstrates how to create the equivalent of a control array in Visual Basic .NET by using common methods to handle the individual controls' click events.

This sample features Windows Forms and control arrays.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the .sln file.
3. Press F5.

See Also

Visual Basic Sample Applications | Visual Basic Walkthroughs

Windows Forms: Localization Sample

The Windows Forms Localization sample demonstrates techniques for localizing a Windows Forms application with Visual Basic .NET. The sample contains a variety of controls and localized content (text string, menus, images, and so forth.). When the user selects a language from the combo box, the user interface will update itself using the locale of the language selected.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the .sln file.
3. Press F5 to start the application.
4. Click the **Click Me** button.

   A greeting is displayed in English.

5. In the combo box, choose a different culture.

   The text of the application and the greeting displayed are now represented in the selected language.

See Also

Visual Basic Sample Applications | Visual Basic Walkthroughs | Localizing Applications

Windows Forms: Multilingual Form Sample

The Multilingual Form sample demonstrates creating and localizing Windows Forms. It shows how to use the Windows Forms Designer to create, edit, and build localized applications.

For more information about localized applications, see Globalizing and Localizing Applications.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the solution **VBMultilingualForm.sln**.
3. On the **Build** menu, click **Build Solution**.
4. On the **Debug** menu, click **Start Without Debugging**.
5. To see a different culture's resources, type a valid RFC 1766 culture name into the text box and click the **switch** button. A list of available cultures will appear when the mouse pointer hovers over the text box.

To localize your own Windows Forms or Web Forms

1. Select the form to be localized in the appropriate forms designer.
2. Set the form's **Localizable** property to **true**.
3. For each language you want to localize to, do the following:
   a. Set the form's **Language** property to the desired language.
   b. Enter the new text in the new language for each control.

You can also change the appearance of the form's controls (size, position, and so on) for each language.

MultilingualForm Sample: Demonstrates Creating and Localizing Windows Forms (Visual C#)

Windows Forms: Multi-Threaded TCP/IP Listener Sample

The MultiThreaded TCP/IP Listener sample demonstrates a technique for creating a multi-threaded application that generates and listens for TCP/IP traffic. The TCPIPClient application submits multiple TCP/IP calls to the listener component. The TCPIPListener application creates threads that listen for TCP/IP requests. This sample shows how to use critical sync locks to update a single counter on the server.

This sample features Windows Forms, the .NET Framework, and threading.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the .sln file.
3. In Solution Explorer, right-click the **TCPIPListener** solution and select **Properties**.

   The Solution Property Pages dialog box is displayed.

4. In the Startup Project page, click **Multiple Startup Projects**.
5. Set the Action to **Start without debugging** for both the Client and Listener projects.
6. Click **OK** to close the dialog box.
7. Press CTRL+F5.
8. Click **Start** in the Client form.

Windows Forms: Performance Monitor Sample

The PerfMon sample is an introduction to performance counters. It demonstrates how to monitor local or remote system performance. It shows how to dynamically create timers, context menus, and graphic displays. It also demonstrates the following activities:

- Including new Visual Basic classes derived from other components.
- Dynamically adding and removing event handlers and components.
- Using the **TreeView** control, **TreeNode** class, and **Timer** component.
- Using the **PerformanceCounterCategory** and **PerformanceCounter** components.

  For more information on performance counters, see PerformanceCounter Class.

  > **Note** This sample is functional only on Windows NT 4.0, Windows 2000, and Windows XP. To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

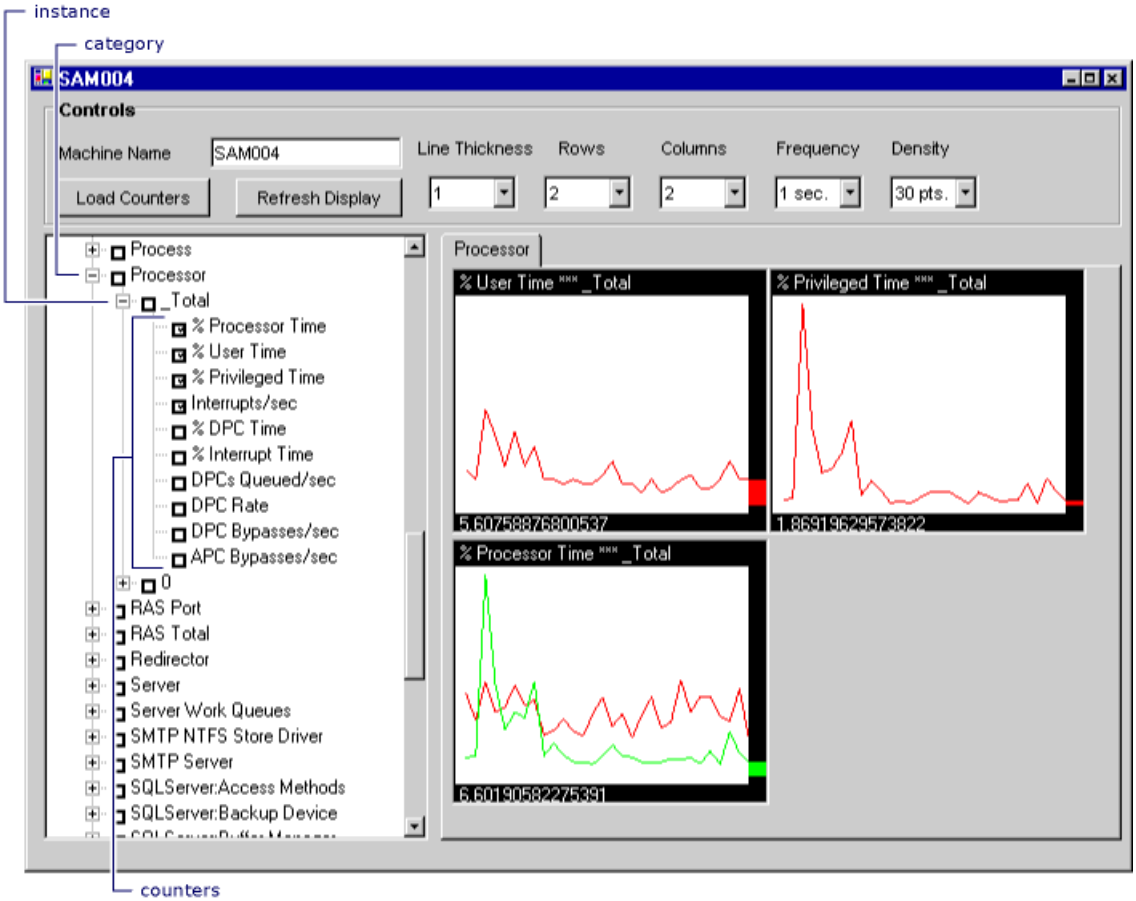
Building and Running the Sample

To build and run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the solution **PerfMon.sln**.
3. On the **Build** menu, click **Build**.
4. On the **Debug** menu, click **Start Without Debugging**.

   The main application window appears.

The following figure shows the performance monitor program running. Refer to the figure, as needed, while you go through the various performance monitoring procedures.



The Display Panel Properties

Each graphic display in the figure shows the following:

- The top of the display shows the name of the counter and the name of the instance separated by "***". If the category does not contain an instance name (for example, the ICMP category), the "***" is followed by a blank space.
- The bottom of the display shows the current counter value. This value may change periodically (the default is every second).
- The right side of the display shows a red bar. The height of the bar depends on the last value monitored on the counter.
- The graph plotted in the display shows the performance history for that counter.

This application is an MDI application. It starts with four windows that can be used to monitor four computers. You can open as many windows as you want by clicking the **New PerfMon** command on the **Options** menu. In the following procedures, only one window is used. Therefore, you can close all of the windows except one.

To load the performance counters of a system

1. In the **Machine Name** field, type the name of the system you want to monitor. If you do not type anything, the local computer will be monitored.
2. Click the **Load Counters** button (or press ALT+L). The application will load **PerformanceCounterCategory**, **InstanceName**, and **PerformanceCounter** components on the specified computer. The **Load Counters** button will be disabled until all of the counters on the system have been loaded.

   The tree view in the left pane will contain all of the performance categories and the performance counters available. Each leaf in the tree represents a performance counter. You can monitor the completion progress by watching the progress indicator on the bottom of the application window. After the tree has been completed, the **Load Counters** button will be enabled again.

   > **Note** To monitor a specific computer, you need administrator rights to the computer; otherwise, the **PerformanceCounterCategory** components will not be able to load the categories (security protection).

To monitor the performance of a system

1. Load the performance counters by performing the preceding steps.
2. Select one of the counters by expanding the corresponding category node. For example, to watch the performance of the processor, expand the **Processor** node, then select one of the **Processor** instances (for example, "**_Total**" or "**0**"). Expand the instance node as well to see the counters.
3. On the leaf level, the counters are represented by check boxes. Select one of the counters, for example, **%Processor Time**. A tab, which has the name **Processor**, will appear in the right pane, and a graphic display of the selected counter will appear on the tab page.
4. To remove a specific graphic display from the tab page, clear the check box for the corresponding counter. When all of the counters in a specific page are cleared, the corresponding tab disappears.

   > **Note** Each time you change any of the display properties, click the **Refresh Display** button to apply the changes. The changes will apply for current or future displays.

To manage the display properties

- To change the line thickness, select the thickness you want from the **Line Thickness** box.
- To change the number of rows per display, select the number you want from the **Rows** box. For example, selecting one row makes the display occupy the full height of the tab page.
- To change the number of columns per display, select the number you want from the **Columns** box. For example, selecting one column makes the display occupy the full width of the tab page.

  > **Note** If the number of graphic displays exceeds the visible area of the tab page, scroll bars will be created automatically.

- To change the time interval, select the number of seconds from the **Frequency** box.
- To change the number of points to display in the graph, select a number from the **Density** box.

To merge two or more displays

1. Select the display you want to move and drag it to the destination display. Notice that the background of the destination display becomes black when it is selected and is ready to receive the moved display. Both displays will merge, and two different graphic colors will appear (red and green in this case). For example, if you drop "**%Processor Time *** _total**" on "**%User Time *** _total**", the green color will represent the first and the red color will represent the second. The data shown in the display's top, bottom, and right side will only represent the **"%Processor Time *** _total**" counter.

2. To switch from one graph to another after a display merge, right-click the display and select the name of the graph from the shortcut menu. In the preceding example, if you want to change the display data from "**% Processor Time *** _total**" to "**%User Time *** _total**", right-click the display and select **"%User Time *** _total**" from the shortcut menu. The display will show the data of the selected counter, and the bar color on the right side will change to red (or the color representing the selected counter).
3. If you have more than two merged counters, each counter will be represented by a different color. To select the data view for any one of the counters, perform the preceding step.

To separate two or more merged displays

1. Locate the counter's check box of the display you want to separate.
2. Clear the counter's check box. The corresponding display will be removed.
3. Select the counter's check box again. A new display will appear on the tab page.

To use menu options

- To stop the graphics plotting:

  1. Click the **Option** menu (or press ALT+O).
  2. Click Stop Graphics.

     The graphics will freeze and no more lines will be plotted.

- To restart the graphics plotting:

  1. Click the **Option** menu.
  2. Click Start Graphics.

     The displays will continue plotting from the last position.

- To quit the application:

  1. Click the **Option** menu.
  2. Click **Exit**.

Visual Basic Sample Applications | Visual Basic Walkthroughs | Introduction to Monitoring Performance Thresholds | PerfMon Sample: Demonstrates How to Monitor System Performance Using Performance Counters (Visual C#)

Windows Forms: Process Controller Sample

The ProcessController sample shows how to build a Visual Basic Windows application for monitoring processes and services. The sample also demonstrates the following activities:

- Dynamically adding and removing event handlers.
- Using the **Process** component to:
  - Read the running processes on the local/remote computer.
  - Start a process on the local computer.
  - Stop a process on the local/remote computer.
  - Read the modules used by some running process.
  - Read all of the characteristics of some running process.
- Using the **ServiceController** component to:
  - Read the running services and device drivers on the local/remote computer.
  - Start/Stop/Pause a service on the local/remote computer.
  - Check properties of the services or device drivers on the local/remote computer.
- Handling security issues related to the use of the **Process** and the **ServiceController** components.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

Building and Running the Sample

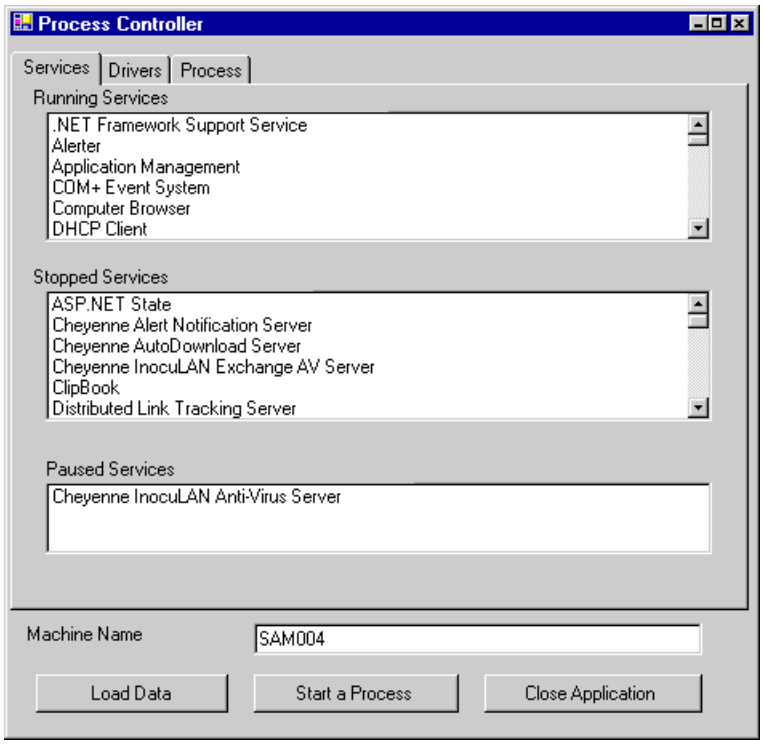
To build and run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the solution **ProcessController.sln**.
3. On the **Build** menu, click **Build**.
4. On the **Debug** menu, click **Start Without Debugging**.

   The main application window appears.

The following figure shows the ProcessController program running. Refer to the figure, as needed, while you perform the following test procedures:

- Load all services, device drivers, and processes running on some computer in the network.
- Start/Pause/Stop a service or a device driver running on the local/remote computer.
- Start a process running on the local computer.
- Terminate a process running on the local/remote computer.



To load all of the services, device drivers, and processes

1. Type the name of the computer you want in the **Machine Name** box.
2. Click the **Load Data** button (or press ALT+L).

To start a service

1. Click a service name in the **Stopped Services** list.
2. Right-click the service and click **Start Service** on the shortcut menu.

   After the service starts, its name should appear in the top-most list labeled **Running Services**.

   > **Note** You cannot start a service if you do not have the administrator rights on that computer.

To stop a service

1. Click a service name in the **Running Services** list.
2. Right-click the service and click **Stop Service** on the shortcut menu.

   After the service has been stopped, the name should appear in the **Stopped Services** list.

   > **Note** Some services do not accept the **Stopped** state. Also, you cannot stop a service if you do not have administrator rights on that computer.

To pause a running service

- Click a service name in the **Running Services** list.
- Right-click the service and click **Pause** on the shortcut menu.

  If the service is paused, the service name should appear in the **Paused Services** list at the bottom of the window.

  > **Note** Some services do not accept the **Paused** state. Also, you cannot pause a service if you do not have administrator rights on that computer.

To check some of the service's information

1. Click a service name in any of the three lists.
2. Right-click the service and click **Show Service Info** from the shortcut menu. A new window containing the service information will appear.

To verify and manage device drivers

1. Click the **Drivers** tab at the top of the window.
2. Go through the preceding steps to start, stop, and pause a service. Exactly the same rules mentioned for services apply to the device drivers.

To verify and manage processes

1. Click the **Process** tab at the top of the window.
2. Select a process name in the left-most list. At this point, information about that service should appear in the list on the right.

   Note If you are not an administrator on the target computer, you will not be able to see or manage any process.

To start a process

1. Click the **Start a Process** button (or press ALT+S).
2. Select the process you want to start in the **Open** dialog box.
3. Click the **Open** button in the dialog box. If your target computer is the local computer, the process name should appear in the left-most list.

   Note If the target computer is a remote computer, the process will start on the local computer, by default, if possible.

To stop a process

1. Click a process in the left-most list.
2. Right-click the process and click **Terminate Process** from the shortcut menu.

   After the process has been terminated, its name should disappear from the list.

To load the services, drivers, and processes from another computer

1. Type the name of the computer in the **Machine Name** box.
2. Click the **Load Data** button (or press ALT+L).

To stop the ProcessController application

- Click the **Close Application** button (or press ALT+C).

  After you click the button, the window will slowly fade away. This effect is obtained by handling the Window's Opacity property (file: MainForm.vb, method: cmdClose_Click).

Description of the Sample Classes

File	Description
MainForm.vb	Describes the MainForm class, which is a System.Windows.Forms.Form type class. Its designer contains most of the UI controls needed for this application.
ProcessControllerManager.vb	Contains the implementation of the ProcessControllerManager class. This class handles processes management.
DriverControllerManager.vb	Contains the implementation of the DriverControllerManager class. This class is in charge of managing the device drivers on a given computer.
ServiceControllerManager.vb	Contains the implementation of the ServiceControllerManager class. This class describes the logic to control the services on a given computer.
ServiceInfo.vb	Implements the ServiceInfo class, which is a System.Windows.Forms.Form class and is used to display services and drivers information only.

Windows Forms: Registry Client Sample

The Registry Client sample demonstrates the use of the Registry classes. It demonstrates how you can use these classes to add a new registry key and manipulate the values associated with that key.

This sample features Windows Forms, the .NET Framework, and the Windows registry.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the .sln file.
3. Press F5.

Windows Forms: Scribble Sample

The Scribble sample shows how to develop a Windows Forms MDI application using Visual Basic and the .NET Framework classes. Scribble is a small drawing application that lets you draw free-hand drawings using the mouse and save the images in a file.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the solution **Scribble.sln**.
3. On the **Build** menu, click **Build**.
4. On the **Debug** menu, click **Start Without Debugging**.

When you run the sample, you get a drawing surface and the following menus:

- **File** menu for input and output operations.
- **Edit** menu to cut, copy, and paste.
- **Pen** menu to select the pen thickness.
- **View** menu to show or hide the toolbar and the status bar.
- **Window** menu to create, tile, or cascade windows.
- **Help** menu to display the help topics and the About Scribble text box.

In addition to the menu options, the user interface includes a toolbar with buttons to duplicate the menu commands: **New**, **Open**, **Save**, **Print Preview**, **Print**, and **Help**.

Windows Forms: System Tray Sample

The System Tray sample demonstrates how to use the status area of the Windows taskbar in a Visual Basic .NET application. When run, the application adds a new icon to your system tray. Right-clicking the icon will display a shortcut menu with options to display a settings form, toggle the image in the tray, or quit the application.

This sample features Windows Forms, the status area of the taskbar, user controls, and context menus.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the .sln file.
3. Press F5.

Windows Forms: Vehicle Sample

The Vehicle sample demonstrates inheritance by implementing a vehicle class for cars and boats. The boat class overrides the base **ComputeRange** method to double the range for sailboats.

This sample features Windows Forms, language changes, and inheritance.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the .sln file.
3. Press F5.

   > **Note** If prompted that the project cannot be started directly, right-click **VehicleSampleBaseClient** in Solution Explorer and choose **Set As Startup Project**. Then press F5 again.

4. Choose a vehicle from the drop down list.
5. Enter Mpg and capacity information and press the **Compute Range** button.

Windows Forms: Weather Sample

The Weather sample uses the .NET Framework's XML classes to query an XML document and retrieve the weather forecast for a specified city. This sample uses the **XML** and **XMLDocumentNavigator** classes to open an XML document and issue an XPath query to find the weather for the selected city. The forecast is then displayed in a message box.

This sample features Windows Forms, the .NET Framework, and XML.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the .sln file.
3. Press F5.

Windows Forms: Winlogger Sample

The WinLogger sample contains a logging component that supports writing to a text file and the Windows Application Event Log. The logging component contains two classes that each implement the custom ILog interface. The client application prompts the user for a message and then provides the ability to call either logging interface.

This sample features Windows Forms, .NET Framework, file I/O, event log, and component.

> **Note** To install and run this sample, you must be a member of your computer's Debugger Users group. If installing this application by means of a remote session, you must be a member of the Administrators group.

To run this sample

1. Copy all files to your local hard drive by means of the **Copy All Files** link.
2. Open the .sln file.
3. Press F5.

   > **Note** If prompted that the project cannot be started directly, right-click **Winlogger** in Solution Explorer and choose **Set As Startup Project**. Then press F5 again.

4. Enter a message you wish to log.
5. Click the **Write to file** button and check the \WinLogger\Bin\LogFile.txt file.
6. Click the **Write to event log** button and check the Application LogStep1.

Visual Basic QuickStarts and Other Samples

You can find Visual Basic and other general samples at Program Files\Microsoft Visual Studio .NET\FrameworkSDK\Samples if you install them with the .NET Framework SDK. If you do not want to install the samples on your computer, go to the StartSamples.htm file in the ...\Samples folder in the .NET Framework SDK installation directory on the product CD or DVD.

QuickStarts

The QuickStarts are a series of samples and supporting documentation designed to quickly acquaint you with the syntax, architecture, and power of Visual Studio .NET and the .NET Framework. To access the QuickStarts, open the Start menu, then click Programs, Microsoft .NET Framework SDK, and then Samples and QuickStart Tutorials. The main page of the "Microsoft .NET Framework SDK QuickStarts, Tutorials and Samples" application will appear. To run the samples, follow the directions to install the samples database and complete the installation. After you have installed the QuickStarts, the "QuickStarts Tutorials" link will be functional.

The following QuickStarts are specific to Visual Basic:

Windows Forms

Description	Location
Hello World	quickstart\winforms\samples\simplehelloworld\vb\SimpleHelloWorld.vbproj quickstart\winforms\samples\designablehelloworld\vb\DesignableHelloWorld.vbproj
The Windows Forms Model	quickstart\winforms\samples\helloworldform\vb\HelloWorldForm.vbproj

Additional Samples

When you install the .NET Framework SDK, you can also access the following samples that represent complete applications or feature various technologies. (You can also find them on the CD at the location specified below.) The application samples demonstrate more complete error handling and object-oriented development, while the technology samples provide instruction on one or more features.

Each sample also contains a Readme.htm file with a brief description of the sample. The readme file is in the parent directory of the Visual Basic directory. For example, the readme file for the TypeFinder application is located in Samples\applications\typefinder.

You can also access the readme files in the "Microsoft .NET Framework SDK QuickStarts, Tutorials and Samples" application. To access the samples, select Start, Programs, Microsoft .NET Framework SDK, and then Samples and QuickStart Tutorials. The main page of the "Microsoft .NET Framework SDK QuickStarts, Tutorials and Samples" application will appear. There are links on this page to the Visual Basic samples described in the following table.

The following samples are specific to Visual Basic:

Sample	Location on CD
TypeFinder: a console application providing a tool that a user with a command-line interface can use to find out about types in the environment	Samples\applications\typefinder\vb\TypeFinderVB.vbproj
WinTalk: a simple "Sockets Chat" Windows application using Windows Forms	Samples\applications\wintalk\vb\WinTalkVB.vbproj
WordCount: a console application that counts the words in a text file and organizes the results depending on the arguments you use in the command line	Samples\applications\wordcount\vb\WordCountVB.vbproj
Object Construction: a technology sample demonstrating object construction strings	Samples\technologies\componentservices\objectconstruction\VB\OCFormVB.vbproj Samples\technologies\componentservices\objectconstruction\VB\OCObjVB.vbproj
Object Pooling: a technology sample demonstrating multiple client programs using one pooled object in a server application	Samples\technologies\componentservices\objectpooling\VB\OPFormVB.vbproj Samples\technologies\componentservices\objectpooling\VB\OPObjVB.vbproj
Queued Components: a technology sample demonstrating COM + queued components	Samples\technologies\componentservices\queuedcomponents\VB\QCFormVB.vbproj Samples\technologies\componentservices\queuedcomponents\VB\QCObjVB.vbproj
Role-Based Security: a technology sample that uses a server application to track a client application's user account and report whether it belongs to the administrator's role	Samples\technologies\componentservices\RoleBasedSecurity\VB\RBSecFormVB.vbproj Samples\technologies\componentservices\RoleBasedSecurity\VB\RBSecObjVB.vbproj
Configuration: a technology sample demonstrating how to use the .NET Framework Configuration WMI provider with the **System.Management** classes to read and write configuration files	Samples\technologies\Configuration\ConfigTest\VB\ConfigTestVB.vbproj
Delegates and Events: a technology sample demonstrating a type-safe callback mechanism	Samples\technologies\delegatesandevents\vb\DelegatesAndEventsVB.vbproj
Exceptions: a technology sample demonstrating structured exception handling	Samples\technologies\exceptions\vb\ExceptionsVB.vbproj
Garbage Collection: a technology sample showing how the heap manages all class objects by monitoring their lifetimes and freeing the objects when they are no longer referenced	Samples\technologies\GarbageCollection\VB\GarbageCollectionVB.vbproj
Permissions: a technology sample demonstrating how to grant or deny access to resources within a method call	Samples\technologies\permissions\vb\PermissionsVB.vbproj
Custom Attributes: a technology sample demonstrating how to create customer attributes and associate them with types and members. The sample also uses reflection to find out if a custom attribute is associated with a type or member	Samples\technologies\reflection\customattribute\vb\CustomAttributeVB.vbproj
Dynamic Type Resolution: a technology sample demonstrating how a distributed application can increase flexibility and fault-tolerance using a type resolution process.	Samples\technologies\reflection\DynamicTypeResolve\VB\DynamicTypeResolveVB.vbproj
Reflection Invoke: a technology sample demonstrating how a distributed application can increase flexibility and fault-tolerance using a type resolution process	Samples\technologies\reflection\invoke\vb\InvokeVB.vbproj Samples\technologies\reflection\invoke\vb\TesterVB.vbproj
Reflection Emit: a technology sample demonstrating how to use a run-time feature that allows code to create dynamic assemblies, modules, and types	Samples\technologies\reflection\reflectionemit\vb\ReflectionEmitVB.vbproj
Serialization: a technology sample demonstrating how the common language runtime can serialize an object graph in memory to a stream using the SoapFormatter or the BinaryFormatter	Samples\technologies\serialization\vb\SerializationVB.vbproj

Join Thread: a technology sample demonstrating the common language runtime feature that allows one thread to either wait for another thread to terminate or "join' with another thread	Samples\technologies\threading\jointhread\vb\JoinThreadVB.vbproj
Monitor Synchronization: a technology sample demonstrating how to use the **Monitor** class to synchronize threading	Samples\technologies\threading\monitorsynchronization\vb\MonitorSynchronizationVB.vbproj
Thread Pools: a technology sample demonstrating how to use the **ThreadPool** class by queuing an asynchronous method call that is executed by a thread from the thread pool managed by the common language runtime	Samples\technologies\threading\pools\vb\PoolsVB.vbproj
Reader-Writer Synchronization: a technology sample demonstrating how to use the **ReaderWriterLock** class. This allows you to enforce exclusive access to a shared resource while a thread is writing or modifying a resource, but allows nonexclusive access when readying or querying the resource	Samples\technologies\threading\readerwritersynchronization\vb\ReaderWriterSynchronizationVB.vbproj
Thread Static: a technology sample demonstrating how to use the **ThreadStaticAttribute** type to create static variables backed by thread local storage	Samples\technologies\threading\threadstaticvariables\vb\ThreadStaticVariablesVB.vbproj
Timers: a technology sample demonstrating how to use timers in the common language runtime	Samples\technologies\threading\timers\vb\TimersVB.vbproj
Wait Synchronization: a technology sample demonstrating how to use the **WaitHandle** class for thread synchronization by enforcing mutually exclusive access to a protected code block	Samples\technologies\threading\waitsynchronization\vb\WaitSynchronizationVB.vbproj
Value and Enum Types: a technology sample demonstrating how to work with value and enumerated types	Samples\technologies\valueandenumtypes\vb\ValueAndEnumTypesVB.vbproj

Visual C# Samples

You can access sample code in two ways:

- Browse the sample abstracts in this section. Each abstract contains a link to open or copy the sample's files. For help on locating a particular sample, see Finding a Sample.
- Browse the Visual C# samples directory structure on the product CD or DVD (Samples\vcsharp).

In This Section

General Samples
Provides links to samples that use Visual Studio project templates and designers and demonstrate different kinds of applications such as Windows Forms and Web Forms.

Tutorial Samples
Provides links to samples that are used in the C# tutorials.

Cross-Language Samples
Provide links to samples that demonstrate cross-language interoperability between Visual C# and Visual C++.

QuickStarts and Other Samples
Provide an overview and installation procedure of many more samples which cover the most compelling features of the .Net Framework technology.

General Samples

This section contains sample abstracts for the Visual C# general samples. The samples in this section use Visual Studio project templates and designers and demonstrate different kinds of applications such as Windows Forms and Web Forms.

Sample	Description
AutoWord	Demonstrates how to automate Word from Visual C#.
CarsSelector	Demonstrates how to create a Web Forms page for selecting cars that simulates a simple e-commerce page. The sample demonstrates using the ASP.NET technology.
LocalizedHelloWorld	Demonstrates how to create and use satellite assemblies for console applications.
MultilingualForm	Demonstrates how to create and localize Windows Forms.
PerfMon	Demonstrates how to monitor system performance using performance counters and is an introduction to p erformance counters.
ProcessController	Demonstrates how to build a Visual C# Windows application for processes and services monitoring.
Scribble	Demonstrates a Windows Forms MDI drawing application.

AutoWord Sample: Demonstrates Automating Microsoft Word

The AutoWord sample includes four examples that show how to automate Microsoft Word from Visual C#. The examples demonstrate how to automate the following activities:

- Starting Word
- Creating a new document
- Opening an existing document
- Hooking events in the Word application

The sample also shows how to create an interop assembly for Microsoft Word, and shows some rudimentary techniques for automating Word.

> **Note** One of the projects in this sample is a C++ project, so Visual C++ must also be installed.

Projects in the Sample

This sample contains five projects and produces three assemblies.

Building and Running the Sample

To create the assemblies

1. Open the solution AutoWord.sln.
2. Right-click the **RunCreateWordAssembly** project, then click **Build.**
3. For each of the example projects, right-click the **References** item, then click **Add Reference**. Click the **Browse** button, select WORD.DLL from the list of .dll files, then click the **Open** button. Click the **OK** button to close the reference browser, and click the **OK** button for the popup window telling you that the directory WORD.DLL was found in will be added to the reference path.
4. If you have installed Microsoft Word XP or Office XP, add **OFFICEXP** to the list of compilation constants. For each of the example projects, right-click the project root, then click **Properties**. Select **Configuration Properties**, then **Build**, and then add **OFFICEXP** to the list of **Conditional Compilation Constants**. Click the **OK** button.

   > **Note** It is not enough to define **OFFICEXP** in the Debug and the Release configurations. You must define **OFFICEXP** in each configuration.

5. From the **Build** menu, click **Build Solution**.

To run the automation examples

1. Right-click **Example1** in **Solution Explorer** and select **Set as Startup Project** from the shortcut menu, then build and run the project.

   This example shows you how to instantiate the Word object without any documents.

2. Right-click **Example2** in **Solution Explorer** and select **Set as Startup Project** from the shortcut menu, then build and run the project.

   This example shows you how to create a new Word document and put some text into it.

3. Right-click **Example3** in **Solution Explorer** and select **Set as Startup Project** from the shortcut menu, then build and run the project.

   This example shows you how to open an existing Word document and modify it.

4. Right-click **Example4** in **Solution Explorer** and select **Set as Startup Project** from the shortcut menu, then build and run the project.

   This example shows you how to hook various events in Word.

Classes and Keywords

This sample demonstrates the following classes:

System.Diagnostics.Process, System.Environment, System.Reflection.Missing, System.Text.StringBuilder, System.Windows.Forms.MessageBox, System.Thread.Sleep, System.Reflection.Missing.Value, Microsoft.Win32.RegistryKey, Word.Application, Word.ApplicationEvents2_DocumentChangeEventHandler, Word.ApplicationEvents2_DocumentOpenEventHandler, Word.ApplicationEvents2_NewDocumentEventHandler, Word.ApplicationEvents2_StartupEventHandler, Word.Documents, Word._Document, Word.Range, Word.Words

This sample demonstrates the following keyword:

event

CarsSelector Sample: Demonstrates Creating and Using ASP.NET Web Pages

The CarsSelector sample shows you how to build Web Forms page for selecting cars that simulates a simple e-commerce page. The sample demonstrate the following features:

- Data binding: In this sample you use more than one type of data binding:
  - Simple data binding.
  - Binding to a data table created programmatically (the data source is not coming from a database).
- Using the event handler to dynamically change the binding of some controls.
- Using validation controls.
- Using the Calendar control and validating its entries without using the validation controls.

Requirements

To build and run this sample, you need a computer running Internet Information Services 5.0 with FrontPage Server Extensions installed.

Building and Running the Sample

To create the solution

1. Copy the sample files to your hard disk.
2. Create a new **Web Application** and name it CarsSelector.
3. Delete the default Web Forms page by right-clicking the file **WebForm1.aspx**, and then click **Delete** on the shortcut menu.
4. Add the file CarsSelectorSample.aspx to the project. To do that, right-click the project name, point to **Add** on the shortcut menu, and click **Add Existing Item**. Change the **Types of files** to All Files (*.*), then browse to the file CarsSelectorSample.aspx, select it, and click **Open**.
5. Add the file CarsSelectorSample.aspx.cs to the project. To do that, right-click the project name, point to **Add** on the shortcut menu, and click **Add Existing Item**. Then browse to the file CarsSelectorSample.aspx.cs, select it, and click **Open**. Click **OK** to overwrite the existing file.
6. Set the Web Forms page as a start page. To do that, right-click the file **CarsSelectorSample.aspx** and click **Set As Start Page** on the shortcut menu.

For more information on creating Web Forms applications**,** see Creating and Managing Web Forms.

To build and run the sample

1. On the **Build** menu, click **Build Solution**.
2. On the **Debug** menu, click **Start Without Debugging**.

   The Web Forms page appears. You can select a car and make choices, and then you see the result bound to a label.

To use the Web form

1. Start by selecting a car brand from the drop-down list **Brand**.
2. Choose a model from the **Model** drop-down list. You will notice that the contents of this list depend on the selected brand of the car.
3. Choose the **Year**, **Color**, and **Mileage** from the appropriate drop-down list.
4. Enter an e-mail address in the **Your Email** text box.
5. Select one or more check boxes from the **Features Desired**.
6. Select a valid date in the **Desired Available Date** calendar.
7. Click **Submit**.

Classes and Keywords

This sample demonstrates the following class:

System.Web.UI.Page

This sample demonstrates the following keywords:

DropDownList, AutoPostback, CheckBoxList, RequiredFieldValidator, RegularExpressionValidator, Dilatable

Visual C# Samples | General Samples

LocalizedHelloWorld Sample: Demonstrates Satellite Assemblies for Console Applications

The LocalizedHelloWorld sample demonstrates creating and using satellite assemblies for console applications. It shows how to create resources for C# console applications, localize the resources, and build localized satellite assemblies.

Although this sample was written using C#, the sample principles and techniques can be used to localize any managed application written in any language.

Building and Running the Sample

To build and run this sample

1. Open the solution LocalizedHelloWorld.sln.
2. From the **Build** menu, click **Build Solution**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Type in a culture supported by the application to see the resources in that culture (the sample ships with **en**, **en-US**, **ko-KR**, and **default** resources which are in English).

To add a new culture

The following procedure adds resources for English (United Kingdom):

1. Add a new text file named "MyResources.en-GB.txt" to the Resources C++ utility project.
2. Add the appropriate <name>=<value> lines to the new text file along with any desired comments.
3. Add a custom build step for the new file (this should be the same as for the other resource files in the project):

   ResGen.exe "$(InputPath)"

4. Set the output of the custom build step to "$(InputName).resources."
5. Build this project (no need to rebuild the main assembly).
6. Add an existing file named "..\Resources\MyResources.en-GB.resources" to the SatelliteAssemblies C++ utility project.
7. Add a custom build step for this file (this should be similar to the other files' custom builds steps):

   mkdir $(ProjectDir)..\bin\$(OutDir)\en-GB

   al.exe /culture:en-GB /out:"$(ProjectDir)..\bin\$(OutDir)\en-GB\HelloWorld.resources.dll" /embed:"$(InputPath)","HelloWorld.Resources.$(InputFileName)" /template:"$(ProjectDir)..\obj\$(IntDir)\HelloWorld.exe"

8. Set the output of the custom build step to "$(ProjectDir)..\bin\$(OutDir)\en-GB\HelloWorld.resources.dll"
9. Build this project (no need to rebuild the main assembly).
10. Run the sample and try your new resource.

To build the sample from the command line

Note You can add options to the C# command-line for debugging or other reasons.

1. Compile the resource for all cultures (from the Resources subdirectory):

   ResGen.exe MyResources.txt

   ResGen.exe MyResources.en-US.txt

   ResGen.exe MyResources.ko-KR.txt

2. Create the output directory "bin\Debug" or use a different directory in the following steps.
3. Compile the main assembly and embed the default resources (from the root project directory):

   csc.exe /out:bin\Debug\HelloWorld.exe /res:Resources\MyResources.resources,HelloWorld.Resources.MyResources.resources Class1.cs AssemblyInfo.cs

4. Build the satellite assemblies (from the root project directory):

   mkdir bin\Debug\en-US

   mkdir bin\Debug\ko-KR

   al.exe /culture:en-US /out:bin\Debug\en-US\HelloWorld.resources.dll /embed:Resources\MyResources.en-US.resources,HelloWorld.Resources.MyResources.en-US.resources /template:bin\Debug\HelloWorld.exe

   al.exe /culture:ko-KR /out:bin\Debug\ko-KR\HelloWorld.resources.dll /embed:Resources\MyResources.ko-KR.resources,HelloWorld.Resources.MyResources.ko-KR.resources /template:bin\Debug\HelloWorld.exe

Projects in the Sample

This sample contains three projects and produces three assemblies.

Resources C++ Utility Project

This is the first project. It builds the managed resources with a custom build step that calls ResGen.exe to compile the .txt files into .resources files. The resource text file contains lines of <name>=<value> statements and comment lines that begin with a pound sign (#). In code, the strings will be loaded using

the name given in this file.

Notice that for the Korean resources the file must be saved as UTF-8 to preserve the non-ASCII characters. Also note that individual cultures are not required to have a value for every name.

If a value doesn't exist for the proper culture, the resource manager automatically falls back to the parent cultures. For example, if the current culture is ko-KR, the resource manager will first look for the name in the "ko-KR" resources, then in the "ko" resource, and then finally in the default resources. Technically these resource files can be named anything, but typically they are named with the following convention:

<basename>[.<culture>].resources

If the culture is empty, it is assumed to be the default culture.

HelloWorld C# Console Project

This is the second project. It builds the main C# application and embeds the default resources (MyResources.resources built from MyResources.txt by the first project).

SatelliteAssemblies C++ Utility Project

This is the third project. It builds the two satellite assemblies that contain the localized resources with custom build steps. It calls Al.exe to create the satellite assembly, passing in the resource file with the "/embed" option, setting the culture with the "/culture" option, and copying the assembly information (title, version, and so on) from the main assembly with the "/template" option.

Note that the satellite assemblies must be in a subdirectory named after their culture of the main assembly, and the satellite assembly's file name is the same as the main assembly, but with ".resources" inserted before the file extension. For example, if the main assembly was "c:\bin\a.dll", the en-US satellite assembly would be "c:\bin\en-US\a.resources.dll".

Also note the second argument to the "/embed" option, the resources name. This name is the name that the resource manager will use to find the given resource group, and the name must include the proper culture string (case-sensitive) after the name and before ".resources". Because Al.exe gets most of the information from the main assembly, this third project must be built after the second one.

Classes and Keywords

This sample demonstrates the following classes:

System.Resources.ResourceManager

This sample demonstrates the following keywords:

managed resources, satellite assembly, localized resources, ResGen.exe, al.exe, /embed, /res, /template, /culture, System.Resources, System.Resources.ResourceManager, System.Resources.ResourceManager.GetString

MultilingualForm Sample: Demonstrates Creating and Localizing Windows Forms

The MultilingualForm sample demonstrates creating and localizing windows forms. It shows how to use the Windows Forms designer to create, edit, and build localized applications.

For more information about localized applications, see Globalizing and Localizing.

Building and Running the Sample

To build and run this sample

1. Open the solution MultilingualForm.sln.
2. From the **Build** menu, click **Build Solution**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. To see a different culture's resources, type a valid RFC 1766 culture name into the edit box and click the **switch** button. (This sample only comes with resources for "en-US" and "ko-KR".)

To localize your own Windows Forms or Web Forms

1. Select the form to be localized in the appropriate forms designer.
2. Set the form's **Localizable** property to true.
3. For each language you want to localize to, do the following:
   a. Set the form's **Language** property to the desired language.
   b. Enter the new text in the new language for each control.

   You can also change the appearance of the form's controls (size, position, and so on) for each language.

Classes and Keywords

This sample demonstrates the following classes:

System.Resources.ResourceManager

This sample demonstrates the following keywords:

System.Windows.Forms.Form.Localizable; System.Windows.Forms.Form.Language; System.Resources; System.Resources.ResourceManager

See Also

Visual C# Samples | General Samples | Windows Forms: Multilingual Form Sample (Visual Basic)

PerfMon Sample: Demonstrates How to Monitor System Performance Using Performance Counters

The PerfMon sample is an introduction to performance counters. It demonstrates how to monitor local or remote system performance. It shows how to dynamically create timers, context menus, and graphic displays. It also demonstrates the following activities:

- Including new C# classes derived from other components.
- Dynamically adding and removing event handlers and components.
- Using the **TreeView** control, **TreeNode** class, and **Timer** component.
- Using the **PerformanceCounterCategory** and **PerformanceCounter** components.

For more information on performance counters, see PerformanceCounter Class.

> **Note** This sample is functional only on Windows NT 4.0 and Windows 2000 and later.

Building and Running the Sample

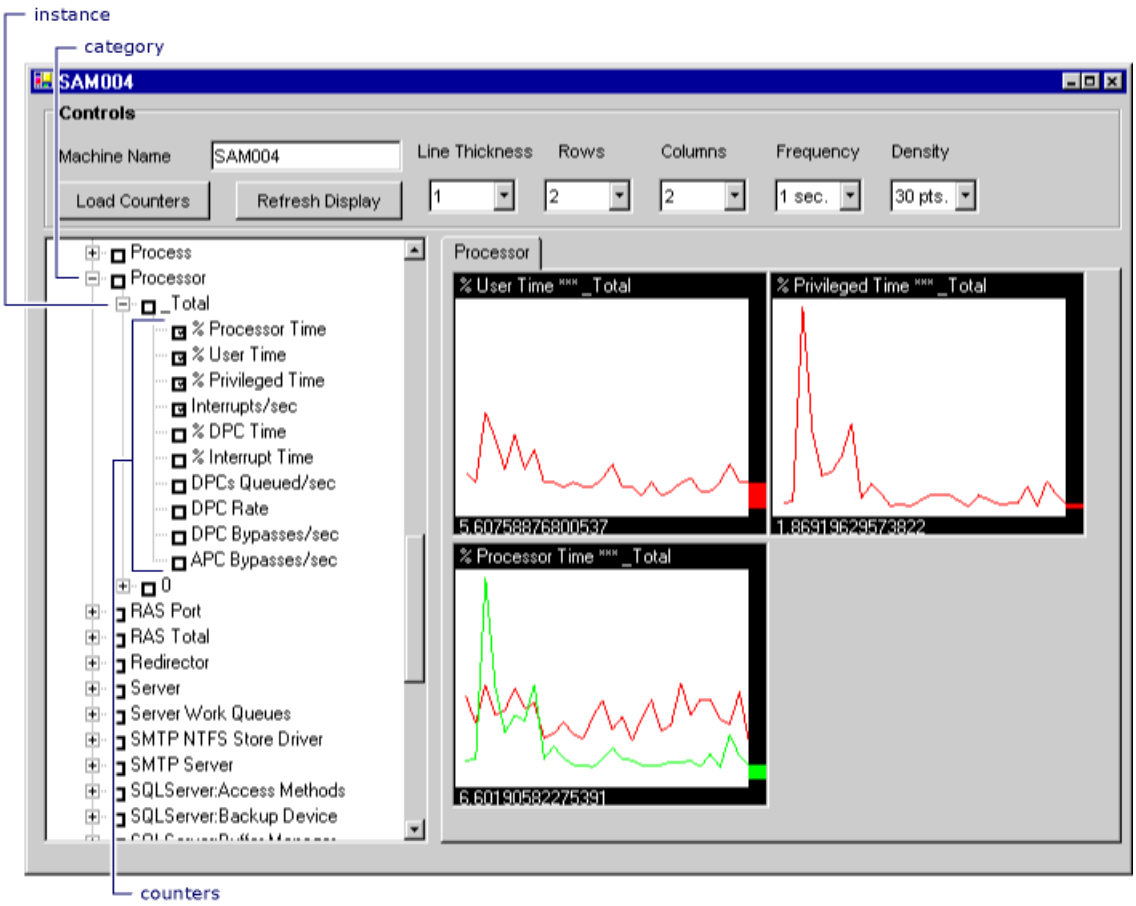
To build and run this sample

1. Open the solution PerfMon.sln.
2. From the **Build** menu, click **Build Solution**.
3. From the **Debug** menu, click **Start Without Debugging**.

   The main application window will appear.

The following figure shows the performance monitor program running. Refer to the figure, as needed, while you go through the various performance monitoring procedures.

Performance Monitor



The Display Panel Properties

Each graphic display in the figure shows the following:

- The top of the display shows the name of the counter and the name of the instance separated by "***". If the category does not contain an instance name (for example, the ICMP category), the "***" is followed by a blank space.
- The bottom of the display shows the current counter value. This value may change periodically (the default is every second).
- The right side of the display shows a red bar. The height of the bar depends on the last value monitored on the counter.
- The graph plotted in the display shows the performance history for that counter.

To load the performance counters of a system

This application is an MDI application. It starts with four windows that can be used to monitor four computers. You can open as many windows as you want by clicking the **New PerfMon** command on the **Options** menu. In the following procedures, only one window is used. Therefore, you can close all of the windows except one.

1. In the **Machine Name** field, type the name of the system you want to monitor. If you do not type anything, the local machine will be monitored.
2. Click the **Load Counters** button (or press **ALT+L**). The application will load **PerformanceCounterCategory**, **InstanceName**, and **PerformanceCounter** components on the specified machine. The **Load Counters** button will be disabled until all of the counters on the system have been loaded.

   The tree view in the left pane will contain all of the performance categories and the performance counters available. Each leaf in the tree represents a performance counter. You can monitor the completion progress by watching the progress indicator on the bottom of the application window. After the tree has been completed, the **Load Counters** button will be enabled again.

   > **Note** To monitor a specific machine, you need administrator rights to the machine; otherwise, the **PerformanceCounterCategory** components will not be able to load the categories (security protection).

To monitor the performance of a system

1. Load the performance counters by performing the preceding steps.
2. Select one of the counters by expanding the corresponding category node. For example, to watch the performance of the processor, expand the **Processor** node, and then select one of the **Processor** instances (for example, "**_Total**" or "**0**"). Expand the instance node as well to see the counters.
3. On the leaf level, the counters are represented by check boxes. Select one of the counters, for example, **%Processor Time**. A tab, which has the name **Processor**, will appear in the right pane, and a graphic display of the selected counter will appear on the tab page.
4. To remove a specific graphic display from the tab page, clear the check box for the corresponding counter. When all of the counters in a specific page are cleared, the corresponding tab disappears.

To manage the displays properties

> **Note** Each time you change any of the display properties, click the **Refresh Display** button to apply the changes. The changes will apply for current or future displays.

- To change the line thickness, select the thickness you want from the **Line Thickness** box.
- To change the number of rows/display, select the number you want from the **Rows** box. For example, selecting one row makes the display occupy the full height of the tab page.
- To change the number of columns/display, select the number you want from the **Columns** box. For example, selecting one column makes the display occupy the full width of the tab page.

  > **Note** If the number of graphic displays exceeds the visible area of the tab page, scroll bars will be created automatically.

- To change the time interval, select the number of seconds from the **Frequency** box.
- To change the number of points to display in the graph, select a number from the **Density** box.

To merge two or more displays

1. Drag the display you want to move and drop it on the destination display. Notice that the background of the destination display becomes black when it is selected and is ready to receive the moved display. Both displays will merge, and two different graphic colors will appear (red and green in this case). For example, if you drop "**%Processor Time *** _total**" on "**%User Time *** _total**", the green color will represent the first and the red color will represent the second. The data shown in the display's top, bottom, and right side will only represent the **"%Processor Time *** _total**" counter.

2. To switch from one graph to another after a display merge, right-click the display and select the name of the graph from the shortcut menu. In the preceding example, if you want to change the display data from "**% Processor Time *** _total**" to "**%User Time *** _total**", right-click the display and select **"%User Time *** _total**" from the shortcut menu. The display will show the data of the selected counter, and the bar color on the right side will change to red (or the color representing the selected counter).
3. If you have more than two merged counters, each counter will be represented by a different color. To select the data view for any one of the counters, perform the preceding step.

To separate two or more merged displays

1. Locate the counter's check box of the display you want to separate.
2. Clear the counter's check box. The corresponding display will be removed.
3. Select the counter's check box again. A new display will appear on the tab page.

To use menu options

- To stop the graphics plotting:

  1. Click the **Option** menu (or press ALT+O).
  2. Click **Stop Graphics**.

  The graphics will freeze and no more lines will be plotted.

- To restart the graphics plotting:

  1. Click the **Option** menu.
  2. Click **Start Graphics**.

  The displays will continue plotting from the last position.

- To exit the application:

  1. Click the **Option** menu.
  2. Click **Exit**.

Classes and Keywords

This sample demonstrates the following classes:

System.Windows.Forms.Form, System.Windows.Forms.TabControl, System.Windows.Forms.TabPage, System.Windows.Forms.Panel, System.Windows.Forms.ProgressBar, System.Windows.Forms.TreeView, System.Windows.Forms.TreeNode, System.Windows.Forms.MouseButtons, System.Windows.Forms.ContextMenu, System.Windows.Forms.MenuItem, System.Collection.HashTable, System.Drawing.Color, System.Drawing.Graphics, System.Diagnostics.PerformanceCounterCategory, System.Diagnostics.PerformanceCounter

This sample demonstrates the following keywords:

PerformanceCounterCategory, PerformanceCounter, Graphics, GraphicTab, HashTable, DisplayPanel, ContextMenu, MenuItem, Draw, Color, TreeView, TreeNode, ProgressBar, TabControl, TabPage

See Also

Visual C# Samples | General Samples | Windows Forms: Performance Monitor Sample (Visual Basic)

ProcessController Sample: Demonstrates Processes and Services Monitoring

The ProcessController sample shows how to build a C# Windows application for processes and services monitoring. The sample also demonstrates the following activities:

- Dynamically adding and removing event handlers.
- Using the **Process** component to:
  - Read the running processes on the local/remote machine.
  - Start a process on the local machine.
  - Stop a process on the local/remote machine.
  - Read the modules used by some running process.
  - Read all of the characteristics of some running process.
- Using the **ServiceController** component to:
  - Read the running services and device drivers on the local/remote machine.
  - Start/Stop/Pause a service on the local/remote machine.
  - Check properties of the services or device drivers on the local/remote machine.
- Handling security issues related to the use of the **Process** and the **ServiceController** components.

  Note This sample only runs on the Windows NT or Windows 2000 operating systems since the **ServiceController** component is only supported on Windows NT platforms.

Building and Running the Sample

To build and run this sample

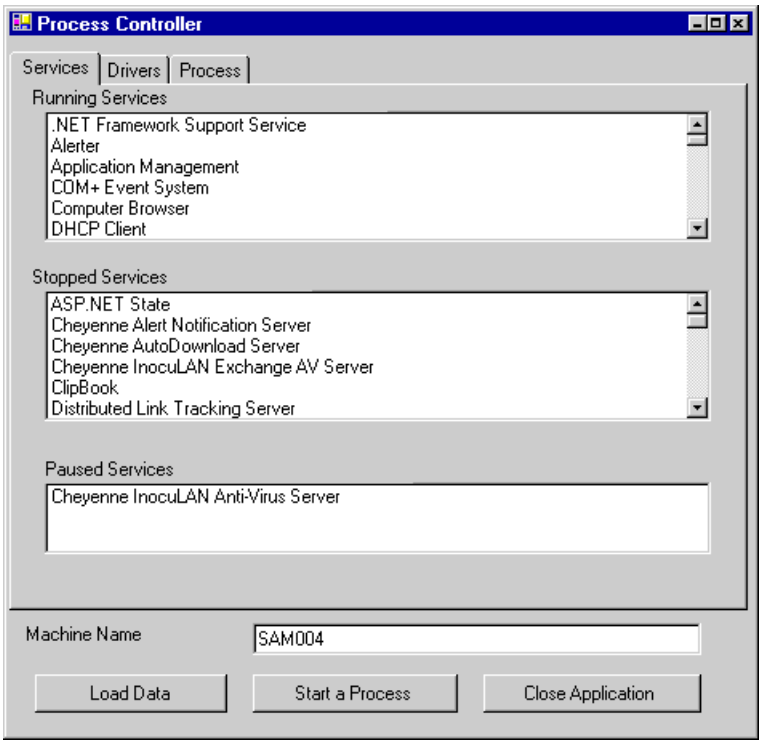
1. Open the solution ProcessController.sln.
2. From the **Build** menu, click **Build Solution**.
3. From the **Debug** menu, click **Start Without Debugging**.

   The main application window will appear.

The following figure shows the ProcessController program running. Refer to the figure, as needed, while you perform the following test procedures:

- Load all services, device drivers, and processes running on some machine in the network.
- Start/Pause/Stop a service or a device driver running on the local/remote machine.
- Start a process running on the local machine.
- Terminate a process running on the local/remote machine.

Process Controller



To load all of the services, device drivers, and processes

1. Type the name of the machine you want in the **Machine Name** box.
2. Click the **Load Data** button (or press ALT+L).

To start a service

1. Click a service name in the **Stopped Services** list.
2. Right-click the service and click **Start Service** from the shortcut menu.

   After the service starts, its name should appear in the topmost list labeled **Running Services**.

   Note You cannot start a service if you do not have the administrator rights on that machine.

To stop a service

1. Click a service name in the **Running Services** list.
2. Right-click the service and click **Stop Service** from the shortcut menu.

   After the service has been stopped, the name should appear in the **Stopped Services** list.

   Note Some services do not accept the **Stopped** state. Also, you cannot stop a service if you do not have the administrator rights on that machine.

To pause a running service

1. Click a service name in the **Running Services** list.
2. Right-click the service and click **Pause** from the shortcut menu.

   If the service is paused, the service name should appear in the **Paused Services** list at the bottom of the window.

   Note Some services do not accept the **Paused** state. Also, you cannot pause a service if you do not have the administrator rights on that machine.

To check some of the service's information

1. Click a service name in any of the three lists.
2. Right-click the service and click **Show Service Info** from the shortcut menu. A new window containing the service information will appear.

To verify and manage device drivers

1. Click the **Drivers** tab at the top of the window.

2. Go through the preceding steps to start, stop, and pause a service. Exactly the same rules mentioned for services apply to the device drivers.

To verify and manage processes

1. Click the **Process** tab at the top of the window.
2. Select a process name in the leftmost list. At this point, information about that service should appear in the list on the right.

   Note If you are not an administrator on the target machine, you will not be able to see or manage any process.

To start a process

1. Click the **Start a Process** button (or press ALT+S).
2. Select the process you want to start in the **Open** dialog box.
3. Click the **Open** button in the dialog box. If your target machine is the local machine, the process name should appear in the leftmost list.

   Note If the target machine is a remote machine, the process will start on the local machine, by default, if possible.

To stop a process

1. Click a process in the leftmost list.
2. Right-click the process and click **Terminate Process** from the shortcut menu.

   After the process has been terminated, its name should disappear from the list.

To load the services, drivers, and processes from another machine

1. Type the name of the machine in the **Machine Name** box.
2. Click the **Load Data** button (or press ALT+L).

To stop the ProcessController application

- Click the **Close Application** button (or press ALT+C).

  After you click the button, the window will slowly fade away. This effect is obtained by handling the Windows Opacity property (file: MainForm.cs, method: cmdClose_Click).

Description of the Sample Classes

File	Description
MainForm.cs	Describes the MainForm class, which is a **System.Windows.Forms.Form** type class. Its designer contains m ost of the UI controls needed for this application.
ProcessControllerM anager.cs	Contains the implementation of the ProcessControllerManager class. This class handles processes managem ent.
DriverControllerMa nager.cs	Contains the implementation of the DriverControllerManager class. This class is in charge of managing the d evice drivers on a given machine.
ServiceControllerM anager.cs	Contains the implementation of the ServiceControllerManager class. This class describes the logic to control the services on a given machine.
ServiceInfo.cs	Implements the ServiceInfo class, which is a **System.Windows.Forms.Form** class and is used to display ser vices and drivers information only.

Classes and Keywords

This sample demonstrates the following classes:

System.Windows.Forms.Form, System.Windows.Forms.TabControl, System.Windows.Forms.ListBox, System.Windows.Forms.TabPage, System.Windows.Forms.OpenFileDialog, System.Collections.Hashtable, System.Windows.Forms.Timer, System.EventHandler, System.Windows.Forms.ContextMenu, System.Diagnostics.Process, System.ServiceProcess.ServiceController

This sample demonstrates the following keywords:

C# Windows Application; Process component; ServiceController component; C# Class inclusion; TabControl and TabPage; Event Handler dynamic load; ListView control; ContextMenu control and MenuItems; HashTable object; Timer control; System security

issues; System.Array.Sort

Scribble Sample: Visual C# MDI Drawing Application

The Scribble sample shows how to develop a Windows Forms MDI application using Visual C# and the .NET Framework classes. Scribble is a small drawing application that lets you draw free-hand drawings using the mouse and save the images in a file.

Building and Running the Sample

To build and run this sample

1. Open the solution Scribble.sln.
2. From the **Build** menu, click **Build Solution**.
3. From the **Debug** menu, click **Start Without Debugging**.

When you run the sample, you get a drawing surface and the following menu items:

- **File** menu for input and output operations.
- **Edit** menu to cut, copy, and paste.
- **Pen** menu to select the pen thickness.
- **View** menu to show or hide the toolbar and the status bar.
- **Window** menu to create, tile, or cascade windows.
- **Help** menu to display the help topics and the About Scribble text box.

In addition to the menu options, the user interface includes a toolbar with buttons to duplicate the menu commands: **New**, **Open**, **Save**, **Print Preview**, **Print**, and **Help**.

Other Versions of Scribble

Scribble is also available as an MFC sample, as a Managed Extensions for C++ sample, and as Visual Basic sample:

- Scribble Sample: MFC MDI Drawing Application
- Scribble Sample: MDI Drawing Application Using Managed Extensions for C++
- Windows Forms: Scribble Sample

Classes and Keywords

This sample demonstrates the following classes:

System.Windows.Forms; System.Collections.Arraylist; System.Drawing.Printing; System.Runtime.Serialization; System.Runtime.Serialization.Formatters.Binary

This sample demonstrates the following keywords:

System.Windows.Forms.Form; System.Windows.Forms.Form.MDIParent; System.Windows.Forms.Form.MDIChildren; System.Windows.Forms.ImageList; System.Windows.Forms.HelpProvider; System.Windows.Forms.ToolBar; System.Windows.Forms.StatusBar; System.Windows.Forms.OpenFileDialog; System.Windows.Forms.SaveFileDialog; System.Windows.Forms.Menu; System.Windows.Forms.MenuItem; System.Windows.Forms.PrintPreviewDialog; System.Windows.Forms.Help; System.Drawing.Printing; System.Drawing.Printing.PrintDocument; System.Drawing.Pen; System.Drawing.Graphics; System.Drawing.Graphics.DrawLine; System.Collections.ArrayList; System.Runtime.Serialization.Formatters.Binary

Tutorial Sample

The code for the ATL Server Tutorial.

Demonstrates Web access to a database for a simple online store. When you run the application, a Web page prompts you for a username and password. You can either enter a username and password for an existing customer in the database, or create a new account, in which case the application will write the new username and password to the database.

Building and Running the Sample

To build and run this sample

1. Open the solution file, Tutorial.sln, in the Visual Studio development environment.
2. Build the solution. This will also deploy the solution to the local Web server.
3. Configure the data link to connect to the Tutorial.mdb database. In the sample's Tutorial\Tutorial\bin directory, double-click Tutorial.udl.

   The **Data Link Properties** dialog box appears.
4. On the **Provider** tab, select **Microsoft Jet 4.0 OLE DB Provider**.
5. On the **Connection** tab, click the Ellipsis (...) button to specify the Tutorial.mdb file in the Tutorial\Tutorial\bin directory. Leave the username and password blank.
6. Ensure that Tutorial.mdb is not read-only. Right-click the file and select **Properties**; on the **General** tab, ensure that the **Read-only** check box is cleared.
7. Change the NTFS security settings on the Tutorial.mdb file to allow read-write access by the Internet Guest Account, **IUSR**_*Machine*. To do this:
   a. Right-click the Tutorial.mdb file and select **Properties** on the shortcut menu.
   b. In the **Properties** dialog box, select the **Security** tab and click **Add**.
   c. The **Select Users or Groups** dialog box appears; in that dialog box, set the following:

      Object Types to **Users**.

      Locations to the local machine.

      Check Names to **IUSR**_*Machine*.

   d. Select the Internet Guest Account that you just created and in the **Permissions** box, check the **Read** and **Write** boxes if they are not already.

      > **Note** See ATL Server Security for information about the accounts used by a typical ATL Server application running in IIS.
8. Change the NTFS security settings on the folder containing Tutorial.mdb to allow only write access by **IUSR**_*Machine* (using the procedure described in Step 7).
9. Change the NTFS security settings on the Tutorial.udl file to allow read access by the **IUSR**_*Machine* account (using the procedure described in Step 7).
10. Use a Web browser to view http://localhost/tutorial/login.srf.

For more information, see ATL Server Tutorial.

Hello World Sample

This sample shows several versions of a Hello World program in C#.

This sample contains the source code for the Hello World Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Hello World samples

1. Open the solution (HelloWorld.sln).
2. In **Solution Explorer**, right-click the HelloWorld1 project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Press any key to close HelloWorld1.
5. In **Solution Explorer**, right-click the HelloWorld2 project and click **Set as StartUp Project**.
6. From the **Debug** menu, click **Start Without Debugging**.
7. Press any key to close HelloWorld2.
8. In **Solution Explorer**, right-click the HelloWorld3 project and click **Set as StartUp Project**.
9. In **Solution Explorer**, right-click the HelloWorld3 project and click **Properties**.
10. Open the Configuration Properties folder and click **Debugging**.
11. In the Command Line Arguments property, type "A B C D" and click **OK**.
12. From the **Debug** menu, click **Start Without Debugging**.
13. Press any key to close HelloWorld3.
14. In **Solution Explorer**, right-click the HelloWorld4 project and click **Set as StartUp Project**.
15. From the **Debug** menu, click **Start Without Debugging**.
16. Press any key to close HelloWorld4.

Building and Running the Sample from the Command Line

To build and run the Hello World samples

1. Use the **Change Directory** command to change to the HelloWorld directory.
2. Type the following:

```
cd HelloWorld1
csc Hello1.cs
Hello1
```

3. Type the following:

```
cd ..\HelloWorld2
csc Hello2.cs
Hello2
```

4. Type the following:

```
cd ..\HelloWorld3
csc Hello3.cs
Hello3 A B C D
```

5. Type the following:

```
cd ..\HelloWorld4
csc Hello4.cs
Hello4
```

Command Line Parameters Sample

This sample shows how the command line can be accessed and two ways of accessing the array of command-line parameters.

This sample contains the source code for the Command Line Parameters Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Command Line Parameters samples

1. Open the solution (CommandLine.sln).
2. In **Solution Explorer**, right-click the CmdLine1 project and click **Set as StartUp Project**.
3. In **Solution Explorer**, right-click the project and click **Properties**.
4. Open the Configuration Properties folder and click **Debugging**.
5. In the Command Line Arguments property, type the command-line parameters (see the tutorial for an example) and click **OK**.
6. From the **Debug** menu, click **Start Without Debugging**.
7. Repeat the preceding steps for CmdLine2.

Building and Running the Sample from the Command Line

To build and run the Command Line Parameters samples

1. Use the **Change Directory** command to change to the CmdLine1 directory.
2. Type the following:

```
csc cmdline1.cs
cmdline1 A B C
```

3. Use the **Change Directory** command to change to the CmdLine2 directory.
4. Type the following:

```
csc cmdline2.cs
cmdline2 John Paul Mary
```

Arrays Sample

This sample describes and shows how arrays work in C#.

This sample contains the source code for the Arrays Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Arrays sample

1. Open the solution (Arrays.sln).
2. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the Arrays sample

- Type the following at the command prompt:

```
csc arrays.cs
arrays
```

See Also

Arrays Tutorial | Tutorial Samples

Properties Sample

This sample shows how properties are an integral part of the C# programming language. It demonstrates how properties are declared and used.

This sample contains the source code for the Properties Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Properties samples

1. Open the solution (Properties.sln).
2. In **Solution Explorer**, right-click the person project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for shapetest.

Building and Running the Sample from the Command Line

To build and run the Properties samples

1. Use the **Change Directory** command to change to the person directory.
2. Type the following:

```
csc person.cs
person
```

3. Use the **Change Directory** command to change to the shapetest directory.
4. Type the following:

```
csc abstractshape.cs shapes.cs shapetest.cs
shapetest
```

Properties Tutorial | Tutorial Samples

Libraries Sample

This sample shows how to create and use a DLL in C#.

This sample contains the source code for the Libraries Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Libraries sample

1. Open the solution (Libraries.sln).
2. In **Solution Explorer**, right-click the FunctionTest project and click **Set as StartUp Project**.
3. In **Solution Explorer**, right-click the FunctionTest project and click **Properties**.
4. Open the Configuration Properties folder and click **Debugging**.
5. In the Command Line Arguments property, enter `3 5 10`.
6. Click **OK**.
7. From the **Debug** menu, click **Start Without Debugging**. This will automatically build the library in Functions and execute the program.

Building and Running the Sample from the Command Line

To build and run the Libraries sample

1. Use the **Change Directory** command to change to the Functions directory.
2. Type the following:

```
csc /target:library /out:Functions.dll Factorial.cs DigitCounter.cs
```

3. Use the **Change Directory** command to change to the FunctionTest directory.
4. Type the following:

```
copy ..\Functions\Functions.dll .
csc /out:FunctionTest.exe /R:..\Functions.DLL FunctionClient.cs
FunctionTest 3 5 10
```

Versioning Sample

This sample demonstrates versioning in C# through the use of the **override** and **new** keywords. Versioning maintains compatibility between base and derived classes as they evolve.

This sample contains the source code for the Versioning Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Versioning sample

1. Open the solution (Versioning.sln).
2. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the Versioning sample

- Type the following at the command prompt:

```
csc versioning.cs
versioning
```

See Also

Collection Classes Sample

This sample shows how to implement a collection class that can be used with the **foreach** statement.

This sample contains the source code for the Collection Classes Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Collection Classes samples

1. Open the solution (CollectionClasses.sln).
2. In **Solution Explorer**, right-click the CollectionClasses1 project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for CollectionClasses2.

Building and Running the Sample from the Command Line

To build and run the Collection Classes samples

1. Use the **Change Directory** command to change to the CollectionClasses1 directory.
2. Type the following:

```
csc tokens.cs
tokens
```

3. Use the **Change Directory** command to change to the CollectionClasses2 directory.
4. Type the following:

```
csc tokens2.cs
tokens2
```

Collection Classes Tutorial | Tutorial Samples

Structs Sample

This sample presents the syntax and usage of structs. It also covers the important differences between classes and structs.

This sample contains the source code for the Structs Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Structs samples

1. Open the solution (Structs.sln).
2. In **Solution Explorer**, right-click the Struct1 project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for Struct2.

Building and Running the Sample from the Command Line

To build and run the Structs samples

1. Use the **Change Directory** command to change to the Struct1 directory.
2. Type the following:

```
csc struct1.cs
struct1
```

3. Use the **Change Directory** command to change to the Struct2 directory.
4. Type the following:

```
csc struct2.cs
struct2
```

Indexers Sample

This sample shows how C# classes can declare indexers to provide array-like access to the classes.

This sample contains the source code for the Indexers Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Indexers sample

1. Open the solution (Indexers.sln).
2. In **Solution Explorer**, right-click the indexers project and click **Properties**.
3. Open the Configuration Properties folder and click **Debugging**.
4. In the Command Line Arguments property, enter `..\..\Test.txt`.
5. Click **OK**.
6. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the Indexers sample

1. To compile the sample program, type the following at the command prompt:

```
csc indexer.cs
```

2. The sample program reverses the bytes in a file given as a command-line argument. For example, to reverse the bytes in Test.txt and see the result, issue the following commands:

```
indexer Test.txt
type Test.txt
```

3. To change the reversed file back to normal, run the program on the same file again.

Indexed Properties Sample

This sample shows how C# classes can declare indexed properties to represent an array-like collection of different kinds of things.

This sample contains the source code for the Indexed Properties Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Indexed Properties sample

1. Open the solution (IndexedProperties.sln).
2. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the Indexed Properties sample

- Type the following at the command prompt:

```
csc indexedproperty.cs
indexedproperty
```

Indexed Properties Tutorial | Tutorial Samples

User-Defined Conversions Sample

This sample shows how to define conversions to or from classes or structures, and how such conversions are used.

This sample contains the source code for the User-Defined Conversions Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the User-Defined Conversions samples

1. Open the solution (UserConversions.sln).
2. In **Solution Explorer**, right-click the Conversion1 project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for Conversion2.

Building and Running the Sample from the Command Line

To build and run the User-Defined Conversions samples

1. Use the **Change Directory** command to change to the Conversion1 directory.
2. Type the following:

```
csc conversion.cs
conversion
```

3. Use the **Change Directory** command to change to the Conversion2 directory.
4. Type the following:

```
csc structconversion.cs
structconversion
```

Operator Overloading Sample

This sample demonstrates how user-defined classes can overload operators.

This sample contains the source code for the Operator Overloading Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Operator Overloading samples

1. Open the solution (OperatorOverloading.sln).
2. In **Solution Explorer**, right-click the Complex project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for Dbbool.

Building and Running the Sample from the Command Line

To build and run the Operator Overloading samples

1. Use the **Change Directory** command to change to the Complex directory.
2. Type the following:

```
csc complex.cs
complex
```

3. Use the **Change Directory** command to change to the Dbbool directory.
4. Type the following:

```
csc dbbool.cs
dbbool
```

Delegates Sample

This sample demonstrates the delegate types. It shows how to map delegates to static and instance methods, and how to combine them (multicast).

This sample contains the source code for the Delegates Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Delegates samples

1. Open the solution (Delegates.sln).
2. In **Solution Explorer**, right-click the Delegates1 project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for Delegates2.

Building and Running the Sample from the Command Line

To build and run the Delegates samples

1. Use the **Change Directory** command to change to the Delegates1 directory.
2. Type the following:

```
csc bookstore.cs
bookstore
```

3. Use the **Change Directory** command to change to the Delegates2 directory.
4. Type the following:

```
csc compose.cs
compose
```

Events Sample

This sample shows how to declare, invoke, and hook up to events in C#.

This sample contains the source code for the Events Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Events samples

1. Open the solution (Events.sln).
2. In **Solution Explorer**, right-click the Events1 project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for Events2.

Building and Running the Sample from the Command Line

To build and run the Events samples

1. Use the **Change Directory** command to change to the Events1 directory.
2. Type the following:

```
csc events1.cs
events1
```

3. Use the **Change Directory** command to change to the Events2 directory.
4. Type the following:

```
csc events2.cs
events2
```

Explicit Interface Implementation Sample

This sample demonstrates how to explicitly implement interface members and how to access those members from the interface instances.

This sample contains the source code for the Explicit Interface Implementation Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Explicit Interface Implementation samples

1. Open the solution (ExplicitInterface.sln).
2. In **Solution Explorer**, right-click the ExplicitInterface1 project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for ExplicitInterface2.

Building and Running the Sample from the Command Line

To build and run the Explicit Interface Implementation samples

1. Use the **Change Directory** command to change to the ExplicitInterface1 directory.
2. Type the following:

```
csc explicit1.cs
explicit1
```

3. Use the **Change Directory** command to change to the ExplicitInterface2 directory.
4. Type the following:

```
csc explicit2.cs
explicit2
```

Explicit Interface Implementation Tutorial | Tutorial Samples

Conditional Methods Sample

This sample demonstrates conditional methods, which provide a powerful mechanism by which calls to methods can be included or omitted depending on whether a symbol is defined.

This sample contains the source code for the Conditional Methods Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Conditional Methods sample

1. Open the solution (ConditionalMethods.sln).
2. In **Solution Explorer**, right-click the project and click **Properties**.
3. Open the Configuration Properties folder and click **Debugging**.
4. Set the Command Line Arguments property to "A B C" (without the quotation marks).
5. In the Configuration Properties folder, click **Build**.
6. Modify the Conditional Compilation Constants property (for example, add or delete DEBUG) and click **OK**.
7. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the Conditional Methods sample

- To include the conditional method, compile and run the sample program by typing the following at the command prompt:

```
csc CondMethod.cs tracetest.cs /d:DEBUG
tracetest A B C
```

Conditional Methods Tutorial | Tutorial Samples

XML Documentation Sample

This sample shows how to use XML to document code.

This sample contains the source code for the XML Documentation Tutorial.

Building and Running the Sample Within Visual Studio

To build the XML Documentation sample

1. Open the solution (XMLdoc.sln).
2. In **Solution Explorer**, right-click the project and click **Properties**.
3. Open the Configuration Properties folder and click **Build**.
4. Set the XML Documentation File property to XMLsample.xml.
5. From the **Build** menu, click **Build**. The XML output file will be in the debug directory.

Building and Running the Sample from the Command Line

To build the XML Documentation sample

1. To generate the sample XML documentation, type the following at the command prompt:

```
csc XMLsample.cs /doc:XMLsample.xml
```

2. To see the generated XML, issue the following command:

```
type XMLsample.xml
```

See Also

XML Documentation Tutorial | Tutorial Samples

Platform Invoke Sample

This sample demonstrates how to call platform invokes (exported DLL functions) from C#.

This sample contains the source code for the Platform Invoke Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Platform Invoke samples

1. Open the solution (Pinvoke.sln).
2. In **Solution Explorer**, right-click the PinvokeTest project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for Marshal and Pinvoke.

Building and Running the Sample from the Command Line

To build and run the Platform Invoke samples

1. Use the **Change Directory** command to change to the PinvokeTest directory.
2. Type the following:

```
csc PinvokeTest.cs
PinvokeTest
```

3. Use the **Change Directory** command to change to the Marshal directory.
4. Type the following:

```
csc Marshal.cs
Marshal
```

5. Use the **Change Directory** command to change to the Pinvoke directory.
6. Type the following:

```
csc logfont.cs pinvoke.cs
pinvoke
```

Platform Invoke Tutorial | Tutorial Samples

COM Interop Part 1 Sample

This sample demonstrates how a C# program can interoperate with an unmanaged COM component.

This sample contains the source code for the COM Interop Part 1: C# Client Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the COM Interop Part 1 samples

1. Open the solution (COMInteropPart1.sln).
2. In **Solution Explorer**, right-click the Interop1 project and click **Set as StartUp Project**.
3. In **Solution Explorer**, right-click the Interop1 project and click **Properties**.
4. Open the Configuration Properties folder and click **Debugging**.
5. In the Command-Line Arguments property, enter an AVI file such as `c:\winnt\clock.avi`.
6. Click **OK**.
7. From the **Debug** menu, click **Start Without Debugging**.
8. Repeat the preceding steps for Interop2.

If the QuartzTypeLib.dll included with Interop1 is out of date

1. In **Solution Explorer**, open **References** for Interop1.
2. Right-click **QuartzTypeLib** and click **Remove**.
3. Right-click **References** and click **Add Reference**.
4. In the **COM** tab, select the component named "ActiveMovie control type library."
5. Click **Select** and **OK**.
6. Rebuild Interop1.

   Note Adding a reference to the component does the same thing as invoking tlbimp at the command line to create QuartzTypeLib.dll (as shown below).

Building and Running the Sample from the Command Line

To build and run the COM Interop Part 1 samples

1. Use the **Change Directory** command to change to the Interop1 directory.
2. Type the following:

```
tlbimp %windir%\system32\quartz.dll /out:QuartzTypeLib.dll
csc /r:QuartzTypeLib.dll interop1.cs
interop1 %windir%\clock.avi
```

3. Use the **Change Directory** command to change to the Interop2 directory.
4. Type the following:

```
csc interop2.cs
interop2 %windir%\clock.avi
```

See Also

COM Interop Part 1: C# Client Tutorial | Tutorial Samples

COM Interop Part 2 Sample

This sample demonstrates using a C# server with a C++ COM client.

This sample contains the source code for the COM Interop Part 2: C# Server Tutorial.

> **Note** Visual C++ must be installed to compile this sample.

Building and Running the Sample Within Visual Studio

To build and run the COM Interop Part 2 sample

1. Open the solution (CSharpServerWithCOMClient.sln).
2. In **Solution Explorer**, right-click the COMClient project and click **Properties**.
3. Open the Configuration Properties folder and click **Debugging**.
4. In the Command Line Arguments property, enter a name.
5. Click **OK**.
6. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the COM Interop Part 2 sample

1. Use the **Change Directory** command to change to the COMInteropPart2\COMClient directory.
2. Copy the C# server code into the COMClient directory:

```
copy ..\CSharpServer\CSharpServer.cs
```

3. Compile the server:

```
csc /target:library CSharpServer.cs
regasm CSharpServer.dll /tlb:CSharpServer.tlb
```

4. Compile the client (make sure the path and environment variables are set properly with vcvars32.bat):

```
cl COMClient.cpp
```

5. Run the client:

```
COMClient friend
```

See Also

COM Interop Part 2: C# Server Tutorial | Tutorial Samples

Attributes Sample

This sample shows how to create custom attribute classes, use them in code, and query them through reflection.

This sample contains the source code for the Attributes Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Attributes sample

1. Open the solution (Attributes.sln).
2. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the Attributes sample

- Type the following at the command prompt:

```
csc AttributesTutorial.cs
AttributesTutorial
```

See Also

Attributes Tutorial | Tutorial Samples

Security Sample

This sample shows how to modify security permissions through permission classes and permission attributes.

This sample contains the source code for the Security Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Security samples

1. Open the solution (Security.sln).
2. In **Solution Explorer**, right-click the Security1 project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for Security2 and Security3.

Building and Running the Sample from the Command Line

To build and run the Security samples

1. Use the **Change Directory** command to change to the Security1 directory.
2. Type the following:

```
csc ImperativeSecurity.cs
ImperativeSecurity
```

3. Use the **Change Directory** command to change to the Security2 directory.
4. Type the following:

```
csc DeclarativeSecurity.cs
DeclarativeSecurity
```

5. Use the **Change Directory** command to change to the Security3 directory.
6. Type the following:

```
csc SuppressSecurity.cs
SuppressSecurity
```

Security Tutorial | Tutorial Samples

Threading Sample

This sample demonstrates various thread activities:

- Creating and executing a thread.
- Thread synchronization.
- Interaction between threads.
- Using a thread pool.

This sample contains the source code for the Threading Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Threading samples

1. Open the solution (Threads.sln).
2. In **Solution Explorer**, right-click the StopJoin project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. Repeat the preceding steps for MonitorSample, SimplePool, and Mutex.

Building and Running the Sample from the Command Line

To build and run the Threading samples

1. Use the **Change Directory** command to change to the Threads directory.
2. Type the following:

```
cd StopJoin
csc StopJoin.cs
StopJoin
```

3. Type the following:

```
cd ..\MonitorSample
csc MonitorSample.cs
MonitorSample
```

4. Type the following:

```
cd ..\SimplePool
csc SimplePool.cs
SimplePool
```

5. Type the following:

```
cd ..\Mutex
csc Mutex.cs
Mutex
```

Unsafe Code Sample

This sample demonstrates how to use unmanaged code (code using pointers) in C#.

This sample contains the source code for the Unsafe Code Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the Unsafe Code samples

1. Open the solution (Unsafe.sln).
2. In **Solution Explorer**, right-click the FastCopy project and click **Set as StartUp Project**.
3. From the **Debug** menu, click **Start Without Debugging**.
4. In **Solution Explorer**, right-click the ReadFile project and click **Set as StartUp Project**.
5. In **Solution Explorer**, right-click the ReadFile project and click **Properties**.
6. Open the Configuration Properties folder and click **Debugging**.
7. In the Command Line Arguments property, enter `..\..\ReadFile.cs`.
8. Click **OK**.
9. From the **Debug** menu, click **Start Without Debugging**.
10. In **Solution Explorer**, right-click the PrintVersion project and click **Set as StartUp Project**.
11. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the Unsafe Code samples

1. Use the **Change Directory** command to change to the Unsafe directory.
2. Type the following:

```
cd FastCopy
csc FastCopy.cs /unsafe
FastCopy
```

3. Type the following:

```
cd ..\ReadFile
csc ReadFile.cs /unsafe
ReadFile ReadFile.cs
```

4. Type the following:

```
cd ..\PrintVersion
csc PrintVersion.cs /unsafe
PrintVersion
```

OLE DB Sample

This sample demonstrates how to use a Microsoft Access database from C#. It shows how you can create a dataset and add tables to it from a database. The BugTypes.mdb database used in the sample program is a Microsoft Access 2000 .mdb file.

This sample contains the source code for the OLE DB Tutorial.

Building and Running the Sample Within Visual Studio

To build and run the OLE DB sample

1. Open the solution (OleDBSample.sln).
2. From the **Debug** menu, click **Start Without Debugging**.

Building and Running the Sample from the Command Line

To build and run the OLE DB sample

- Type the following at the command prompt:

```
csc oledbsample.cs
oledbsample
```

See Also

OLE DB Tutorial | Tutorial Samples

Cross-Language Samples

The following table provide links to samples that demonstrate cross-language interoperability between Visual C# and Visual C++.

Sample	Description
DataSetConsumer	Demonstrates how to consume multiple-table DataSets in a SPROXY-generated SOAP client. The Visual C# code creates a multiple-table DataSet and exposes it through a Web method.
ManagedEvents	Demonstrates event handling interoperability between Managed Extensions for C++ and Visual C# objects. The Visual C# code implements both an event source and an event receiver.
JrnlPost	Creates a single DLL containing native business logic, an interface and type library for COM clients, and an assembly with corresponding metadata for .NET Framework clients. The Visual C# code instantiates a managed object from the DLL and calls a couple of methods on it. It illustrates that the DLL contains both COM and .NET Framework classes.
MCppWrapper	Illustrates how a Managed Extensions __gc class can be used as a proxy class (or wrapper) for an unmanaged C++ class in a DLL. The Visual C# code is a client that reads a string and position from the console and displays a suffix.
TilePuzzle	An interactive sliding tile puzzle that demonstrates the interoperability of managed and unmanaged components. The Visual C# code provides the user interface to the tile-puzzle board. This component interfaces with the TileDriver Managed Extensions for C++ component to find valid states when a user tries to move a tile. It also calls into the algorithm engine when solving a puzzle.
CustomAttributes	Demonstrates implementing a custom attribute. Custom attributes can be used to create type-checked user-defined metadata. The Visual C# custom attribute adds several different types of information to the metadata of the target class and defines several different parameter lists for usage.
Delegates	Demonstrates custom delegates in a managed application. The Visual C# DLL in the sample implements a basic Visual C# class (`CDel`) with a custom method.
OnlineAddressBook	Stores an address book in an XML Web service created with ATL Server. The sample has a Visual C# client that calls into the XML Web service.
PlaneParts	Demonstrates how the various technologies available in Visual Studio .NET can be used together in an enterprise application. Visual C# is used for the Web Forms and to create a Windows Service.

Visual C# Samples

Tailspin Toys Application

The Tailspin Toys application demonstrates how the various technologies available in Visual Studio .NET can be used together in an Enterprise application. The application demonstrates a simple transacted ordering system internal to a company, arbitrarily chosen as airplane parts.

The application is a multitier application with a browser client, a Web server, server components, and a database tier. In addition, business-to-business (B2B) communication with an external vendor that accepts orders via an XML Web service is demonstrated.

Installing Tailspin Toys

The Tailspin Toys application can be found at Samples\VCSharp\General\Tailspin on the MSDN CD (disk 1) or DVD. It is packaged as a self-extracting executable file containing two installation files (.msi) that contain Visual Studio solutions and accompanying documentation.

Description

The application consists of ATL Server-based Web applications used for ordering parts and for fulfilling orders from a warehouse, a message-queue–based order-handling system written in Visual C# running as a Windows Service and using serialization to convert XML messages to and from objects, a SQL 2000 database using SQL XML and OLE DB, a transactional accounting system based on Visual C# ServicedComponents, a Visual C# Web Forms application, and business-to-business communication using XML Web services with a separate vendor site.

Features

Features demonstrated include:

- ATL Server Web application using database session management
- Visual C# Web Forms application using ADO.NET
- Transacted, stateless account management using Visual C# ServicedComponents and ADO.NET
- Use of MSMQ to implement an order-handling system
- Use of Visual C# Windows Service to process MSMQ messages
- Use of MSXML Document Object Model (DOM)
- XML Web services used for business-to-business communication
- COM Interop from Visual C#
- Use of SQL 2000 XML support via OLE DB
- Interop of native COM+ and managed ServicedComponents
- Serialization of common language runtime objects as XML
- Secure logins using password encryption

QuickStarts and Other Samples

The .NET Framework SDK includes QuickStart tutorials and other samples that demonstrate .NET Framework features and Visual C# code. For more information, see the following topics in the .NET Framework SDK:

- Samples
- QuickStarts

Samples

If you install the samples with the .NET Framework SDK, you can find them at the following path:

\Program Files\Microsoft Visual Studio .NET 2003\FrameworkSDK\Samples

If you do not want to install the samples on your computer, you can browse the Samples folder in the .NET Framework SDK installation directory on the product CD or DVD.

QuickStarts

The QuickStart Tutorials are the fastest way to understand what the .NET Framework technology offers leading-edge developers. The QuickStarts are a series of samples and supporting documentation designed to quickly acquaint you with the syntax, architecture, and power of Visual Studio .NET and the .NET Framework.

To access the QuickStarts

1. Click the Windows **Start** button.
2. Point to **Programs**.
3. Point to **Microsoft .NET Framework SDK version 1.1**.
4. Click **Samples and QuickStart Tutorials**.

   The main page of the "Microsoft .NET Framework SDK QuickStarts, Tutorials and Samples" application will appear.

To run the samples, follow the directions to install the samples database and complete the installation. After you have installed the QuickStarts, the "QuickStarts Tutorials" link will be live.

The QuickStart tutorials include samples on the ASP.NET and Windows Forms applications, in addition to many how-to applications that cover the most compelling features of the .NET Framework technology.
